Herbs & Natural Supplements

An evidence-based guide 3RD EDITION

evolve ebooks
learning system

Herbs and Natural Supplements is now also available as an ebook!

Browse across Elsevier's comprehensive elibrary and build your own personalised ebookshelf to create an integrated electronic study centre. With your ebookshelf you can search across this book and other texts electronically, so you can spend less time searching and more time learning.

This allows you to

- make notes in the electronic files
- highlight material
- bookmark important pages
- create custom folders
- share notes and highlights

Evolve ebooks allow all these functions within an individual book or across multiple books, and provide an integrated, comprehensive way to access the core information you need.

1. Go to **http://www.vitalsource.com/software/evolve-select/**, follow the prompts and download the bookshelf. You will also be prompted to download Microsoft.Net Framework 2.0.
2. After the bookshelf installation is complete, open Evolve ebooks using this icon from your desktop: 
3. The bookshelf should open on the welcome page. If not, click the welcome button on the left side.
4. Click on "Register" and fill in the registration information requested. Record your username and password in case it is needed in the future.
5. Fill in the redemption code on the inside front cover.
6. This book will appear in your bookshelf. The book title will appear with a small triangle beside it. This indicates that you have access to the book but it is not installed yet. The book will be downloaded using the internet.
7. Books may automatically download over the internet. On the left-hand side of the bookshelf you will notice the downloading status of the book. If you do not want to download all the books, click the "x" beside the books indicating "pending downloading".
8. Any books can be downloaded at another time by double clicking on the title.
9. The complete installation of books will depend on the number of books being downloaded. It may take 2–5 minutes to download one book.

If you find more than 1 code in this pack, you will need to use them all.

Disclaimer
Complementary medicine and pharmacology are ever-changing fields. Standard safety precautions must be followed but, as new research and clinical experience broaden our knowledge, changes in treatment become necessary or appropriate. The authors and publisher have, in so far as it is possible, taken every care to ensure that the information contained within the text is as accurate and as up-to-date as possible. Readers are, however, advised always to check available product information with the herb, supplement or drug manufacturer to verify the recommended dose, the method and duration of administration, and contraindications. It is the responsibility of the treating person to determine dosages and the best treatment for the patient. Neither the publisher nor the editors assume any responsibility for any injury and/or damage to persons or property.

 indicates a herb or supplement action with particular significance for pregnant women.

 indicates a warning or cautionary note regarding the action of a herb or supplement.

 indicates FAQs about the herb or supplement.

ORGANISATION OF THIS BOOK

This third edition of *Herbs & natural supplements – an evidence-based guide* is organised into four sections. The first section provides a basic introduction to complementary medicine in general and then, more specifically, to herbal medicine, clinical nutrition, aromatherapy, and food as medicine. It is hoped that many of your general questions will be answered here.

The second section focuses on issues relating to clinical practice and explores the relatively new fields of integrative medicine and wellness, as it relates to health. These areas are gaining popularity around the globe and complementary medicine philosophy and treatments are often an integral part of the approach. This section also contains chapters with a focus on safety because the wise clinical use of all interventions must be based on a benefit versus risk assessment. There are general chapters discussing the safety of herbs and natural supplements and drug interactions, and then specific chapters focusing on safety in pregnancy, before surgery and for people undertaking treatment for cancer. These topics are discussed in both a theoretical and a practical way to clarify the key concerns and produce some general guidelines that can be used to inform practice.

The third and largest section comprises 130 evidence-based reviews of some of the most popular herbs and natural supplements available over the counter. Exhaustive reviews of the peer-reviewed literature have been undertaken by the author team to update, modify and expand information from the previous edition, and 10 new monographs are included. Common names, chemical components, main actions, clinical uses, dosage range and safety issues are included for each herbal medicine. For nutritional supplements, background information and pharmacokinetics, food sources, deficiency signs and symptoms and the new Australian and New Zealand recommended daily intakes (RDIs) are also included where appropriate. Although technical language is frequently used, there is also a summary in non-technical language (Practice Points and Patient Counselling) and answers to key questions patients may have about the product (Patients' FAQs). A 'Historical note' is included where appropriate and occasionally there are also 'Clinical note' boxes that provide further information.

The fourth section consists of ready-reference appendices, the largest of which is a table that outlines the interactions possible between the 130 complementary medicines reviewed and pharmaceutical drugs (Appendix 2). Although investigation into this area is still in its infancy, we have provided a brief explanation for each possible interaction and a general recommendation based on what is currently known or suspected. It is intended as a guide only, to be used to inform practice when clinicians take a medical and medication history: obviously it should be interpreted within the individual patient's context. It is anticipated that this section will continue to change in future editions as more clinical studies are published and theoretical predictions are tested. Appendix 5 is a guide to the safe use of complementary medicines in the preoperative period. Appendix 7 is a table organised by pharmacological action giving the herbs and nutrients that produce that action and the type of evidence available to support this. For example, to find which herbs and nutrients exert an anti-inflammatory action, check under 'Anti-inflammatory'. We have also included a glossary of medical, research, integrative and complementary medicine terms and abbreviations (Appendix 1), a list of Australian and New Zealand poisons information centres and their phone numbers (Appendix 3), and the contact details for teaching institutions, complementary and integrative medicine associations and product manufacturers in Australia and New Zealand (Appendix 4). These lists are not exhaustive but aim to provide a general guide for the reader.

ACKNOWLEDGMENTS

This third edition of *Herbs and Natural Supplements* is bigger than the second edition, which in turn was much bigger than the first. This is partly because 10 new monographs and two new chapters have been added, but also because the amount of published research in complementary medicine is still growing exponentially and there are now over 40,000 articles cited on Medline alone in this area.

The task of amassing, critiquing and reporting on the plethora of complementary medicine studies available is a daunting one that requires dedication, tenacity, patience and resourcefulness. This edition draws on the expertise of an expanded team of 12 contributors. I believe they are among the brightest and most talented CM writers in Australia. Without their valuable involvement, this book might never have been completed.

On a personal note, I'd like to thank my husband Gary for making it possible for me to step aside from our busy lives for many months to sit, think and write, while he took on the main family responsibilities. This work requires a lot of mental energy and introspection, which means retreating from the details of daily routine so it can all happen. His understanding, motivation and patience are invaluable and always greatly appreciated.

I'd also like to thank all my parents Shana and Fred Green, Judy Braun and Magenesta and Zonti Kustin for their emotional and hands-on support; my late father-in-law Emil Braun and grandfather Leon Kustin, who continue to serve as reminders to have courage and persevere; and the rest of my wonderful extended family and friends who accept that I'm off the radar every now and again, working on another book.

I'd like to thank contributing writers Liza Oates, Rachel Arthur, Jane Daley and Trisha Dunning, who have stayed on the ride for this edition and continue to share their valuable expertise. Thank you also to Marc Cohen, who remains a visionary, and to new team members Ondine Spitzer, Gina Fox, Evelin Tiralongo, Louise Zylan, Leah Hechtman, Emily Bradley, Clare Francis and Surinder Baines for their commitment and professionalism.

I'd also like to thank Professor Franklin Rosenfeldt, who inspires me every day at the Alfred Hospital, colleagues at the National Herbalists Association of Australia (NHAA), colleagues in the Alfred Hospital pharmacy department, Steven Chong at the Journal of Complementary Medicine, Matthew Eton at the Australian Journal of Pharmacy, fellow practitioners, academics and researchers (in all the health fields) and, of course, patients. At Elsevier, I'd like to thank everyone involved in this project for making it as seamless as possible.

Finally, a very special thanks to my three adorable daughters, Sarah, Lori and Jaimie who have grown so much bigger in the last three years and understand now more than ever why this book is important to so many people, and how they are so important to me.

Lesley Braun
Melbourne, Australia

ABOUT THE AUTHORS

Dr Lesley Braun PhD, BPharm, DipAppSci Naturopathy, GradDip Phytotherapy

Dr Lesley Braun is a registered pharmacist and naturopath. She holds a PhD from RMIT University, Melbourne, Australia, in which she investigated the integration of complementary medicine into hospitals in Victoria. She is currently Research Fellow in the Cardiothoracic Surgical Research Unit at the Alfred Hospital (Department of Surgery, Monash University), where she conducts clinical trials using integrative medicine in the hospital setting, supervises research students and is involved in the National Institute of Complementary Medicine Collaborative Centre for Natural Medicines and Neurocognition. Her other role at the Alfred hospital is as Research Pharmacist in the Pharmacy Department, where her work focuses on complementary medicine products and the practice of integrative medicine within pharmacy settings.

Dr Braun is also Vice President of the National Herbalists Association of Australia, a member of the Therapeutic Goods Administration's (TGA) Complementary Medicine Evaluation Committee (CMEC), an advisory board member to the Australasian Integrative Medicine Association (AIMA), on the editorial board of the Journal of Complementary Medicine (JCM), a member of several advisory committees for the National Institute of Complementary Medicine (NICM), on the academic board of the Endeavour College of Natural Health and a member of several complementary medicine working groups for the Clinical Oncology Society of Australia (COSA).

Since 1996 she has authored numerous chapters for books and more than 100 articles, and since 2000 has written regular columns for the *Australian Journal of Pharmacy* and the *Journal of Complementary Medicine*. She lectures to medical students at Monash University and to chiropractic students at RMIT University, and is regularly invited to present at national and international conferences about evidence-based complementary medicine, drug interactions and complementary medicine safety.

Her role as the main author of *Herbs and Natural Supplements — An Evidence-based Guide* represents a continuation of a life-long goal to integrate evidence-based complementary medicine into standard practice and improve patient outcomes safely and effectively.

Professor Marc Cohen MBBS(Hons), PhD(TCM), PhD(Elec Eng), BMedSc (Hons), FAMAC, FICAE

Marc Cohen is currently Professor of Complementary Medicine at RMIT University, where he leads the world's first online postgraduate Master of Wellness program, supervises postgraduate research students and conducts research funded by the National Health and Medical Research Council and other agencies into various aspects of wellness and complementary medicine. He is also Senior Research Fellow at the Centre for Medical and Health Sciences Education, Monash University, Expert Advisor to the Therapeutic Goods Administration's (TGA) Complementary Medicine Evaluation Committee (CMEC), a member of the Scientific Advisory Committee for the National Institute of Complementary Medicine (NICM), a current Board Member and Past-President (President 2000–2007) of the Australasian Integrative Medicine Association (AIMA) and a member of the Royal Australian College of General Practitioners (RACGP)/AIMA Joint Working Party, which has guided the development of the RACGP curriculum on integrative medicine.

Professor Cohen is a registered medical practitioner with degrees in Western medicine, physiology and psychological medicine, as well as PhDs in both Chinese medicine and biomedical engineering. He sits on the

editorial boards of a number of international journals and has published widely, including writing more than 50 peer-reviewed journal articles as well as co-editing the text 'Understanding the Global Spa Industry'. Professor Cohen has organised eight International Holistic Health Conferences and is on the board of the Global Spa Summit. He is a sought-after presenter and in the past five years has been an invited speaker at more than 100 conferences including more than 50 international and 50 national conferences. As one of Australia's foremost pioneers of complementary medicine, he has made significant impacts on education, research, clinical practice and policy, and his achievements have been recognised with three consecutive RMIT Media Star Awards and the inaugural award for leadership and collaboration from the National Institute of Complementary Medicine.

CONTRIBUTORS

Rachel Arthur BHSc, BNat (Hons)
Rachel is a naturopath, lecturer, researcher and author. Graduating with a Bachelor of Health Science (Naturopathy) from the Southern School of Natural Therapies, Melbourne, she now lectures in clinical nutrition and naturopathic practice at a number of institutions including Southern Cross University. In addition to this Rachel is frequently asked to speak on nutrition by a variety of organisations, including professional medical organisations across Australia and overseas. A contributing author for the previous editions, Rachel is also a regular contributor to a range of complementary medicine (CM) publications. In this edition, Rachel was involved with updating Chapter 3, Introduction to Clinical Nutrition, and the monographs Calcium, Evening Primrose Oil, Fish Oils, Flaxseed Oil, Folate, Iodine, Magnesium, S-Adenosyl-L-Methionine (SAMe), Vitamin B1, Vitamin B2 — Riboflavin, Vitamin B5 — Pantothenic Acid, Vitamin D and Zinc.

Dr Surinder Baines BSc (Hons), GradDipNutr, GradDipDiet, PhD, APD
Dr Surinder Baines graduated with a Bachelor of Science in Microbiology and attained postgraduate diplomas in nutrition and dietetics and a PhD from the University of London. In the UK, Surinder has worked as a lecturer, research nutritionist and senior clinical dietitian in London. Her various roles have covered clinical hospital practice and community-based projects. At present Surinder is a senior lecturer at the University of Newcastle, where she has taught a range of nutrition topics and now teaches courses in clinical nutrition and food science in the School of Health Sciences. In this edition, Surinder was involved with updating Probiotics, as well writing new material for Prebiotics, Taurine and Arginine.

Emily Bradley BHSc (Nat)
Emily is a practising naturopath with more than 10 years' clinical experience. She is a lecturer in nutrition therapeutics and student clinic supervisor at Endeavour College of Natural Health and the Southern School of Natural Therapies in Melbourne. She is an expert advisor on complementary medicine for *Prevention* magazine, and is also currently finishing a masters degree in nutrition medicine at RMIT. In this edition, Emily was involved with updating Honey, Lycopene, L-Lysine, Selenium and Vitamin A, as well contributing to new material for Chapter 11, Herbs and Natural Supplements in Pregnancy.

Jane Daley BHSc, DBM, GradCertAppSc
Jane is a practising herbalist, lecturer and author. Since graduating from Nature Care College, Sydney, and subsequently from Charles Sturt University, she has completed the postgraduate program at the graduate School of Integrative Medicine (Swinburne University) and is currently completing her master's degree at Southern Cross University in Clinical Science. Jane has published many peer review articles and contributed to several textbooks in the field of complementary medicine. She is a senior lecturer at the Southern School of Natural Therapies, where she teaches herbal medicine therapeutics and supervises student clinics. In this edition, Jane was involved with updating Chapter 2, Introduction to Herbal Medicine, and the monographs Albizia, Andrographis, Baical Skullcap, Calendula, Chamomile, Damiana, Goldenrod, Goldenseal, Lemon Balm, Meadowsweet, Myrrh, Passionflower, Schisandra, Slippery Elm, Thyme and Turmeric, as well writing new material for Elder.

Trisha Dunning AM, RN, MEd, PhD, CDE
Professor Trisha Dunning is Director of Endocrinology and Diabetes Nursing Research at St Vincent's Hospital and the University of Melbourne. She has been a diabetes educator for 20 years and is passionate about holistic nursing care. Trisha is the author of several books for people with diabetes and many books and papers for health professionals, mainly addressing complementary health. She is an active researcher with a focus on people's beliefs and attitudes and how they affect professional care and self-care. Her qualifications include aromatherapy and relaxation massage. In this edition, Trisha was involved with updating Chapter 4, Introduction to Aromatherapy, and the monographs Eucalyptus, Ginger, Lavender, Orange, Rosemary and Sage.

Gina Fox BA Hons, BHSc (Nat)
Gina is a naturopath, lecturer and writer. She studied at the Australian College of Natural Medicine and graduated with a Bachelor of Health Science (Naturopathy) degree. She now lectures and supervises student clinics at the Endeavour College of Natural Health. Gina is an educator and a clinician at Fertile Ground Health Group in Melbourne, specialising in pre-conception health and fertility. She is also a meditation teacher and runs a mindfulness-based stress reduction program. In this edition, Gina was involved with updating Cloves, Colostrum, Creatine, Grapeseed Extract, Green Tea, Guarana, Gymnema Sylvestre, Olive, Shark Cartilage and Vitamin B6.

Clare Francis BPharm, GradCertClinPharm
Clare is a senior oncology pharmacist working at the Peter MacCallum Cancer Centre, Melbourne. After graduation from Otago University, New Zealand, Clare went on to the UK, completing her Graduate Certificate in Clinical Pharmacy through the University of London, and then specialising in oncology, before moving to Melbourne last year. She is involved in education, overseeing the practical placements of undergraduate students, and also works with the palliative care team. Clare delivers lectures to PeterMac staff on various topics, including the use of complementary medication in the oncology setting. She has a keen interest in the field of integrative oncology and is a member of the PeterMac Integrative Therapies working group and the Clinical Oncology Society of Australia's CAMs special interest group. In this edition, Clare was involved with updating Chapter 10, Cancer and Safety of Complementary Medicine.

Leah Hechtman MSci (RHHG) (USyd), BHSc (Nat), ND, AACNEM, MNHAA, MATMS
Leah has qualifications in reproduction, endocrinology, infertility and genetics; naturopathy; Western herbal medicine; and clinical nutrition and environmental medicine. Her primary passion is her clinical practice, where she is regularly inspired and humbled by her patients. In addition, she is Vice President of the National Herbalists Association of Australia; lecturer at the University of Western Sydney to both the undergraduate and postgraduate naturopathy students; is authoring a clinical naturopathic text due to be published by Elsevier; regularly contributes to texts and journals within professional publications; presents at conferences and seminars throughout the country and has a little fun with her weekly newspaper column. She is also a regular media spokesperson for the industry and stays grounded by maintaining her own further studies. In this edition, Leah was involved with updating Adhatoda, Aloe Vera, Bilberry, Brahmi and Vitamin C and also contributed new material for Chapter 11, Herbs and Natural Supplements in Pregnancy.

Liza Oates, BHSc (Nat), BA, GradCert Evid-based CompMed
Liza is a naturopathic practitioner, educator, writer and broadcaster. She teaches the courses 'Complementary Medicine in Chronic Diseases' and 'Health Enhancement' to Monash University medical students, and 'Food as Medicine' in the Master of Wellness program at RMIT University where she is also a PhD candidate. Liza has written for the *Journal of Organic Systems*, the *Journal of Complementary Medicine*, *Australian Pharmacist*, and *Complementary Therapies & the Management of Diabetes & Vascular Disease*. She has been a contributing author to this book since the first edition. In this edition, Liza was involved with updating Chapter 5, Introduction to Food as Medicine, and the monographs Carnitine, Chromium, Ginseng (Korean), Ginseng (Siberian), L-Glutamine, Horse Chestnut, Iron, Liquorice, Oats, Quercetin, Tyrosine, Vitamin B_3 – Niacin, Vitamin B_{12} and Withania, as well writing new material for Rhodiola and Shatavari.

Ondine Spitzer MSocHlth, BHlthSci, DipAppSci
Ondine has 15 years' clinical experience as a naturopath, and has been a lecturer and clinical supervisor for naturopathy students, a tutor for medical students and a research assistant on a number of health projects at the University of Melbourne and the Alfred Hospital. She holds a bachelor degree in naturopathy and a master's degree in medical anthropology, has presented at many conferences and has contributed to a number of books. She has a special interest in herbal medicine and is a past president of the Victorian Herbalists Association. In this edition, Ondine was involved with updating Chapter 2, Introduction to Herbal Medicine, and the monographs Black Cohosh, Celery, Chaste Tree, Cranberry, Dandelion, Fenugreek, Globe Artichoke, Hops, Horseradish, Perilla, Raspberry Leaf, Red Clover, Tribulus and Willowbark.

Evelin Tiralongo BPharm (Hons), PhD, GradCertHigherEd
Evelin trained as a pharmacist in Germany and has extensive knowledge in herbal medicines. She has completed an Honours degree in pharmacognosy and a PhD in biochemistry. Her experience is practice based, with more than two years spent working in CM-oriented community pharmacies in Germany. Evelin is a senior lecturer at Griffith University's Pharmacy School and has been instrumental in the establishment of integrated CM education for Griffith's pharmacy students. She has researched CM education aspects for pharmacy students, provided online CM resources for an Australian pharmacology book and is regularly reviewing CM-related research papers for various journals. Currently Evelin is involved in several clinical, practice and laboratory CM research projects funded by the Pharmacy Guild, the National Institute of Complementary Medicine and the CM industry. In this edition, Evelin was involved with updating Devil's Claw, Echinacea, Hawthorn, Peppermint and St Mary's Thistle.

Louise Zylan BHSc, ND
Louise is a practising naturopath and nutritionist, having graduated with a Bachelor of Health Science in Naturopathy from the Australian College of Natural Medicine. She currently lectures at the Endeavour College of Natural Health and Southern School of Natural Therapies in nutritional and herbal medicine. Louise is currently completing a master's degree in nutrition medicine at RMIT University. In this edition, Louise was involved with updating the monographs Chickweed, Garlic, Ginger, Psyllium and Pygeum, as well as the appendixes.

REVIEWERS

John Baxter BHSC, ND, DBM, DipNut, DipHom, DRT, DRM, MNHAA
President, National Herbalists Association of Australia

Sandy Davidson GradDipPubHealth, AdvDipNaturopathy, ND
Naturopathic practitioner and lecturer at Australasian College of Natural Therapies, Sydney, and Nature Care College, Sydney

Dr Peter Dobie MBBS
Member American Academy of Anti-Aging Medicine, Member Australasian College of Nutritional and Environmental Medicine
General practitioner, Lismore, New South Wales

Elizabeth Hammer BHSc (CompMed, Nursing), AdvDip Western Herbal Medicine
Coordinating Examiner, Board of Directors National Herbalists Association of Australia
Lecturer, Academy of Complementary health, WEA Hunter, New South Wales

Lecturer in Medicinal Chemistry, School of Biomedical Sciences, Charles Sturt University, Wagga Wagga, New South Wales
Australian Regional Representative, International Council for Medicinal and Aromatic Plants (ICMAP)

Dr David Mitchell MBBS, FAMAC
Acupuncture physician, integrative medicine general practitioner, Adelaide, South Australia

George Qian Li PhD, MRACI
Sesquicentenary Lecturer in Herbal Medicines
Coordinator, Herbal Medicines Research and Education Centre
Faculty of Pharmacy, University of Sydney

Dr Sandra Palmer MBBS, FAARM, ABAARM Diplomate, DipObs RACOG
Nutritional, environmental, herbal, anti-ageing and functional medicine practitioner

Dr Lorna Scott MBBS, MFHom
Integrative medicine general practitioner, Sydney

Dr Bill Webster PhD
Professor of Reproductive Toxicology, Department of Anatomy and Histology, University of Sydney

Dr Michelle Woolhouse MBBS FRACGP, Dip Acupuncture, Dip Hypnotherapy
Medical Director of Peninsula Holistic General Practice, Victoria, Australia
Board member of the Australasian Integrative Medicine Association and a current member of the Joint Working Party for Integrative medicine for the RACGP

Dr Katriona Wylie BMMS, BHSci
Discipline of General Practice, Adelaide University, South Australia

CHAPTER 1
INTRODUCTION TO COMPLEMENTARY MEDICINE

The practice of medicine aims to reduce human suffering through the treatment and prevention of disease, and has been part of every human society and civilisation throughout history. Although medicine has a single aim, over the ages many different practices and techniques have evolved to achieve this. We are currently living at a time when the wisdom of many different cultures and philosophies is available to us as never before. Despite the existence of a wide range of therapies, medicine in the Western world has been largely institutionalised and dominated by the scientific biomedical model that centres on treating disease with drugs and surgery. In more recent times a new model has started to emerge; it attempts to integrate some of those therapies and medicines that are not based on the biomedical model and that have been previously termed 'alternative'. Although still in its infancy, integrative medicine, as some have called it, views 'alternative medicine' as complementary to the existing system and seeks to improve and enlarge the scope of the existing biomedical model.

WHAT IS COMPLEMENTARY MEDICINE?

The definition of complementary and alternative medicine (CAM) has been the subject of some debate. In 1995 the following definition was formulated at a conference held by the National Institutes of Health's Office of Alternative Medicine in the USA, with the aim of producing a definition that has the broadest and most consistent applicability and that excludes bias and partisanship:

> Complementary and alternative medicine (CAM) is a broad domain of healing resources that encompasses all health systems, modalities, and practices and their accompanying theories and beliefs, other than those intrinsic to the politically dominant health system of a particular society or culture in a given historical period. CAM includes all such practices and ideas self-defined by their users as preventing or treating illness or promoting health and well-being.
>
> *National Institutes of Health Panel on Definition and Description 1997*

Like many definitions produced by committees, this definition seems a little unsatisfying. Simply dividing interventions into those that are part of the politically dominant health system and those that are not does not provide useful insight. This classification is also subject to regional political differences that may be unrelated to healthcare.

Rather than focus on political acceptance as the basis for defining alternative and complementary medicine, a discussion paper by the Australian Medical Council addresses 'unorthodox therapies' and states that 'the practices they embrace are by definition unscientific and of unproven efficacy until proved otherwise (in which case they become part of mainstream medicine)' (Australian Medical Council, 'Undergraduate medical education and unorthodox medical practice', unpublished discussion paper, 1999).

The division of therapies into unorthodox or mainstream based on scientific merit is a little simplistic and open to subjective interpretation. For example, there are many practices that can be considered mainstream but are not necessarily scientifically proven, and many practices that can be considered 'unorthodox'

but have scientific support. Furthermore, scientific evidence for a therapy may exist for only a specific clinical condition, or a therapy may be considered orthodox in one context, such as the use of vitamin supplements for treating a deficiency syndrome, but unorthodox in another, such as the use of vitamins in megadoses.

When defining therapies on political or scientific grounds, further confusion is added by the time that it takes to gain wide acceptance. For example, even though scientific evidence in support of acupuncture has been accumulating since the discovery of endogenous opioids in the mid-1970s, and government rebates via Medicare have been available for acupuncture for nearly two decades, this therapy is not universally accepted as mainstream.

Overall, it is generally accepted that there are two broad classes of medicine, and terms such as 'conventional', 'mainstream', 'orthodox', 'biomedicine' and 'scientific medicine' are often contrasted with 'unconventional', 'complementary', 'alternative', 'unorthodox' and 'fringe medicine'. Perhaps the most common distinction is between 'conventional' and 'complementary' therapies, yet these terms seem to defy precise definition. Even so, complementary medicine generally refers to the use of interventions that complement the use of drugs and surgery. The range of such therapies is vast and includes treatments based on traditional philosophies, manual techniques, medicinal systems, mind–body techniques and bioenergetic principles (Table 1.1). These techniques vary widely with respect to levels of efficacy, cost, safety and scientific validation, yet they often share common principles, including the concept of supporting the body's homeostatic systems, as well as acknowledging the role of lifestyle practices, personal creativity, group sharing, the mind–body connection and the role of spiritual practice in health.

COMPLEMENTARY MEDICINE IN AUSTRALIA

The practice of complementary medicine is flourishing in Australia. In 2000 it was estimated that about 50% of the Australian population took a 'natural supplement', about 20% formally saw a complementary medicine practitioner, and public spending on complementary medicines (A$2.3 billion in 2000) was more than four times patients' contributions for all pharmaceutical medications (MacLennan 2002). A follow-up survey performed in 2004 found that although spending on complementary medicines had decreased to A$1.8 billion, there was a slight increase in the number of people taking natural supplements and visits to complementary medicine practitioners rose to 26.5% (MacLennan et al 2006). More recent statistics reveal that up to 70% of the Australian population has used complementary medicine in a number of different forms (Xue et al 2007). Data from the Australian Bureau of Statistics indicates that in the 10 years leading up to 2006, the number of people visiting CM practitioners within a 2 week period rose from approximately 500,000 to 750,000 and over the same period there was an 80% increase in the number of people employed as a CM practitioner. The most commonly consulted CM practitioners were chiropractors, naturopaths and acupuncturists (Censuses of Population and Housing and from the ABS 2004-05 National Health Survey).

These figures are comparable to those from the USA, which further suggest that the use

TABLE 1.1 The Range of Complementary Therapies

Philosophical systems	Medicinal	Bioenergetic
• Ayurvedic	• Herbal therapies	• Magnetism
• Yoga	• Homeopathy	• Pulsed electromagnetic fields
• Traditional Chinese medicine	• Diet modification	• Qi gong
• Shamanic healing	• Nutritional supplementation	• Reiki
• Naturopathy	• Aromatherapy	• Therapeutic touch
Mind–body	**Manual**	
• Meditation	• Chiropractic	
• Hypnosis	• Massage	
• Self-help/support groups	• Reflexology	
• Biofeedback	• Shiatsu	
• Prayer/spiritual healing	• Osteopathy	

of CAM is increasing. Between 1990 and 1997 expenditure on these therapies in the USA increased by 45.2%, with the total of more than US$21 billion exceeding out-of-pocket expenditures for all US hospitalisations. Furthermore, visits to CAM practitioners exceeded total visits to all US primary-care physicians (Eisenberg 1998).

Similarly, use of complementary therapies by general practitioners seems to be increasing. Recent surveys have estimated that 30–40% of Australian GPs practise a complementary therapy and more than 75% formally refer their patients for such therapies (Cohen et al 2005, Hall 2000, Pirotta 2000). It is also estimated that more than 80% of GPs think it appropriate to practise therapies such as hypnosis, meditation and acupuncture and that most GPs desire further training in various complementary therapies (Cohen et al 2005, Pirotta 2000).

Interestingly a recent survey of Australian GPs found that, based on their opinions, complementary therapies could be classified as follows: non-medicinal and non-manipulative therapies such as acupuncture, massage, meditation, yoga and hypnosis, which GPs considered to be highly effective and safe; medicinal and manipulative therapies, including chiropractic, Chinese herbal medicine, osteopathy, herbal medicine, vitamin and mineral therapy, naturopathy and homeopathy, which more GPs considered potentially harmful than potentially effective; and esoteric therapies such as spiritual healing, aromatherapy and reflexology, which were seen to be relatively safe yet also relatively ineffective. Furthermore, according to GPs the risks of complementary therapies were seen to arise mainly from incorrect, inadequate or delayed diagnoses and interactions between complementary medications and pharmaceuticals, rather than the specific risks of the therapies themselves (Cohen et al 2005).

The interest of GPs in CAM is supported by the forming of links between the Australasian Integrative Medicine Association and the Royal Australian College of General Practitioners with the release of a joint position paper on complementary medicine (RACGP/AIMA 2005), as well as the introduction of teaching of CAM in undergraduate medical courses. Further academic support is evident by the establishment of departments of complementary medicine at respected universities and a proliferation of peer-reviewed journals documenting the growing body of rigorous research in the field. In line with these developments, the status of complementary medicine practitioners has been elevated, with the establishment of degree courses in natural medicine and formal registration of some professions.

There appear to be many reasons for the popularity of complementary medicine. Certainly, orthodox medicine does not have a monopoly on cure and, despite its effectiveness in treating trauma and acute disease, when it comes to chronic illness there are many people in the community who continue to suffer despite its best efforts. The public are also demanding greater autonomy and involvement in their own healthcare, and want to prevent or slow down ageing and achieve higher levels of functioning. Additionally, the exponential increase in scientific studies being published on complementary medicine therapies has no doubt added to the public's interest and confidence in its use.

Although interest in CAM has increased among both practitioners and patients, this has been paralleled by increased support from the federal and state governments. In Australia this has been demonstrated by the granting of degree status to schools of natural medicine, the exemption of some complementary therapies from the Goods and Services Tax, and government support for private health insurance companies, many of which cover complementary medicine. The federal government has also provided these therapies with formal recognition by establishing an Office of Complementary Medicine as part of the Therapeutic Goods Administration and the Complementary Medicine Evaluation Committee (CMEC), and the Victorian Government is the first outside of China to regulate the practice of traditional Chinese medicine (TCM). From the viewpoint of government spending, this encouragement makes fiscal sense, as natural therapies do not attract Medicare benefits and spending on complementary medicines is patient- rather than government-funded.

Despite moves to support complementary therapies, in practice it seems that there are two distinct healthcare systems operating in parallel, and interaction is still in its infancy. It is estimated that, of the patients who go to complementary practitioners, more than 57% do not inform their doctor they are doing so (MacLennan et al 2006). This lack of communication is potentially hazardous, as it raises the possibility of treatment interactions; this is even more significant when it is considered that in the USA more than 80% of people

seeking complementary treatment for 'serious medical conditions' were found to be receiving treatment from a medical doctor for the same condition (Eisenberg 1993).

COMPLEMENTARY MEDICINE IN NEW ZEALAND

Complementary medicine has been practised in New Zealand since the 19th century (Duke 2005). In 1908, the Quackery Prevention Act was enacted to prevent the sale of dubious medicines or medical devices and represents an early attempt to regulate the practice of CAM. At the time, what is now termed CAM had achieved a level of acceptance among the medical profession; however, a division began to emerge between medical and complementary practices because of the Act.

Over the past decade, studies indicate that conventional medical practitioners in New Zealand practise some form of complementary therapy or refer their patients to complementary medicine practitioners (Duke 2005). One study of 226 GPs in Wellington suggested that they saw their role as ranging from comprehensive provider of both conventional and complementary medicine to selective practitioner of some options (Hadley 1988). Of these GPs, 24% had received complementary medicine training, 54% wanted further training in a complementary therapy, and 27% currently practised at least one therapy. The study also found that acupuncture, hypnosis and chiropractic were the most popular therapies among this group.

In June 2001, the Ministerial Advisory Committee on Complementary and Alternative Health (MACCAM) was established in order to advise the New Zealand Minister of Health. Policies regarding regulation, consumer information needs, research evidence and efficacy and integration were investigated, together with a range of strategies to allow CAM to contribute to the mainstream objectives of the New Zealand Health Strategy (MACCAM 2004).

Currently, the New Zealand Charter of Health Professionals estimates that there are 10,000 CAM practitioners nationally. The 2002–03 New Zealand Health Survey (n = 12,000) indicated that approximately 24% of adults had visited a CAM practitioner over the 12-month study period (MACCAM 2004). Massage therapists, chiropractors, osteopaths, homeopaths or naturopaths were the most commonly consulted CAM practitioners. The survey found that 32.5% of people seeing CAM practitioners did so for the treatment of a chronic condition, long-term illness or disability, while 33% also saw a GP for the same condition. A belief that CAM practitioners can provide help with conditions that other healthcare professionals are unable to treat was the main driving force behind their choice. Most referrals came from friends; however, 12% reported that they had been referred to the service by a medical doctor.

THE MEDICAL SPECTRUM

The range of available therapies is vast, but there is a common benchmark for all — reducing human suffering. On this criterion, it is possible to classify all medicine into good and bad, with good medicine defined as effective, safe, practical and, ideally, evidence based, and bad medicine defined as ineffective or potentially harmful.

Additionally, the different therapies can be seen to exist across a spectrum with multiple dimensions, such as safety, efficacy, practicality, availability, utility and cost-effectiveness. At one end of this spectrum is the science of medicine, which aims to understand and combat the disease process from a pathophysiological perspective. Therapies using this approach are often at the core of mainstream medicine, require practitioner intervention, target a specific organ, system, tissue or biochemical process, and are usually subsidised by the public purse. At the opposite end is the art of medicine, which aims to support the body's homeostatic processes to facilitate healing and enhance the subjective sensation of wellness. Therapies using this approach often involve philosophical systems with a spiritual dimension, are highly individualised, consider the whole person and may require significant patient involvement and cost. When considering the different dimensions of medical practice, it becomes clear that best practice should incorporate both approaches and combine the art and science of medicine.

Health and disease can also be considered to inhabit opposite ends of an illness–wellness spectrum, with health being classified into three broad areas — ill-health, average health and enhanced health (Figure 1.1) (see also Chapter 12). In the past, Western medicine has focused on helping people move from ill-health to average health and has viewed the

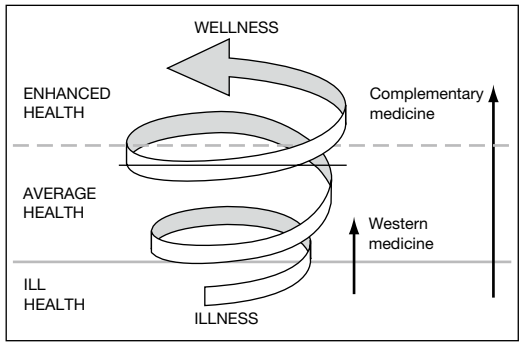

FIGURE 1.1 Conceptualisation of the spectrum of health

absence of disease as an ideal goal. In relatively recent times, preventative treatment has also been incorporated into medical management, in an attempt to reduce the incidence or exacerbation of disease states. In comparison, CAM has always maintained a focus on preventative approaches and moving people from average health to a state of enhanced health. In Eastern medicine there is a concept of a 'perfect health' state, in which a person is totally balanced and 'at one with the universe', and hence in a state of perpetual bliss or 'nirvana'.

INTEGRATIVE AND HOLISTIC MEDICINE

When complementary and conventional approaches to medicine are combined, their practice is often called holistic or integrative medicine (see Chapter 6). This combined approach aims to achieve a balance between art and science, theory and practice, mind and body, and prevention and cure. The practice of integrative medicine is highly individualised and focuses on *how* medicine is practised rather than the use of any particular modalities. It embraces a philosophy that adheres to certain principles, such as the BEECH principles:

- **B** **B**alance between complementary aspects
- **E** **E**mpowerment and self-healing
- **E** **E**vidence-based care supporting the concept 'First, do no harm'
- **C** **C**ollaboration between practitioner and patient, and between different practitioners
- **H** **H**olism and the recognition that health is multidimensional.

Integrative medicine focuses on patient self-healing and empowerment through education and health promotion, and aims for a collaborative approach through a partnership model. Overall, an evidence-based, patient-centred care approach is adopted that includes the fundamental principle of *primum non nocere* or 'First, do no harm'. This approach considers the best available evidence on safety and efficacy, and recognises that each person is an individual whose health involves physical, psychological, social, spiritual and environmental dimensions. Integrative medicine also recognises that optimal healthcare requires a multidisciplinary approach, with each discipline having its own defined strengths, weaknesses and limitations.

Besides the use of disease-specific treatments, integrative medicine also incorporates general health-enhancing and supportive interventions to improve wellbeing. This may include stress management techniques such as meditation and relaxation training, exercise programs to improve physical activity, dietary recommendations to improve nutritional status, and education to provide a greater sense of control and understanding of illness and health. These interventions form the pillars of a holistic approach to healthcare and can be summarised by the SENSE approach:

- **S** **S**tress management
- **E** **E**xercise
- **N** **N**utrition
- **S** **S**ocial and spiritual interaction
- **E** **E**ducation

HERBAL MEDICINES AND NATURAL SUPPLEMENTS

Since the beginning of time, humans have sought to ease pain, heal sickness and improve energy levels by using various substances as medicines. These attempts began by using things found in the local environment, such as plants, minerals and animal parts, and has now evolved to include many previously unknown chemical entities, such as vitamins, minerals and phytochemicals. Today, an unprecedented range of herbal and natural supplements and functional foods is available.

As with all treatments, the benefits of using a medicine, changing a diet or making lifestyle changes must be weighed against the potential for doing harm: that is, the risk of using/taking/doing something and causing harm, or of not using/taking/doing it and causing harm (Table 1.2, p 6). Adverse effects from the use of natural supplements can result from an inherent property of the substance itself, inappropriate use, product adulteration or contamination not related to the substance but found within the preparation, and interactions with other substances or preexisting medical conditions.

TABLE 1.2 Reasons for Using Herbal Medicines and Natural Supplements	
Efficacy	When they will alleviate symptoms of disease, reduce exacerbation or present a cure.
Safety	When they present a safer treatment option than other therapies.
Cost	When they provide cost-effective treatment options.
Adjunct	If the efficacy and/or safety of other interventions can be improved with adjunctive use.
Prevention	When they provide safe prevention strategies in at-risk populations.
Enhance health	If they give a sense of improved wellbeing and quality of life.
Enlists	They involve patients in their own healthcare.

These issues are discussed in greater depth in the following chapters.

PRODUCT QUALITY AND REGULATION

Risk assessments are a key factor in the decision to use any intervention. Australia has an international best-practice, risk-based, regulatory system for both complementary and prescription medicines. This system is regulated by the Therapeutic Goods Administration (TGA), which aims to ensure safety, quality and truth in the labelling of therapeutic goods available to the Australian public. The TGA acts to control the supply of therapeutic goods, including complementary medicines, through three main processes — regulation of manufacturers, and pre- and post-marketing assessment and surveillance. These elements are supported by penalties for breaches of regulations.

The TGA acts to ensure that all therapeutic goods sold in Australia, including herbs and natural supplements as well as prescription medicines, are manufactured according to good manufacturing practice. It licenses manufacturers and conducts regular inspections to audit their compliance. High-risk products such as prescription medicines, or low-risk products with high-level claims, are individually evaluated for safety, quality and efficacy and are entered into the Australian Register of Therapeutic Goods (ARTG) as 'registered' goods, thereby carrying an 'AUST R' number on their labels. Low-risk products such as most herbs and natural supplements are evaluated only for safety and quality, 'listed' on the ARTG and then carry an identifying 'AUST L' number on their label.

Listed products are awarded low-risk status based on a number of controls, including assessment of the scientific evidence, the presence of label advisory information, dosage limits, mode of administration, restriction on the use of particular plant parts or other preparation restrictions, and container type. These products are able to carry a wide range of low- and medium-level medicinal claims, which must be supported by the appropriate level of evidence (Table 1.3). It should be noted that the levels of evidence designated by the TGA are slightly different from the levels designated by the National Health and Medical Research Council (NHMRC 1999), because the TGA acknowledges evidence from traditional use, accepting that, if a substance has been used with good effect and apparent safety for three generations, it may be considered safer than a newly created substance that has never existed in nature (TGA 2001).

In addition to regulating manufacturing and the control over label claims, the TGA also conducts post-marketing surveillance such as:

- monitoring of adverse drug reactions
- targeted and random laboratory testing of products and ingredients
- audit of good manufacturing practice
- an effective co-regulatory approach to controlling advertising of therapeutic goods. The Complementary Medicine Evaluation Committee (CMEC) is a ministerially appointed committee that advises the Office of Complementary Medicine within the TGA about matters relating to complementary medicine products.

Although Australia employs the same rigorous system for maintaining the quality of herbs and natural supplements as for prescription pharmaceuticals, this is not the case in many other countries. The problem of poor product quality has become a major concern in some Asian countries, where authorities have undertaken random sampling of suspected herbal products to determine whether adulteration has occurred. Huang et al (1997) report one survey in Taiwan where 2609 herbal samples were collected by eight major general hospitals. Analysis with thin-layer chromatography found an average of 23.7% of samples to be adulterated with chemical substances not stated on the label. Of these, more than half (52.8%) contained two or more adulterants (Awang 1996, Huang et al 1997).

TABLE 1.3 Levels of Evidence Used by the Australian TGA

Level of evidence	Type of evidence required
High-level scientific evidence	Evidence obtained from a systematic review of all relevant RCTs, without significant variations in the direction or degree of results. *OR* Evidence obtained from at least one properly designed randomised, controlled (preferably multicentre), double-blind trial. It is preferable to have data from at least two trials independent of each other, but in some cases, one large well-conducted trial may suffice (advice should be sought from the TGA in such cases).
Medium-level scientific evidence	Evidence obtained from well-designed controlled trials without randomisation. In the case of a homeopathic preparation, evidence from a well-designed, controlled homeopathic proving. *OR* Evidence obtained from well-designed analytical studies, preferably from more than one centre or research group, including epidemiological cohort and case–control studies. *OR* Evidence obtained from multiple time series with or without intervention, including within-country and between-country population studies. *Note:* In practice, the sources of most medium-level evidence will be peer-reviewed published papers and evidence-based reference texts. However, other evidence that meets the requirements, including independently reviewed unpublished evidence, may also be acceptable. Websites evaluating peer-reviewed published evidence may be a source of suitable evidence.
Low-level or general scientific evidence	Descriptive studies, case series or reports of relevant expert committees. Texts, such as TGA-approved pharmacopoeias or monographs, or other evidence-based reference texts, may be included in this level. Evidence derived from non-human data, such as in vitro studies and animal studies, and non-clinical studies, such as biochemical, nutritional and microbiological studies, does not stand alone and may be used only as supporting evidence.
Traditional evidence	Three or more generations of recorded use of a substance for a specific health-related or medicinal purpose that are documented by at least one of the following: • TGA-approved pharmacopoeia • TGA-approved monograph • three independent written histories of use in the classical or traditional medical literature • availability through any country's government public dispensaries • authenticated evidence of use from an oral tradition; modern texts that accurately report the classical or traditional literature may be used to support claims.

Government actions: the PAN Pharmaceuticals recall in Australia

On 28 April 2003 the TGA suspended the licence of Pan Pharmaceuticals, Australia's largest manufacturer of herbal, mineral and nutritional supplements at the time, and ordered the immediate withdrawal of hundreds of products it had manufactured. The company was accused of substituting ingredients, manipulating test results and having substandard manufacturing processes. The TGA was first alerted to possible manufacturing problems when dozens of adverse reaction reports to a pharmaceutical motion sickness tablet known as Travacalm were lodged. After some investigation, it was found that manufacture of this product was substandard and doses of the active ingredient varied enormously from that stated on the label.

Although the original product in question was a pharmaceutical drug, over the next few months media attention remained focused on natural medicine products, with some commentators seizing the opportunity to call into question the value of CAM in general. As a result, the Federal Government set up an expert committee to examine the role of complementary medicines in the healthcare system, including the supply of safe, high-quality complementary medicines, quality use of and timely access to these medicines, and the maintenance of a responsible and viable complementary medicines industry. The terms of reference set for this committee were very broad, not unlike those of the White House Commission on Complementary Medicine. The recommendations made by the expert

committee, which covered the regulation of complementary medicines and complementary healthcare practitioners, research, and the information and education needs of healthcare practitioners and consumers to improve community confidence in, and the viability of, the complementary medicines industry, could be viewed online at http://www.tga.gov.au/cm/cmreport2.htm, along with the government's response to these recommendations.

Following recommendations from this committee, and in recognition of the growing importance of complementary medicine in the Australian health system, the Federal Government established the National Institute for Complementary Medicine (NICM) in 2007. Its role was to provide leadership and support for complementary medicine research and the translation of evidence into clinical practice and policy, as well as to build research capacity and foster collaborations amongst researchers from different disciplines (see www.nicm.edu.au). NICM was provided with A$4.8 million for 2 years to achieve these goals. As part of its role in developing Australia's complementary medicine research capacity, NICM established three NICM collaborative research centres after a competitive submission process. The government's ongoing commitment to the future of NICM, however, remains uncertain.

What does seem certain, however, is that research into complementary medicine is likely to increase. The establishment of NICM coincides with the National Health and Medical Research Council making complementary medicine a priority area for research with over A$5 million of research funding being allocated to complementary medicine research in 2008. This has encouraged interdisciplinary collaboration, as many established researchers from other disciplines have become involved in funded projects in different areas of complementary medicine. Government recognition and support for complementary medicine in Australia seems to be paralleled around the world, although the level of funding support still lags far behind the United States. In 1992 the US government established the Office of Alternative Medicine with US$2 million funding. This office has now grown to become the National Centre for Complementary and Alternative Medicine (NCCAM) as part of the National Institute of Health (see http://nccam.nih.gov), with US$121 million in funding allocated in 2008. Complementary medicine also seems to be on the US policy agenda: the recent Senate Committee on Integrative Care: A Pathway to a Healthier Nation received testimony from leaders of integrative medicine (US Senate Committee 2009).

EVIDENCE-BASED COMPLEMENTARY MEDICINE

When faced with the vast array of herbs and natural supplements, the question naturally arises as to which are effective (and in what way and under what conditions), and which are ineffective or potentially dangerous. Attempting to answer this question is extremely complex; it is also compounded by the possibility of either beneficial or harmful interactions with pharmaceutical interventions, and the highly individual physiological, psychological, social and spiritual factors that contribute to overall health status.

Although much empirical wisdom has been handed down through the ages via folklore and systems of traditional medicine, modern medicine attempts to distinguish between different therapeutic options by using the scientific method and the different forms of scientific evidence. In recent times, many herbal and natural supplements have been subjected to thousands of scientific studies in the same way as pharmaceutical medicines have been investigated, and examples of these are found on nearly every page of this book. The scientific study of herbs and natural products adds to previous knowledge and will provide a greater understanding of these medicines.

IN VITRO STUDIES

In vitro testing generally looks at fundamental biological and biochemical processes and can provide important information about biochemical pathways, as well as pharmacokinetic data. Although in vitro tests are helpful, caution should be taken when extrapolating results from them, as the results may not accurately reflect the biological effects seen in the human body.

An example of this is St John's wort. In vitro tests have found that St John's wort inhibits several cytochrome P450 isoenzymes (Budzinski et al 2000, Obach 2000). Clinical tests, however, show that the herb actually has enzyme inducer activity, which is the opposite finding to that of the in vitro tests (Durr et al 2000, Roby et al 2000, Ruschitzka et al 2000).

Anomalies such as this are not restricted to herbal preparations, but have also been observed in regular drug testing. Thus, while

in vitro evidence may be useful, the most accurate method for determining biological activity of a substance is to test it directly in humans (Wienkers 2002).

IN VIVO STUDIES

Studies conducted in animals are able to examine dietary manipulations or administration of experimental agents in specific diseases and deficiency states, and to determine the effects on organ systems and physiological functions. These studies allow for a more rigorous investigation of pharmacological activity than in vitro testing. However, in vivo studies can never be more than suggestive when attempting to assess clinical significance because of interspecies differences. Additionally, the relevance of the dose used must be considered, and extrapolation to clinical relevance in humans is not always accurate.

HUMAN STUDIES

Studies conducted in humans range from anecdotal reports or individual case series, to case–control and cohort studies, and randomised placebo-controlled trials of specific interventions for particular diseases, as well as meta-analyses and systematic reviews of RCTs.

Case reports

Case reports supply informative and realistic information within a clinical setting involving the relevant patient population. Rather than providing definitive information, case reports are merely an investigative starting point for determining clinical relevance.

Extrapolating information from case reports presents some unique challenges and may lead to an overestimation of significance when confounders are not identified and considered carefully. Some of the confounding influences that need to be considered include patient factors such as the placebo effect and concomitant illness and/or the administration or interactions of other agents, as well as factors concerning the substance itself, including errors in labelling, herbal substitution, product adulteration and contamination. It is therefore of prime importance that the product be chemically analysed to confirm its contents, especially when an adverse reaction or interaction is reported in this way.

Randomised controlled trials

Randomised controlled trials (RCTs) provide the most solid foundation for clinical decision making. Those trials performed in the population of patients likely to use the therapeutic agent being tested have the highest validity.

The conduct of an RCT is specifically designed to remove possible sources of bias so that the results are as impartial as possible. The specific nature of RCTs means they cannot answer the general (and non-specific) question as to whether a certain intervention works. An RCT is a specific research tool designed to show whether a specific (active) intervention improves clearly defined outcomes for a specific group of patients suffering from a particular medical condition better than a comparative intervention. These trials are generally defined by four parameters designated by the mnemonic PICO:

- **P** a specifically defined patient **P**opulation
- **I** a well-defined **I**ntervention
- **C** a suitable **C**omparative intervention (often a placebo)
- **O** specific **O**utcome measures.

Although RCTs provide solid evidence, it must be realised that these trials do not always accurately reflect real life, because they are set in a controlled, experimental context with strict inclusion and exclusion criteria and standardised interventions and outcomes. Furthermore, individual variation still occurs, and it is imperative that a study has sufficient statistical power (largely determined by sample size) to be able to detect a clinically relevant result.

Systematic reviews and meta-analyses

When more than one randomised trial has been conducted to answer a particular question, it is possible to statistically combine their results and perform an analysis using the summary statistics from each study as data points. Such a meta-analysis requires that studies use similar measures. By accumulating the results of multiple studies a meta-analysis can provide greater statistical power and therefore a more accurate representation of the relationship under investigation than the individual studies.

Systematic reviews also provide a way of reviewing and summarising the result of multiple RCTs. These reviews attempt to identify all the individual RCTs conducted for an intervention; after systematically examining the methodology and results of each study, they provide a summary of the results and then reach an overall conclusion. Because systematic reviews rely on the results of RCTs, they must be updated regularly as new RCTs are

The Cochrane Collaboration

The Cochrane Collaboration (www.cochrane.org) is an international, not-for-profit collaborative effort that aims to produce up-to-date systematic reviews of all RCTs for both conventional and complementary therapies. The Cochrane Collaboration takes its name from physician and humanitarian Archie Cochrane (1906–88), who strongly advocated the production of critical summaries of research evidence as a way of creating 'evidence-based medicine'.

A systematic review assembles all the RCTs on a given health topic and uses explicit methods to minimise bias (systematic errors) and random error (simple mistakes). It then critically reviews the evidence and summarises the results to determine the safety and effectiveness of an intervention. The Collaboration publishes its systematic reviews quarterly in the Cochrane Library, which is freely available through the National Institute of Clinical Studies via www.nicsl.com.au/cochrane/index.asp.

The Cochrane Consumer Network (www.cochraneconsumer.com) aims to help healthcare consumers make sense of medical research. Its website provides useful information about research jargon and styles, explains how to tell a good study from a bad one, and provides help in finding and understanding health and medical research results.

published. Although many researchers publish systematic reviews, the Cochrane Collaboration has standardised the methodology for performing systematic reviews and regularly publishes results of reviews through the Cochrane Library (see box).

ASSESSING EVIDENCE

There are many dimensions to consider when assessing evidence from clinical studies. Thus, it is important not only to consider the level of evidence, but also to determine the quality of the study (how well the investigators carried out the particular study design), as well as the certainty (statistical precision) of the results. Furthermore, it is important to assess whether the outcome measures and the size of the observed effect are clinically relevant. These dimensions are considered by the NHMRC (2000) and are summarised in Table 1.4.

LIMITATIONS OF EVIDENCE

The rational use of medicines has recently moved towards 'evidence-based care' and recognises that this relies on the conscientious, explicit and judicious use of the *best available evidence* in making decisions about the care of individual patients (Sackett et al 1996). An evidence-based approach recognises both different levels of evidence and that the most rigorous types are not always available. In the light of this, many clinical questions cannot be answered by reference to well-conducted trials and require additional information such as that obtained from experience and historical use.

TABLE 1.4 Dimensions of Evidence

Type of evidence		Definition
Strength of evidence	Level	The study design used, as an indicator of the degree to which bias has been eliminated by design.
	Quality	The methods used by investigators to minimise bias within the study design.
	Statistical precision	The *P*-value or, alternatively, the precision of the estimate of the effect (as indicated by the confidence interval). It reflects the degree of certainty about the existence of a true effect.
Size of effect		The distance of the study estimate from the 'null' value and the inclusion of only clinically important effects in the confidence interval.
Relevance of evidence		The usefulness of the evidence in clinical practice, particularly the appropriateness of the outcome measures.

Source: NHMRC 2000

Randomised controlled trials have been commonly performed only since the 1950s and are complex and costly processes that require large investments of time and money, as well as access to specialised infrastructure and technical and clinical skills. These hurdles are often even higher for herbs and natural supplements than for pharmaceutical medicines, because the lack of patent protection for these products means there is little incentive for companies to invest millions of dollars in research when they cannot obtain a commercial advantage from the results. The relative lack of funding also means that very few research centres are dedicated to exploring this field and few dedicated researchers with the necessary skills are available. Inevitably, there is a smaller scientific evidence base for herbal and natural substances than for synthetic pharmaceuticals.

It is also important to recognise that a lack of evidence for a particular effect does NOT mean that there is evidence for a lack of effect. Put another way, no evidence is not the same as negative evidence. It may simply mean that the research has not yet been conducted because of lack of funding and specialised resources, methodological or logistical constraints and a general lack of opportunity. As a result, there may never be evidence for some treatments, but this does not necessarily mean that the treatment is not effective.

There are several other serious limitations to the sole use of existing scientific evidence, as most are based on statistics that aim to produce results that can be applied to populations of people rather than individuals. Additionally, they are based on averages and probabilities, which also fail to account for individual factors. Thus, despite some recent studies that have attempted to address these issues through novel methodological approaches, the application of scientific evidence is often extremely limited when assessing the effectiveness of individualised therapy.

A further problem arises when trying to make decisions about health rather than disease. Most clinical trials are interested in studying movement across the line that separates 'defined disease' from 'average health' (Fig 1.1). While it is possible to define the particular disease in question through reference to objective parameters, such as biochemical and/or physiological variables, as well as to specific patterns of symptoms, defining optimal health and wellbeing is not as easy. Optimal or enhanced health is a subjective and highly individual state that does not lend itself easily to scientific scrutiny. It is therefore difficult to provide scientific evidence for measures designed to move people from 'average health' towards 'enhanced health' or 'optimal health'.

APPLYING EVIDENCE

Despite the publication of the NHMRC and TGA guidelines for assessing scientific evidence, applying evidence in clinical practice can be extremely complex. Not only does evidence take many different forms, it can also be applied to answer many different types of questions, such as whether a particular therapy works in theory (a question of efficacy) or in clinical practice (a question of effectiveness), as well as whether the use of a therapy is safe and/or cost-effective. Furthermore, there is the question of how a therapy actually works: it is common for evidence to suggest that a therapy is beneficial, even though the mechanism of action remains unknown or, if it is known, for questions about whether the therapy provides clinical benefit to remain unanswered.

The complexity of applying evidence to clinical decision making is compounded by the tens of thousands of studies published every year, with varying degrees of clinical relevance and methodological rigour. Evaluating this evidence can be very confusing, as the results of studies are not always obvious, and their relevance to a particular clinical situation is not always clear. There may also be conflicting results and ongoing controversies in which even the experts disagree. Furthermore, it can be difficult to determine the independence of the information provided, as many influences may be involved: for example, governments, regulatory authorities, commercial interests such as the pharmaceutical, natural medicine and food industries, disease advocacy and consumer groups, the personal interests of the individual researchers and the editorial board, and publication bias.

FINDING EVIDENCE

Obtaining and assessing the available evidence can be both difficult and time-consuming for the busy clinician. Although general medical information is freely available on the internet and via electronic bibliographical databases, fees may need to be paid to access specialised resources for CAM. Additionally, the information available varies considerably in its scope, quality and practicality.

NPS review of complementary medicine information resources

In 2008 the National Prescribing Service (NPS) in Australia commissioned a review of complementary medicine information resources. It aimed to identify high-quality resources that could be recommended for use by Australian health professionals and consumers. A list of 52 information resources from reputable sources was tested against broad criteria encompassing currency, coverage, transparency and content quality to produce a short list of 26 electronic resources. These final resources were evaluated for technical quality, content quality and clinical utility, producing a final list of nine resources.

This book was included in the final list of highest-quality resources, a feat of which the authors are particularly proud, as it was the only resource not to be linked to an online database. A summary of the report can be obtained from the NPS website (www.nps.org.au/research_and_evaluation).

Collections of original research with bibliographical data and abstracts include services such as Medline, Embase, Science Direct and ProQuest. Other databases such as Herbmed, MicroMedex and the Natural Medicines Comprehensive Database provide summaries of current research for numerous herbal and natural medicines. Other collections such as the Cochrane Collaboration Library attempt to produce the most authoritative guide to medical research by providing only systematic reviews of RCTs.

Although databases that provide references to original research are extremely useful, there is a definite need for more summarised and critically reviewed material. This need is met to a certain extent by the publication of review articles in textbooks such as the German Commission E Monographs, or by commercially available databases such as Integrative Medicine Gateway, Natural Medicines Comprehensive Database and the Natural Standard Database.

MISLEADING HEADLINES

Unfortunately, many health professionals do not have ready access to research papers or are too busy to be able to read through full reports and therefore rely on short summaries to provide information. As in the popular press, the medical press is prone to creating sensational headlines to attract interest, but this can lead to inaccurate assumptions. A good example is the case of an apparent coma state brought on by the combination of the herbal medicine kava kava and the benzodiazepine alprazolam. The case was reported with the headline 'Coma from the health food store: interaction between kava and alprazolam' (Almeida & Grimsley 1996). A closer look at the report reveals that the patient described was lethargic and disoriented, but at no time comatose. Additionally, he was also taking cimetidine, a CYP450 inhibitor that can affect alprazolam metabolism, resulting in raised serum levels and symptoms of lethargy. An interaction with kava kava is unlikely.

FACTORS TO CONSIDER IN DECISION MAKING

As previously discussed, scientific evidence provides useful and important information; however, it must be combined with several other important factors in clinical practice to be truly effective for the individual patient. An expanded approach, often discussed as 'evidence-based patient-centred care', is becoming more widely adopted, the chief principles of which are in unison with the integrative medicine approach to incorporating evidence into clinical practice. The key principles may be summarised by the PEACE mnemonic:

- **P** acknowledgment and respect for the **P**ersonal preferences of both the practitioner and the patient
- **E** the strength of the available scientific **E**vidence
- **A** the range of possible **A**lternatives
- **C** the associated **C**osts and risks versus the potential benefits of a proposed treatment
- **E** aspects of **E**xpedience, such as availability, accessibility and immediacy of treatment.

It is easy to become overwhelmed when reviewing the vast range of therapeutic options available, the complexities of accessing and appraising the different types of scientific evidence, and the other factors that must be considered when making choices about treatment options. This evidence-based book is an

attempt to provide some guidance through the current maze of information and evidence. Certainly, more information is needed: in an ideal world every therapy would have clear evidence to support or refute its use in different conditions, and this information would be freely available and without inherent bias. However, that time is still far away, and clinical decision making remains both a subtle art and an inexact science, where there is always room for more information, research and debate.

CHAPTER 2
INTRODUCTION TO HERBAL MEDICINE

Herbal medicine, also known as phytomedicine, can be broadly defined as both the science and the art of using botanical medicines to prevent and treat illness, and the study and investigation of these medicines. The term 'phytotherapy' is used to describe the therapeutic application of herbal medicines and was first coined by the French physician Henri Leclerc (1870–1955), who published numerous essays on the use of medicinal plants (Weiss 1988).

Phytotherapy can be considered one of the oldest forms of medicine. Since the dawn of time, plants have been used by people of all races, religions and cultures to sustain life and alter the course of disease. Over this time, the medicinal use of plants has evolved along two parallel paths, with the comparatively recent evolution of modern medicine. One path involves the accumulation of empirical knowledge over centuries. Gathered through careful observation of nature and disease, and from cumulative experiences of informed trial and error, the empirical knowledge base for herbal medicines is very large and diverse. For example, the *Rig veda*, a text from India, and the Egyptian papyri *Antiquarium* both date from 3000 BC and contain extensive lists of medicinal plants used to treat illness (Berman et al 1999). In South America, the use of herbal medicine has also been documented, such as in the *Badianus* manuscript, a text written by the Aztecs (Walcott 1940). Their use of herbs, such as datura and passionflower, has been adopted in modern European and American pharmacopoeias. Native Americans were particularly knowledgeable about the botanical medicines in their environment. It has been estimated that more than 200 medicines that were used by one or more Indian nations have been incorporated into the US Pharmacopoeia or National Formulary (Vogel 1970).

Two of the most prominent historical figures in European herbal medicine are Dioscorides and Galen, who were both physicians in ancient Greece. Dioscorides was a Greek army surgeon in the service of the Roman emperor Nero (54–68 AD). He is best known for his *De materia medica*, which describes more than 600 herbs and their uses. Today this work is considered to be the first book ever written about medical botany as an applied science. Galen (131–201 AD) not only wrote several dozen books on pharmacy, but also developed an elaborate system of herbal polypharmacy in which herbal combinations were devised to produce more specific results. The modern term 'galenicals' is still used to describe herbal simples.

Alongside the 'empirical knowledge' approach, a second path developed, which involved a more theoretical and formalised method of diagnosis and treatment. The resulting 'healthcare' systems were complex and often used herbal medicines as an important part of a more comprehensive approach to treatment that also included dietary control, lifestyle changes and spiritual practice. This approach reached its peak in the East with traditional Chinese medicine and Ayurvedic medicine in India.

Although contemporary clinical practice of herbal medicine still relies heavily on traditional wisdom, this knowledge is now being re-examined with the aid of modern analytical methods and scientific methodology. The use of science to establish an evidence base in modern healthcare is changing the way herbalism is being practised and who is using herbs. An

emphasis on phytochemistry and an assessment of risk are inherent features of contemporary research into herbs. While these are important gains in knowledge about the actions and uses of herbs, there is an accompanying shift in the practice of herbal medicine, with less emphasis on the importance of traditional and empirical knowledge, which in time may lead to a loss of the paradigm of holistic and individualised care (Evans 2008). Whether this improves patient outcomes remains to be seen.

HERBS, DRUGS AND PHYTOCHEMICALS

Most pharmaceutical medicines contain a single, highly purified, often artificially produced substance that has a well-known (and occasionally specifically designed) chemical structure that can be patented and owned by the company that developed it. The dosage of these chemicals can also be precisely calculated down to the microgram and can usually be characterised by a very clear pharmacokinetic profile. Additionally, pharmaceutical drugs tend to have a generally agreed upon mechanism of action and series of indications that guide their use within the Western medical model.

As most of these drugs do not exist in nature, they must go through extensive testing to ensure efficacy and safety. New drugs are assessed in test-tube and animal studies for their potential to cause cancer, fetal malformations and other toxic effects, and are ultimately tested on humans to further define the safety profile, pharmacokinetics and drug effectiveness in a targeted disease (Wierenga & Eaton 2003). This process is very costly and requires the application of highly specialised knowledge and infrastructure, as well as many years of concentrated effort. It is estimated that the development of a new drug requires the investment of approximately US$800 million, but it is also extremely lucrative (Di Masi & Grabowski 2003).

PHARMACOGNOSY

In 2001 and 2002, approximately one-quarter of the best-selling drugs worldwide were natural products or derived from natural products. Research on natural products further accounted for approximately 48% of the new chemical entities reported from 1981 to 2002.

Modern drug discovery from medicinal plants has evolved to become a sophisticated process that includes numerous fields of enquiry and various methods of analysis. Typically, the process begins with a botanist, ethnobotanist, ethnopharmacologist or plant ecologist collecting and identifying plants based on the biological activity suggested by their traditional use. Additionally, plants are randomly selected for inclusion in screening programs based on molecular targets identified through the human genome project (Balunas & Kinghorn 2005).

Pharmacognosy is the term used to refer to the study of botanical supplements and herbal remedies, as well as to the search for single-compound drugs from plants. Increasingly, pharmaceutical medicines and preclinical research into herbal medicines are focused on identifying suitable chemical entities that may form the basis for novel treatments (Balunas & Kinghorn 2005).

CHEMICAL COMPLEXITY

In contrast to pharmaceutical drugs, which are based on single molecules that may or may not be derived from natural substances, herbal medicines are chemically complex and may contain many hundreds or even thousands of different 'phytochemicals', including various macro- and micro-nutrients such as fats, carbohydrates and proteins, enzymes, vitamins and minerals. A group of important secondary metabolites are also present, which are generally chemicals used to defend against herbivores, pathogens, insect attack and microbial decomposition, or which are produced in response to injury or infection, or used for signalling and growth regulation. It is these compounds, such as tannins, isoflavones, saponins, flavonoids, glycosides, coumarins, bitters, phyto-oestrogens etc, that are often responsible for the therapeutic properties of herbal medicines (Mills & Bone 2001).

As the secondary metabolites largely dictate a herb's pharmacological nature, a knowledge of herbal chemistry is essential to understand a herb's use and provide valuable insight into its clinical effects. It is sometimes tempting to take the modern reductionist approach and predict the pharmacological activity of a herbal medicine from an understanding of the effects of one key constituent or chemical group; however, this is unlikely to be entirely accurate. In practice, the overall pharmacological activity and safety of each herb is the result of the interaction of numerous constituents, some

of which have demonstrated pharmacological effects, rather than the effect of a single active ingredient.

An example of this is the herb *Paullinia cupana*, commonly known as guarana. As there are limited clinical studies on guarana, it is often reported that the herb owes its pharmacological activity to one key constituent, caffeine, which may be present in concentrations as high as 10%. Studies referring to the isolate caffeine provide some clues about the effects of guarana, but are not entirely accurate, as other important constituents are also present in the remaining 90%. This has been borne out recently in clinical studies of low-caffeine-containing guarana preparations, which still demonstrated significant effects on cognitive function.

Because of the range of phytochemicals present in plants, herbal medicines often include many different active substances with different pharmacokinetics that work at different sites with different mechanisms of action. Herbal medicines therefore potentially have multiple pharmacological actions and many different clinical indications. Furthermore, in addition to the active ingredients, herbs may also contain substances that act to inhibit or promote the active properties, and/or potential unwanted side effects of the active agents. Thus, although specific components may not be active themselves, they may influence the activity of other components by altering their solubility, absorption, distribution or half-life.

For instance, berberine is a constituent of herbs such as goldenseal and barberry and exhibits numerous activities in vitro; however, in vivo, it has poor bioavailability (Pan et al 2002). Berberine has been shown to upregulate the expression and function of the drug transporter P-glycoprotein (P-gp) (Lin et al 1999), thereby reducing the absorption of P-gp substrates. Studies with the P-gp inhibitor cyclosporine have shown that it increases berberine absorption six-fold, as it counteracts the inducing effect of berberine (Pan et al 2002). P-gp inhibitors are also found in nature, such as the virtually ubiquitous quercetin, and when they are present in the same herb competing effects on P-gp expression and function will occur.

The herb St John's wort provides yet another example. The extraction method used in Germany in the product's commercial manufacture was modified in the late 1990s, resulting in higher concentrations of hyperforin than previously obtained (Madabushi et al 2006). Since then, numerous reports and studies have identified pharmacokinetic drug interactions with St John's wort, based on its ability to induce cytochromes and P-gp. It is now well established that hyperforin is the key constituent responsible for these unwanted effects, and St John's wort preparations manufactured with this newer extraction method, such as LI 160, can put people at risk of interactions. Meanwhile, studies with low-hyperforin preparations, such as Ze117, have found that it fails to induce the same interactions (Madabushi et al 2006). Unfortunately, this distinction between St John's wort preparations is not well known and many references and texts fail to mention this important point.

As these examples and many others in this book demonstrate, each herb is chemically complex and produces a pharmacological effect based on the total sum of actions produced by a myriad of constituents that may be acting in synergy. This complexity complicates the ability to test herbal medicines as they are most commonly used (that is, in their more natural states) and in combination with other herbal medicines.

SYNERGISTIC INTERACTIONS

The concept of synergistic interactions is another fundamental difference between herbs and drugs and explains how a single herb may have a number of seemingly unrelated mechanisms of actions and be indicated for a variety of conditions. Intra-herbal interactions between active and apparently non-active constituents also mean that tests performed with single, isolated constituents will not accurately represent the actions and safety of the entire herbal medicine. As such, these tests provide limited information. By and large, it is suspected that it is the intra-herbal interactions that give herbs a broad therapeutic range and very good tolerability.

St John's wort, popularised as a useful treatment for depression, is also an excellent example of intra-herbal interaction. It contains many different constituents, such as hypericin and pseudohypericin, flavonoids such as quercetin and rutin, vitamins C and A, phenolics such as hyperforin, sterols, and an essential oil. Although many of the herb's pharmacological activities appear to be attributable to hypericin and hyperforin, it is now known that the flavonoid content also contributes to its antidepressant activity. In other words, the antidepressant effects identified for isolated

hypericin or hyperforin are greater when the whole herb is used.

In practice, synergistic interactions are used in another important way — herbal polypharmacy. This is the combining of different herbal medicines within the same treatment for a more specific outcome, and is similar to the method Galen described centuries ago. In Chinese medicine the concept of synergistic interactions has reached a great level of sophistication, with Chinese formulas containing as many as 20 different herbs. In that system, the herb possessing the primary action of the formula is considered the 'emperor herb', while 'minister herbs' support the primary action and 'assistant herbs' modify the formula according to the needs of the individual. Finally 'messenger herbs' are used to aid absorption or reduce side effects of the formula. The practice is also common in Ayurvedic medicine and, in fact, in all traditional systems of herbal practice. Although it may be common in conventional medicine to give certain drugs specifically to reduce the side effects of other drugs, such as the administration of antiemetics and laxatives together with opiates, generally the giving of multiple drugs in combination is discouraged. In contrast, in herbal medicine this practice is often considered essential to provide both safety and the best effects.

KEY CONSTITUENT GROUPS

To better understand a herb's mechanisms of action, pharmacokinetics, pharmacodynamics, interactions and side effects, a basic knowledge of the key constituent groups is helpful. Here is a brief outline of the main constituent groups found in popular herbal medicines.

Flavonoids

Flavonoids are plant pigments that are largely responsible for the colour of flowers, fruits and berries. There are many different types of flavonoids including flavones, flavonols, isoflavones and flavins. They are generally anti-inflammatory, antioxidant and anti-allergic, and may decrease capillary fragility. Herbs that are well known for their flavonoid content are ginkgo (*Ginkgo biloba*), St Mary's thistle (*Silybum marianum*) and calendula (*Calendula officinale*).

Flavanols may be further oxidised to yield anthrocyanins. These bluish/purplish compounds contribute to the colour of blueberries and red grapes. They are greatly revered for their antioxidant and anti-inflammatory properties.

Tannins

Tannins are astringent and often taste bitter. They can be divided into two groups, hydrolysable tannins and non-hydrolysable tannins (sometimes called condensed tannins or proanthocyanidins). Tannins have the ability to stabilise proteins and were used historically to tan or preserve animal hides. In herbal medicine, tannins are valued for their ability to dry and tone tissue. Some plants with appreciable levels of tannins include witch hazel (*Hamamelis virginiana*), oak bark (*Quercus robor*) and lady's mantle (*Alchemilla vulgaris*).

Coumarins

Coumarins have a limited distribution in plants and may be either naturally present or synthesised by the plant in response to a bacteria or fungus (Heinrich et al 2004). They are a heterogeneous group, and thus different compounds have various effects on the body. For example, some coumarins demonstrate antispasmodic activity (for example, scopeletin from *Viburnum* spp), others anticoagulant activity (for example dicoumarol from sweet clover), and others anti-oedema effects (for example, coumarins from clivers and red clover).

Alkaloids

Alkaloids are so named for their alkaline properties. This group of phytochemicals has contributed much to modern medicine, and more than 10,000 have been isolated (Evans 2002). Consequently, they are perhaps the best-known constituent group. There are many different types of alkaloids with many different therapeutic properties; however, they commonly contain nitrogen, usually in a heterocyclic ring. Below is a brief outline of the main subgroups:

- **Pyridine, piperidine & pyrrolizidine alkaloids.** Nicotine (*Nicotiana tabacum*) is perhaps the best-known example of the pyridine class. The very poisonous piperidine alkaloid coniine is isolated from hemlock (*Conium maculatum*) and the pyrrolizidine alkaloid senecionine is the reason comfrey (*Symphytum officinale*) was withdrawn from sale in Australia due to concerns over hepatotoxicity.
- **Phenylalkylamine alkaloids.** This group of alkaloids differ in that nitrogen is not part of the heterocyclic ring. The most

commonly known example is ephedrine, a central nervous system stimulant, bronchodilator and vasoconstrictive agent from *Ephedra sinica*.

- **Quinoline alkaloids.** The antimalarial quinine from *Cinchona* spp belongs in this category. Quinine was used in the synthetic production of many antimalarial drugs against *Plasmodium falciparum*. Interestingly, *Plasmodium* has become resistant to the synthesised medications such as chloroquinine, but not to naturally occurring quinine (Heinrich et al 2004).
- **Isoquinoline alkaloids.** Opium, from *Papaver somniferum*, contains over 30 alkaloids, including morphine, codeine, thebaine, papaverine and noscapine. Morphine is well known for its pain-relieving effects. Other examples are the protoberberines, consisting of berberine, berbamine and hydrastine. Golden seal (*Hydrastis canadensis*) contains berberine and hydrastine, barberry (*Berberis vulgaris*) contains berberine and berbamine, and oregon mountain grape (*Mahonia aquifolium*) contains all three. They are strongly antibacterial.
- **Indole alkaloids.** Examples include reserpine from *Rauwolfia serpentina*, which in the past has been used for hypertension; however, its use has largely been discontinued due to toxic side effects. The anticancer agents vincristine and vinblastine, from *Cantharanthus roseus*, are other notable examples.
- **Tropane alkaloids**. Hyoscyamine, from *Atropa belladonna*, is an anticholinergic agent. It has also been used to dilate the pupil of the eye for optical examinations.
- **Xanthine alkaloids.** These are the most widely known and used alkaloids, and include caffeine from tea (*Camellia sinensis*), coffee (*Coffea arabica*) and chocolate (*Theobroma cacao*), which is known to be beneficial to health in small amounts and detrimental in large amounts. Cocoa also contains theobromine and tea contains theophylline and theobromine, both of which are purine alkaloids.

Terpenes

Terpenes are widespread in the plant kingdom. There are many different types:

- **Monoterpene hydrocarbons.** Monoterpenes have a 10-carbon structure. They are major constituents of volatile oils and often have antimicrobial properties. Examples include limonene (lemon, caraway, peppermint and thyme) and alpha-pinene (rosemary, lemon, fennel and eucalyptus).
- **Sesquiterpene hydrocarbons.** Sesquiterpenes have a 15-carbon structure. They are also major constituents of volatile oils and are broadly antimicrobial and insecticidal. Subclasses include alcohols (linalool from lavender, menthol from peppermint), phenols (linalool from lavender), phenols (thymol from thyme, caevacrol from oregano), aldehydes (citronella from citronella), ketones (menthone from peppermint, thujone from wormwood), ethers (anethole from fennel) and esters (methyl salicylate from wintergreen).
- **Diterpene hydrocarbons**. Diterpenes have on average a 20-carbon structure and so are much denser molecules, with higher boiling points, than other hydrocarbons. They are often associated with volatile oils (oleoresins), gums (gum-resins) or with both (oleo-gum-resins) (Evans 2002). Examples include guaiacum resin obtained from *Guaiacum officinale* and gum-resins from frankincense (*Boswellia serrata*).

Glycosides

Glycosides are composed of two parts: the glycone (sugar molecule) and the aglycone (non-sugar molecule). The aglycone may be a terpene, a flavonoid or potentially any other natural compound (Heinrich et al 2004). Below are the most common classes:

- **Triterpene glycosides.** These may also be called saponins. They are a diverse group and exert many different effects on the human body. Depending on their structure, they may be anti-inflammatory (aescin from horse chestnut) or expectorant (senegin from snakeroot), or may demonstrate steroidal effects (glycyrrhetic acid from licorice, diosgenin from wild yam).
- **Glucosinolates.** Also called mustard oil glycosides, these important compounds are found in the Brassicaceae family of vegetables, such as broccoli, mustard and horseradish. They are topically mildly irritant and have digestive, circulatory and anticancer properties when ingested.
- **Cardiac glycosides.** These glycosides have a specific action on heart muscle. They are steroidal in structure and are related to steroidal saponins and phytosterols. A number of herbs contain cardioactive glycosides, including lily of the valley (*Convallaria majus*) and foxglove (*Digitalis* spp). Digoxin

and digitoxin are naturally occurring compounds in digitalis, and digoxin is commonly used in drug form for heart failure.

- **Anthraquinone glycosides.** These compounds have osmotic and stimulant effects in the lower bowel and therefore have laxative properties. Examples of herbs that contain these compounds include cascara (*Rhamnus purshiana*), senna (*Cassia senna*), aloe (*Aloe vera*) and rhubarb root (*Rheum palmatum*).

CHEMOTHERAPEUTICS VERSUS HERBALISM

In practice, drugs and herbs are prescribed quite differently. Drug prescription is often based on the results obtained from clinical trials that measure the effects in populations and use averages to predict outcomes. Investigation and usage is based on the Western medical model and is replicated in almost identical ways by each practitioner who uses this system. By contrast, the same herb may be understood and prescribed in distinctly different ways by different practitioners, depending on the prescribing system being used, with an emphasis on individual prescribing. For example, in Chinese medicine, a herb such as andrographis (*Andrographis paniculata*) is used to clear 'heat' from the blood, because it is considered to be a 'cold' herb, whereas in Western herbalism, it is used to boost immune function and treat the common cold. Further, traditional herbal practice entails combining a number of herbs into a prescription that is tailored to the individual. This customised approach to herbal prescribing is guided by the underpinning paradigm of herbal practice — holism and vitalism. This philosophical basis is lost when herbs are viewed as vehicles for one or two active components or with the increasing cultural emphasis on self-prescribing.

Not only are herbs described and prescribed differently by different medical systems, the properties of herbal medicines are often defined using unique terms not found in drug pharmacology. These properties have traditionally been classified into herbal actions. Thus herbs that relax the gastrointestinal tract and reduce flatulence may be described as carminatives, or those that stimulate bile flow as cholagogues. These actions may be due to particular chemical constituent groups found within the herb or some other property of the herb. Throughout this book, terms specific to herbal medicine and not generally used in drug pharmacology are explained in *Clinical notes*.

Clinical note — German Commission E

The German Commission E is a German government regulatory agency composed of scientists, pharmacists, toxicologists, physicians and herbalists. It has produced a series of monographs based on the available scientific evidence, as well as evidence from traditional use, case studies and the experience of modern herbalists. These monographs are considered to provide authoritative information on herbs, as well as approved indications, contraindications, side effects, interactions, doses, and so on.

In contrast to pharmaceutical medicine, the evidence available to support herbal medicines originally comes from traditional sources, and scientific investigation has only recently been added. Over the past two to three decades there has been an exponential increase in the amount of scientific research being conducted on herbal medicines, chiefly in Europe and Asia, where there are fewer political, economic and regulatory reasons for rejecting traditional medicines. For some herbs there is now sufficient clinical trial evidence to enable meta-analyses to be performed. For many of the popular herbs available over the counter, clinical trial evidence is now being published that can be used to further clarify and determine their place in practice. For others, research may still be in its infancy, with only in vitro testing or testing in experimental models having been conducted so far. Although a general lack of resources, infrastructure, government funding and financial incentive for companies to invest in non-patentable medicines has slowed down investigation, great public popularity continues to fuel further study. Despite the limitations of randomised controlled trials in evaluating complex interventions characterised by traditional herbal practice (Evans 2008), data collections such as the German Commission E monographs are widely cited as gold-standard references, because they use a combination of traditional and scientific evidence to interpret data and make recommendations.

PRODUCT VARIATION AND STANDARDISATION

The chemical complexity of herbal medicines is compounded by the variation that occurs in their production, which starts with the quality

of the original plant material. This may be influenced by the identification methods used (and any misidentification or contamination), genetic variability in the original cultivar and the growing conditions, including the soil type, geographical location, aspect, altitude and climate. Other factors further modify a herb's purity and quality, such as growing techniques (for example, wild harvesting, or organic or conventional farming methods), the timing and method of harvesting, drying, processing and storage, as well as the extraction techniques and solvents used. There are therefore numerous factors that determine the compositional profile of a given herbal extract, and attempts to ensure batch-to-batch consistency are confounded by the inherent chemical complexity of the herb and the natural variations that occur.

As a consequence, clinical research is never simply done on a herb itself. Rather, research must be done on a particular herbal preparation at a specific dose, and the evidence for the efficacy of herbal preparations must be related back to the preparation used in the research. The results of clinical trials are therefore only relevant to the specific herbal preparation that has been tested, at the specific dosage, dose form and route of administration used in the actual trial and cannot necessarily be used to support the use of other extracts or doses of the same herb. The challenge for manufacturers and clinicians, then, is to reproduce a particular preparation, administer it in the proven doses and achieve the expected result. More commonly in practice, herbs are used in variable ways, with different preparations, at a range of doses, and in combination with other herbs or treatments. It is thus hard to guarantee outcomes, either beneficial or adverse, based solely on controlled clinical trials.

STANDARDISATION

Efforts to ensure batch-to-batch reproducibility of herbal medicines have generated a great deal of controversy, particularly involving the term 'standardisation' or the production of so-called standardised extracts. The lack of an agreed definition and the variety of meanings attributed to these terms make them confusing to both consumers and health professionals. Yet they are still used as the basis for product labelling and promotion, where they are used by suppliers for marketing purposes to imply quality, safety or efficacy.

A commonly used (and some may say abused) definition of the term 'standardised' in relation to herbal extracts relies on measuring a specified concentration of an identified constituent or class of constituents known as 'markers'. Markers are usually stable components of a herb that can easily be identified, analysed and measured, but they may or may not be pharmacologically active. An example of this is seen with *Ginkgo biloba*, which is standardised to contain 24% flavonoid glycosides and 6% terpenoids in commercial herbal products, although the active constituents are largely unknown. Sophisticated laboratory techniques are now used to perform this analysis and measurement. Methods include chromatographic techniques, such as thin layer chromatography and high-performance liquid chromatography, both of which provide a visual characterisation of the presence of different chemical constituents, including 'marker' substances in the herb. The graphs produced from chromatographic testing are referred to as 'fingerprints' and are commonly used to determine the identity of herbal material and the integrity of the extraction process, as well as to measure quantities of individual constituents.

Limitations

Although it is generally accepted that herbal standardisation is a useful procedure, it does raise many problems and concerns. First, standardisation to non-active constituents does not necessarily reflect potency. Second, the more perplexing issue of identifying the exact active constituents in a herb is still the subject of much debate for many herbs. Lastly, individual chemical isolates do not fit the accepted definition of a herb, so if the concentration of an isolate is significantly altered for standardisation purposes, the final product may not be truly representative of the original herbal medicine and may even be considered to be 'adulterated' if marker substances are added. Furthermore, despite recent attempts to standardise herbal extracts, there are still no official standards, and herbal products can vary widely with regard to their quality and clinical effectiveness (American Herbal Products Association 2003).

Although conventional pharmaceutical thinking is based on milligrams of an active substance, such an approach is not appropriate for herbal medicines, which have many biologically active, often unmeasurable constituents. Because there can be hundreds of constituents in a complex herbal extract, standardisation is

not possible by merely ensuring that one or two marker constituents are present in the same quantities from batch to batch. The therapeutic actions of herbal medicines rely on the complex combination and interactions of chemicals in the extract rather than on single constituents, and two total extracts can have very different profiles, despite there being a consistent level of one or two marker substances.

The biological activity of any compound, even a marker compound with demonstrated bioactivity, depends on the composition of the rest of the extract. Other components of the extract, even those with no direct physiological effect, may influence the uptake, distribution, metabolism and excretion of other components. Furthermore, this background matrix may affect the solubility, stability and bioavailability of any given compound (Eisner 2001). Thus the presence of chemical markers alone cannot be used to translate clinical evidence from one extract to another.

True standardisation requires more elegant procedures. The American Herbal Products Association has the following definition: 'Standardization refers to the body of information and controls that ensure product consistency from one batch to the next. This is achieved through minimising the inherent variation of natural product composition through quality assurance practices applied to agricultural and manufacturing processes' (American Herbal Products Association 2003). This definition accords more closely with the approach taken in Europe, where process control is an integral component of standardising herbal medicines. The methodology involves proceeding with the aim of standardising all the inputs and processes involved in making a particular extract, in order to ensure batch-to-batch consistency — from the genetic identity of the seed or plant, through to the agricultural processes employed and climatic factors (temperature, rainfall, sunlight), and finishing with drying, processing, extraction, solvent (or solvents), concentration, manufacture, storage, formulation and packaging of the finished product.

In addition to standardising the amount of certain chemical constituents in a herbal preparation, it is also necessary to have a means of standardising doses. Not only can different batches of the same herb have quite different potencies, there are many different formulations. Commercially available herbal preparations include fresh and dried herbs, teas, tinctures, fluid extracts, tablets, capsules and powders, as well as essential oils. When translating doses between different formulations, the amount of dried herb used to produce a set amount of the particular product is often used to give an indication of dosage strength. However, this may not give an accurate indication of potency; for example, fresh grapes, sultanas, grape juice, wine and sherry may all contain the same equivalent dry weight of grapes, but yield very different products with different biological properties.

Because of the lack of formalised standards and the need to prove 'phytoequivalence' for scientific rigour, it is increasingly common for clinical trials to specify the exact dose and extract used and for this information to be used as a basis for government regulation and for marketing purposes. When standardised extracts have been used in clinical trials, this information is included in each monograph.

HERBAL SAFETY

As with all medicines, a risk–benefit profile should be considered before using any herbal medicine. The vast majority of herbal medicines are generally considered to be safe, whether commercially or domestically produced. Most have a wide therapeutic index and only a few have toxic potential. However, adverse reactions may arise from a number of factors and may or may not be predictable. These include inappropriate usage (for example, dose, indication, time frame, administration route) and idiosyncratic reactions such as allergic responses and anaphylaxis.

In addition to adverse reactions arising from the properties of the herb itself, it is also possible for adverse events to arise from contamination or adulteration of herbal products. Contamination occurs when additional substances are inadvertently included in a herbal product. Contaminants can include toxic substances such as heavy metals, pesticide residues and microorganisms, as well as plant material from species other than the intended species, arising from either misidentification or poor quality control. Adulteration, on the other hand, is the intentional inclusion of foreign substances in herbal products, such as pharmaceutical steroids, NSAIDs or synthetic hormones, and may have very serious consequences. The standard of manufacture of commercial herbal products in Australia is generally very high.

Representing Western herbalists in Australia

In Australia, the knowledge and practice of contemporary herbal medicine has been preserved and nurtured mainly by Western herbalists. In fact, the National Herbalists Association of Australia (NHAA) has represented medical herbalists since 1920. Today, many industry insiders consider NHAA to be the industry standard setter for education in medical herbalism. Clinicians are encouraged to check whether herbal practitioners to whom they refer have undergone accredited courses. Further information can be found by contacting the association or accessing the website www.nhaa.org.au.

INTERACTIONS WITH PHARMACEUTICAL DRUGS

One safety issue that has become more recognised over the past decade is the potential for herbs to interact with pharmaceutical drugs. Evidence has emerged to suggest that some herb–drug interactions may be detrimental and have the potential to cause dangerous outcomes, whereas others may be beneficial when an interaction is manipulated to produce positive results (see Chapters 7 and 8).

The popularity of herbal medicine, and the increasing desire among patients for self-treatment and less use of pharmaceutical drugs, have meant that many medical doctors and pharmacists are now dealing with patients who regularly take these types of medicines. As neither doctors nor pharmacists receive comprehensive herbal training as part of their standard education, a potentially detrimental situation can arise in regard to not only patient safety but also negligence. Practical questions, such as whether a herb works in a particular scenario, or is dangerous in another, or compares favourably to a pharmaceutical drug, or can reasonably be expected to have an effect within a certain time frame, are important facts to know. It is hoped that resources such as this text will enable all health practitioners to ensure the safe and rational use of herbal medicines.

CHAPTER 3
INTRODUCTION TO CLINICAL NUTRITION

Nutrition may be defined as the science of food, its nutrients and substances, and their association with the body in relation to health and disease. In every stage of life, nutrition is important and influences clinical practice in many branches of healthcare. Clinical nutrition is the use of this information in the diagnosis, treatment and prevention of disease that may be caused by deficiency, excess or imbalance of nutrients and in the maintenance of good health.

CONSEQUENCES OF POOR NUTRITION

Nutrition plays a vital role in the health of both individuals and society, with poor nutrition and inadequate intake having a devastating effect. Overall, it has been estimated that more than 60% of all deaths in Australia result from nutrition-related disorders, such as cardiovascular disease, diabetes and cancer (Sydney-Smith 2000).

MORTALITY RISK: CARDIOVASCULAR DISEASE AND CANCER

Atherosclerotic cardiovascular disease is the most common cause of death in most Western countries (Anderson 2003). In Australia, it is the leading cause of death, accounting for 34% of all deaths in 2006. Cardiovascular disease kills one Australian nearly every 10 minutes according to the Australian Heart Foundation website. It is well known that dietary factors such as carbohydrate and fat intake affect several important physiological parameters and risk factors, such as hypertension, lipid levels, diabetes and antioxidant status. With the exception of tobacco consumption, diet is probably the most important factor in the aetiology of human cancers, responsible for around one-third of all cases (Ferguson 2002). Diet-related cancers have often been considered to relate to exogenous carcinogens; however, it is increasingly apparent that many carcinogens may be endogenously generated, and that diet plays an important role in modifying this process (Ferguson 1999).

Overeating and poorly balanced meals have also led to significant increases in metabolic syndrome (syndrome X) and obesity, which are now major health concerns. A 2003 review stated that the World Health Organization estimates there are one billion people around the world who are now overweight or obese, and that 20–25% of the adult population in the USA have metabolic syndrome (Keller & Lemberg 2003).

Although overweight and obesity in adulthood is associated with decreased longevity, and the link with cardiovascular disease is well known, a recent series of meta-analyses revealed statistically significant associations for overweight with the incidence of type II diabetes, all cancers (except oesophageal [female], pancreatic and prostate), asthma, gall-bladder disease, osteoarthritis and chronic back pain (Guh et al 2009). It has further been established that obesity is associated with increased death rates from cancer (Peeters et al 2003). A large prospective study of more than 900,000 people found that a BMI above 40 was associated with a higher combined death rate from all cancers of 52% for obese men and 62% for obese women, compared with people of normal weight (Calle et al 2003). The adverse effects of obesity on health are not limited to adults. Overweight children and adolescents are now being diagnosed with impaired

glucose tolerance and type 2 diabetes, and show early signs of insulin resistance syndrome and cardiovascular risk (Goran et al 2003).

A large body of research exists that attempts to isolate the influence of individual food groups and nutrients on morbidity and mortality. Research with macronutrients has found that the consumption of diets rich in plant-derived foods, wholegrains and fish reduces the risk of morbidity and mortality. However, numerous surveys have identified inadequate intakes of these foods in many Australian subpopulations (Barzi et al 2003, He et al 2002, Mozaffarian et al 2003, Rissanen et al 2003, Slavin 2003). The relative roles of micronutrients, phytochemicals and non-nutrients are still under debate.

FOOD UNDER THE MICROSCOPE

More than 25,000 different bioactive components are thought to occur in the foods consumed by human beings (Milner 2008). These components represent a veritable cocktail of chemicals that includes macronutrients (such as carbohydrates, protein, fat, water and fibre) and micronutrients (such as vitamins and minerals as well as phytochemicals), many of which are health-promoting, plant-based compounds. Additives such as preservatives, colourings and flavourings, together with contaminants introduced through farming or processing techniques, may also be present.

Nutrients can be divided into two main subgroups — essential and non-essential. Essential nutrients are those that cannot be synthesised by the human body in sufficient quantities to meet average requirements, such as vitamin C, and therefore must be taken in through the diet. Non-essential nutrients can be synthesised in the body from other compounds, although they may also be ingested in foods.

MACRONUTRIENTS

Macronutrients supply energy and essential nutrients, making up the bulk of food. Carbohydrates, lipids, proteins, water and some minerals comprise this group and are all necessary to sustain life. Some macronutrients are produced in supplement form and are used as therapeutic agents. As a result, a number of these are reviewed in this book.

Carbohydrates

Simple carbohydrates, also known as sugars, are termed 'monosaccharides' because they are the single sugar units that form the basis of all sugar structures. Glucose is a monosaccharide and the primary source of energy for most human cells. Most glucose is not ingested through the diet, but rather synthesised from sucrose (common sugar) in the liver (Wardlaw 1997). More complex forms of carbohydrates, such as starches and fibres, are composed of many units of smaller carbohydrates found in grains, vegetables and fruit and are termed 'polysaccharides'. Overall, carbohydrates are important as a fuel. They are considered protein-sparing, as they prevent the breakdown of proteins in the muscles, heart and liver into amino acids and ultimately glucose to produce fuel.

Lipids

The term 'lipid' is a generic one used to describe a number of chemicals that share two main characteristics: they are insoluble in water and contain fatty acids. When they are solid at room temperature, they are called fats, whereas those that are liquids are called oils. Fatty acids are the simplest form of lipids, and more than 40 different types occur in nature (Wahlqvist et al 1997). Of all the various classes of lipids, only precursors of the omega-3 and omega-6 fatty acids are considered essential, meaning they are necessary in the diet to maintain health. The amount of dietary fat ingested and the ratios between saturated, monounsaturated and polyunsaturated fatty acids are important influences on overall health and disease.

Protein

Protein is formed by linking individual amino acids together, with the order of the amino acid sequence determining the protein's ultimate form and function. Proteins are crucial to the regulation and maintenance of many vital body processes, such as blood clotting and fluid balance, cell repair, and hormone and enzyme production.

Amino acids can be divided into two broad groups: essential or non-essential. There are nine essential amino acids that must be ingested through the diet to maintain health. Protein foods that contain all nine essential amino acids are also referred to as complete protein sources (e.g. animal protein). By contrast, almost all plant foods are incomplete protein sources, with the possible exception of spirulina and soy. During times of growth, tissue repair or pronounced catabolism, such as after surgery, the body requires additional protein

for efficient new tissue growth to occur. There is also emerging evidence that supplementation with individual amino acids produces a variety of pharmacological effects that can be manipulated to provide therapeutic benefits. Several of these amino acids are reviewed in the monograph section.

Minerals

Some minerals fall into the category of macronutrients because they are required in gram amounts every day, although they do not directly produce energy. These include sodium, potassium, calcium, phosphorus and magnesium.

MICRONUTRIENTS

Micronutrients do not in themselves provide energy or fuel for the body, but they may be involved in the chemical processes required to produce energy from macronutrients.

Vitamins and trace minerals fall into this category and are required to sustain life, typically through their roles as enzymatic co-factors in diverse biochemical processes. Many micronutrients are available in supplement preparations and are reviewed in this book.

Vitamins

Vitamins are organic substances (i.e. they contain a carbon atom) essential for normal growth and functioning of the body. They have been divided into two broad groups: vitamin C and the eight members of the B complex (B_1, B_2, B_3, B_5, B_6, B_{12}, biotin and folic acid) are defined as water-soluble vitamins, whereas vitamins A, D, E and K are fat-soluble. Levels in the body need to be replenished on a regular basis, as only vitamins A, E and B_{12} are stored to any significant extent. Just as a vitamin deficiency causes adverse outcomes, high doses of these supplements can also do so if used inappropriately.

Essential trace minerals

These are minerals required by the body, usually in milligram or microgram amounts. They include iron, iodine, fluoride, zinc, chromium, selenium, manganese, molybdenum and copper. All trace minerals have the potential to be toxic when consumed in high doses.

Phytochemicals

Phytochemicals are components in plant foods that appear to provide significant health benefits, yet are not essential. Considerable research

TABLE 3.1 The Chemical Complexity of Food

Nutrients	
Micronutrients	Vitamins: A, B complex, C, D, E, K, coenzyme Q10 Minerals: iron, iodine, fluoride, zinc, chromium, selenium, manganese, molybdenum and copper Others?
Macronutrients	Carbohydrates: simple and complex Proteins: amino acids Lipids: saturated, monounsaturated and polyunsaturated fatty acids Fibre: soluble and insoluble Water Minerals: sodium, potassium, calcium, magnesium, phosphorus Others?
Phytochemicals	Bioflavonoids, carotenoids, isoflavones, glutathione, lipoic acid, caffeic acid, ferulic acid, lignans, allyl sulfides, indoles
Non-nutrients	
Food additives: natural or synthetic	Colourings: restore colours lost during processing or alter natural colour Flavourings: alter natural flavours Preservatives: prolong shelf-life by reducing bacterial, mould and yeast growth Thickeners: modify texture and consistency of food Humectants: control moisture levels and keep food moist (mainly used in baked foods) Food acids: used to standardise acid levels between different food batches Antioxidants: used to preserve foods mainly containing fats and oils
Contaminants	Natural contaminants Industrial pollutants Processing contaminants Others?

has been undertaken in the past few decades to understand the role they play in maintaining health and preventing certain diseases, such as cancer, but there is still much to learn. Some of the better known phytochemicals include isoflavones (e.g. genistein), bioflavonoids (e.g. procyanidins), carotenoids (e.g. lycopene), glutathione and alpha-lipoic acid. Many of the phytochemicals found in food are also found in medicinal herbs and may partly explain their therapeutic qualities.

FOOD LABELS

According to Nutrition Australia, by law all packaged foods must carry labels that state the following information:

- name of food
- name and business address of manufacturer
- country of origin
- ingredients, listed by weight from greatest to smallest (including added water)
- percentage of the key ingredient or component present in the food product
- warnings about the presence of major allergens in the food, such as nuts, seafood, eggs, gluten and soy
- a nutrition information panel, unless the food is not packaged or the package is too small (e.g. tea bags)
- an expiry date.

For further information about labelling, see Food Standards Australia New Zealand website at http://www.foodstandards.gov.au/thecode/.

Currently, more than 35 genetically modified (GM) foods have been approved for sale in Australia and New Zealand (FSANZ 2009), including foods derived from soy, sugar beet, corn, cottonseed oil, canola and potatoes. As from December 2001, labels must also state whether a food contains a GM-derived component or protein introduced through genetic modification.

Additives are listed as either numbers, known as additive codes, or by name. Up-to-date lists of the food additives found in Australian and New Zealand food products can be located at <www.foodstandards.gov.au>.

NUTRITIONAL DEFICIENCIES

Malnutrition and other deficiency states, such as kwashiorkor (protein deficiency), scurvy or rickets, are major causes of morbidity and mortality in both developing and developed countries under conditions of deprivation. Malnutrition can occur as a result of alcoholism, medication use, fussy eating, anorexia, small bowel obstruction and numerous other medical conditions.

More specific or individual nutritional deficiencies can be classified as either a 'primary deficiency' or a 'secondary deficiency', according to their aetiology.

PRIMARY DEFICIENCY

Primary deficiency is defined as a state arising from inadequate dietary intake. Although considered to be rare in developed countries, inadequate intake and primary deficiency states are not uncommon, as evidenced by numerous dietary surveys both here and overseas.

Inadequate dietary intake

The Australian National Nutrition Survey (NNS) conducted in 1995 found that approximately 30% of 2–7-year-old children ate no fruit or vegetables. Among 8–11-year-olds, 44% of boys and 38% of girls ate no fruit on the previous day and approximately one in four older children consumed no vegetables. Additionally, neither age group consumed the minimum number of serves of dairy products (Cashel 2000). Later results from the Australian Institute of Health and Welfare in 1998 reported that approximately one in two Australian children under 12 were not eating fruit or fruit products, and more than one in five consumed no vegetables in a typical day.

The dietary intakes of adults are also far from ideal. The 1995 NNS also found that approximately 44% of adult males and 34% of females did not consume fruit in the 24 hours preceding the survey, and 20% of males and 17% of females did not consume vegetables (Giskes et al 2002).

Interestingly, dietary intakes were influenced by income level, with lower-income adults consuming a smaller variety of fruits and vegetables than their higher-income counterparts. Additional research has consistently identified other groups at risk of poor dietary habits, such as the elderly, institutionalised individuals and the indigenous population.

Surveys of individual vitamin and mineral intakes also identify a number of at-risk subpopulations. Calcium intakes for 1045 randomly selected Australian women (20–92 years) as estimated by questionnaire showed that 76% of women aged 20–54 years, 87% of older women and 82% of lactating women had intakes below the recommended dietary intake

(Pasco et al 2000). Of these, 14% had less than the minimum requirement of 300 mg/day and would, therefore, be in negative calcium balance and at risk of bone loss. The 1997 New Zealand National Nutrition Survey found that 20% of all New Zealanders and one in four women had calcium intakes below the UK estimated average requirements, and 15–20% of women aged 15–18 years were considered to have frank deficiency (Horwath et al 2001).

Surveys in Australia and New Zealand report that many adolescent girls have insufficient dietary intakes of iron and zinc to meet their high physiological requirements for growing body tissues, expanding red cell mass, and onset of menarche (Gibson et al 2002).

Evidence of deficiency in Australia and New Zealand

It is a common perception that although dietary intakes are not ideal, vitamin and mineral deficiencies are not a major health concern; however, research has shown that several subpopulations, such as children, pregnant and lactating women, older adults, institutionalised individuals, indigenous peoples and vegetarians, are at real risk.

For example, several local surveys have found that mild to moderate iodine deficiency is more prevalent than once thought (Li et al 2001). This is of great concern because mild iodine deficiency during childhood and pregnancy has the potential to impair neurological development. One survey of Sydney schoolchildren, healthy adult volunteers, pregnant women and patients with diabetes found that all four groups had urinary iodine excretion values below those set by the World Health Organization for iodine repletion (Li et al 2001). Another survey of 225 children in Tasmania identified evidence of mild iodine deficiency in 25% of boys and 21% of girls (Guttikonda et al 2002). A research group at Monash Medical Centre in Melbourne screened 802 pregnant women and found that 48.4% of Caucasian women had urinary iodine concentrations below 50 micrograms/L compared to 38.4% of Vietnamese women and 40.8% of Indian/Sri Lankan women (Hamrosi et al 2005). These figures are disturbing when one considers that normal levels are over 100 micrograms/L, mild deficiency is diagnosed at 51–100 micrograms/L and moderate to severe deficiency at < 50 micrograms/L (Gunton et al 1999). A study conducted at a Sydney hospital involving 81 women attending a 'high risk' clinic found moderate to severe iodine deficiency in 19.8% of volunteers and mild iodine deficiency in another 29.6% (Gunton et al 1999).

In Australia and New Zealand, the prevalence of vitamin D deficiency varies, but it is now acknowledged to be much higher than previously thought (Nowson & Margerison 2002). The groups at greatest risk are dark-skinned and veiled women (particularly in pregnancy), their infants, and older persons living in residential care. The study by Nowson and Margerison found marginal deficiency in 23% of women, and another frank deficiency in 80% of dark-skinned women in Australia. A study conducted in a large aged-care facility in Auckland identified frank vitamin D deficiency in 49% of elderly participants in midwinter and in 33% in midsummer (Ley et al 1999). Even in studies of 'healthy' adults, vitamin D insufficiency has been found to affect more than 40% of residents in Queensland (Kimlin et al 2007, van der Mei et al 2007) and over 65% of Tasmanians (van der Mei et al 2007).

Barriers to good nutrition

Clearly, living in a developed country is not a guarantee of healthy nutrition. Western first-world countries have a wide range of good-quality foods available at affordable prices, yet healthy eating is not commonplace. There are four key levels of influence on dietary behaviours:

1. individual factors
2. interpersonal factors
3. organisational factors
4. environmental factors.

At each level, barriers to healthy eating behaviours exist. Table 3.2 (p 28) lists some of the more common barriers. Successful nutritional interventions that aim to modify individuals' eating patterns should help people develop new routines and simple internalised rules that they can use to navigate sensibly through the multitude of food choices and personal influences.

Nutritional intervention is a central component of disease prevention and management. Health professionals play a pivotal role in undertaking nutritional interventions with patients because of their knowledge, access to information and credibility as patient educators.

SECONDARY DEFICIENCY

Secondary deficiency may develop when there is reduced nutrient absorption, or increased metabolism or excretion of any given nutrient.

TABLE 3.2 Influences over Food Choices	
Nutritional knowledge	Income: food choices based on affordability
Religious beliefs and practices	Childhood experiences
Family beliefs and practices	Dental health: for example, ill-fitting dentures, sensitive teeth
Cultural beliefs and practices	Availability and convenience: for example, convenience of fast food
Ethnicity	Muscle weakness or joint pain: problems with shopping and cooking
Education	Problems chewing and swallowing
Occupation	Gastrointestinal problems: for example, nausea, diarrhoea
Peer and social influences	Following a specific diet: for example, fad diets
Advertising	Psychosocial problems: loneliness, depression, confusion, isolation
Emotional factors: for example, indulging in 'comfort' foods	
Medication: dietary alterations may be necessary; side effects may alter appetite	
Food: flavour, texture, appearance, odour	

Of these, malabsorption states are the most common and associated with many diseases such as those characterised by chronic diarrhoea (e.g. Crohn's disease), alterations to gastrointestinal tract architecture (e.g. coeliac disease) and liver cirrhosis. In these cases, malabsorption may be specific to certain nutrients and fats or may be more generalised.

The effects of pharmaceutical medicines on nutritional status must not be forgotten. A significant number of drugs affect appetite, nutrient absorption and synthesis, transport and storage, metabolism and excretion. In fact, some of the side effects of medicines may not be related to the medicine directly, but rather to the nutritional deficiencies that develop with their use over time. These will not always produce clinically significant adverse effects, but when combined with a poor diet, or when several medicines affecting the same nutrients are taken, the risk of deficiency is heightened.

Medicines that can reduce intake of nutrients include those that induce nausea, dyspepsia, or decrease appetite, such as non-steroidal anti-inflammatory drugs (NSAIDs), and opioid drugs such as codeine and morphine. Medicines with the potential to reduce nutrient absorption include those that reduce gastric motility (e.g. opioid drugs), greatly increase gastric motility (e.g. metoclopramide), compromise digestive enzyme output and function (e.g. proton pump inhibitors), and bind nutrients, preventing their traverse across gastrointestinal membranes, such as anion exchange resins (e.g. cholestyramine). Certain medicines can also increase nutrient excretion, such as thiazide diuretics, which increase potassium excretion. Others can reduce vitamin biosynthesis, such as statins, which reduce the production of coenzyme Q10.

In each of these cases, either increased nutritional intakes may be required to offset possible depletions, or medicines should not be administered with meals or supplements to reduce the likelihood of more direct interactions.

RDA AND RDI REFERENCE VALUES FOR AUSTRALIA AND NEW ZEALAND

The concept of recommended daily allowances (RDAs) originated in the United States in the 1940s as a basis for setting the poverty threshold and food-stamp allocations for the military and civilian populations during times of war and/or economic depression (Russell 2007). At this time, the first RDAs were determined by observing a healthy population's usual dietary intakes and extrapolating RDAs from this information. Over the subsequent decades, scientific research into health and nutrition became more sophisticated, rendering the original concept of RDAs incomplete and in need of modification. The main findings to emerge were as follows:

1. Many additional nutrients found in food are important for health, so a longer list of nutrients with recommended levels will be required.
2. Nutrient intake recommendations need to be related to a specific use, as requirements will vary for different subpopulations.
3. Nutritional intake recommendations need to take into account longer-term disease prevention, not just deficiency prevention.
4. Clearer endpoints will be required by which to set adequacy levels.

5. Risk assessment of nutrients will be necessary.

In the mid-1990s a new framework was developed to address these issues. It aimed to establish new nutrient intake recommendations to meet a variety of uses and to base nutrient requirements on the reduction of chronic disease risk, with a clear rationale for the endpoints chosen. The new guidelines still contain RDAs, but have been expanded to include three new intake recommendations: estimated average requirements (EARs), adequate daily intake (ADI) and upper level (UL) of intake.

Revisions to the nutrient intake framework occurred all around the world and in 2006 the National Health and Medical Research Council (NHMRC) of Australia published its adjusted nutritional guidelines for the adequate intake of vitamins and minerals (NHMRC 2006). These guidelines were far more comprehensive than previous versions and incorporated some of the initiatives developed in the United States.

The NHMRC guidelines are intended for healthy people and specify requirements based on both gender and age, while assuming average body weights of 76 kg for the adult male and 61 kg for the adult female.

Four key dietary reference value terms are defined here:

1. **Estimated average requirement (EAR).** A daily nutrient level estimated to meet the needs of 50% of the healthy population in a particular life cycle and gender.
2. **Recommended daily intake (RDI).** A daily nutrient intake estimated to meet the needs of up to 98% of healthy people in a particular life cycle and gender. This remains the most common benchmark of individual nutrient adequacy.
3. **Adequate daily intake (ADI).** When RDI cannot be determined, this is based on observed or experimentally derived estimates of daily nutrient intake to meet the needs of healthy individuals.
4. **Upper level (UL) of intake.** An estimate of the highest level of regular intake that carries no appreciable risk of adverse health effects to almost all people in the general population. It is meant to apply to all groups of the general population, including sensitive individuals, throughout the life stages.

In some instances, the 2006 RDI values for specific nutrients represented a substantial increase (e.g. iron and folate), whereas others increased only marginally (e.g. calcium) or decreased (e.g. zinc requirements for adult females).

RDI and nutritional deficiencies

Although the RDIs provide a guide to preventing nutrient deficiency signs and symptoms in a 'healthy' population, they are only general recommendations and do not take into account each individual's requirements or specific circumstances. As a result, seemingly adequate food intake can provide false security, owing to a number of factors that influence the nutritional content of food and the way important nutrients are absorbed, utilised and excreted.

Unfavourable cooking and storage conditions can significantly reduce the nutritional content of food before it is consumed, no longer providing the expected vitamins and minerals. Many vitamins and minerals are sensitive to changes in temperature, light and oxygen. Up to 50% of vitamins A, D and E and 100% of vitamin C and folate can be lost during cooking (Wahlqvist et al 1997).

Issues relating to various farming techniques have often been cited as affecting the nutritional content of food and are readily reflected in the variability of resulting mineral composition. A good illustration of this is selenium, which, like most other minerals, enters the food chain through incorporation into plants from the soil. Plants grown in soils with low selenium levels are likely to contain smaller quantities than those grown in selenium-rich soils. Acid soils and complexation with metals, such as iron or aluminium, also reduce plant selenium content.

Beyond the actual quantities of nutrients provided by our food, reduced bioavailability of nutrients can occur as a result of interactions between food constituents. Phytates found in dietary fibre and tannins found in tea (and several herbal medicines) are able to bind to iron, zinc and other minerals, impairing the body's ability to absorb them. Therefore, adequate intake of mineral-rich food does not necessarily prevent deficiency. In addition to this, there are other potential contributors to secondary nutrient deficiencies, such as impaired absorption, compromised or accelerated utilisation, and increased excretion of individual nutrients as well as genetic variables.

Serious deficiencies of reference values

Setting nutrient reference values is a complex task, which produces only approximate values. Russell from the Human Nutrition Research Centre on Aging at Tufts University has outlined eight different obstacles that prevent

accurate determination of reference values (Russell 2007):

1. Few long-term studies are available so information is extrapolated from short-term studies (e.g. 1–2 weeks).
2. Little good quality information is available about individual variability in response to the indicators in question.
3. Most research fails to consider the interaction between nutrients (which may be important for good health).
4. Many databases used when determining reference values provided information from studies that evaluated only dietary intakes and ignored supplemental intakes.
5. Most studies fail to consider the variation in nutrient bioavailability that is influenced by the food matrixes in which the nutrient presents.
6. Little good quality information is available about children, adolescents and the elderly from which to establish reference values with any degree of certainty.
7. Little good quality dose-response information is available (i.e. responses to multiple levels of the same nutrient in the same individual).
8. The cause and effect of a nutrient on a specific outcome is sometimes still speculative, as multiple factors may affect an outcome, not simply a single nutrient.

The obstacles outlined here clearly indicate that *the scientific basis for many of the reference values is weak*. They also indicate that for many nutrients and food components the RDI and UL levels are only approximations that are loosely relevant to the general healthy population, and even less relevant to the individual with comorbidities or special needs. Substantial research would be required to create a set of reference values with greater accuracy and relevance, but even then some values, such as ULs, may never be entirely accurate, as ethical considerations would prevent such research from ever being conducted.

OPTIMAL NUTRITION: A STATE BEYOND RDI

Dietary reference values are based on the concept of nutrient requirement. When considering these, it is important to keep in mind how we define or identify 'adequacy'. Historically, one measure of adequacy has been the dose of nutrient required to prevent the clinical manifestations of the corresponding deficiency. This method has yielded RDI reference values, which prevent overt deficiency presentations in most healthy people but do not guarantee the prevention of a less well defined suboptimal intake that may over time contribute to other pathology.

There is considerable evidence some nutrients may have health benefits at intake levels greater than the RDI. Higher intake levels appear to play a role in the prevention of many degenerative diseases such as cancer, cardiovascular disease, macular degeneration and cataract, cognitive decline and Alzheimer's dementia, as well as of developmental conditions such as neural tube defect. The NHMRC guidelines for the adequate intake of vitamins and minerals acknowledge this fact and state that 'there is some evidence that a range of nutrients could have benefits in chronic disease aetiology at levels above the RDI or AI' (NHMRC 2006).This has given rise to a new concept, 'suboptimal nutrition'.

The phrase 'suboptimal nutrition' was first coined by Fairfield and Fletcher in their 2002 systematic review evaluating the evidence indicating that certain nutrients had long-term disease prevention properties (Fairfield & Fletcher 2002). They defined suboptimal nutrition as a state in which nutritional intake is sufficient to prevent the classical symptoms and signs of deficiency, yet insufficient to significantly reduce the risk of developmental or degenerative diseases. As such, avoiding a state of suboptimal nutrition requires adequate dietary intakes of all key food groups with an emphasis on health-promoting foods, and possibly the use of additional nutritional supplements. Furthermore, the balance between micronutrients or macronutrients is important, such as the ratio of omega-3 to omega-6 fatty acids and of high to low glycaemic carbohydrates.

Huang et al extended this work and conducted another comprehensive review to determine whether evidence supported the use of multivitamin/mineral supplements and certain single nutrient supplements in the primary prevention of chronic disease in the general adult population (Huang et al 2006). This review concluded that multivitamin/mineral supplement use may prevent cancer in individuals with poor or suboptimal nutritional status.

As a reflection of these new developments, the term 'suggested dietary target' has been adopted by the NHMRC to describe the 'daily average intake from food and beverages for certain nutrients that may help in prevention

of chronic disease'. It is a move that recognises that food components offer more than just deficiency prevention; however, the general recommendations still relate only to the general healthy population.

Theoretically, it can be imagined that there is a level of intake that could be considered to provide optimal nutrition that is above the RDI yet below the UL levels. Figure 3.1 illustrates a theoretical description of beneficial health effects of a nutrient as a function of level of intake. The solid line in the figure represents risk of inadequacy in preventing nutritional deficiency and the broken line represents the risk of inadequacy in achieving a health benefit, that is, disease risk reduction (Renwick et al 2004). As intake falls below the RDI, the risk of adverse effects due to inadequate intake increases, and as intake increases beyond an optimal level, there is an increased risk of adverse effects due to toxicity. Naturally, however, such an optimal intake may be highly individualistic, based on the previous discussion of confounding factors.

Redefining an essential nutrient

Clearly the line between essential and non-essential nutrients has blurred as a result of modern scientific inquiry and experimentation (Yates 2005). In the first half of the 20th century, nutrients were termed 'essential' when their removal from the diet caused severe organ dysfunction or death. Since then, modern scientific techniques have enabled us to detect finer gradations of inadequacy well before organic pathology, such as a decline in health status or ability to function optimally, sets in. They have also allowed us to glimpse the potential of nutrients and certain food compounds to prevent genomic mutations, alter metabolic processes and ultimately prevent disease, possibly even extending longevity concomitantly. If we broaden the aim of nutrition beyond prevention of deficiency to include the promotion of wellness and optimal health, many additional nutrients and food components are likely also to be able to be termed 'essential'.

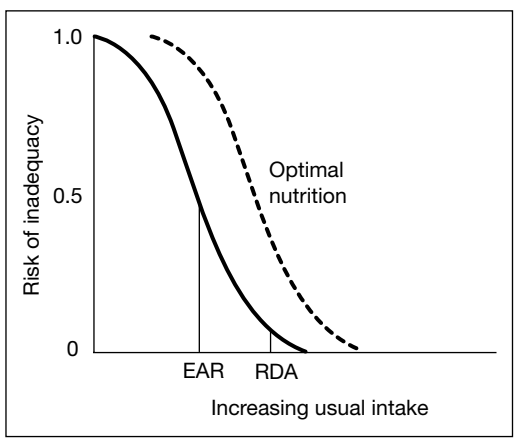

FIGURE 3.1 A theoretical description of beneficial health effects of a nutrient as a function of level of intake (Renwick et al 2004)

NUTRITIONAL GENOMICS

Nutritional genomics is a field that has emerged alongside the Human Genome Project. It has a unique focus on disease prevention and healthy ageing through the manipulation of gene–diet interactions. Several key scientific domains in nutritional genomics focus on specific areas of this interaction.

Nutrigenomics, also known as nutritional epigenetics, refers to the effect of nutrients on gene expression. Involving the identification, classification and characterisation of human genetic variants or polymorphisms (mutations) that modify individual responses to nutrients (Fig 3.2), its application in the manipulation of biological pathways to produce health benefits is called systems biology, or nutritional engineering. This opens up the possibility of truly individualised nutritional management through its potential to compensate for

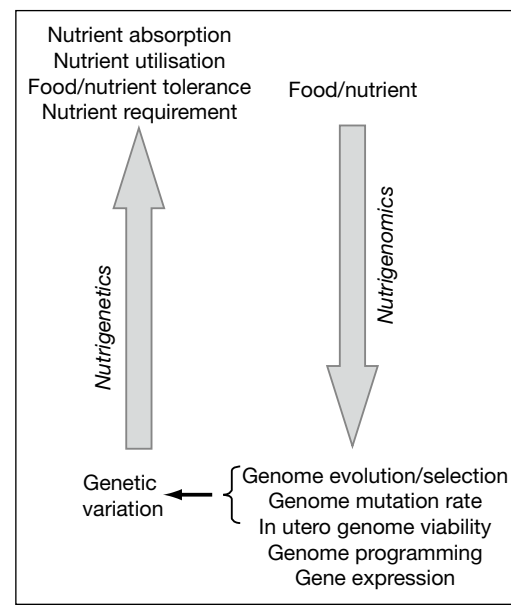

FIGURE 3.2 Nutrient genome interactions (From Stover and Caudill 2008)

EURRECA: Europe's new collaboration

EURRECA stands for EURopean Micronutrient RECommendations Aligned. Its overall objective is to create a sustainable collaborative network to develop science-based aligned nutrient recommendations across Europe with special focus on vulnerable groups and consumer understanding (Pijls et al 2009).

To better understand inter-individual variation and its determinants, EURRECA plans to establish the quantitative extents to which genetic, epigenetic and dietary factors determine the nutritional phenotype, as well as the way in which they interact in doing so.

For more details about EURRECA, see <http://www.eurreca.org>.

metabolic deficiencies and genetic susceptibility, simply by using dietary modification and nutritional supplementation (Stover & Caudill 2008).

It is widely considered that nutritional genomics holds the promise to revolutionise both clinical and public-health nutrition practice in other ways. These include facilitating the establishment of genome-informed nutrient and food-based dietary guidelines for disease prevention and healthy ageing, and better targeted public health nutrition interventions (including micronutrient fortification and supplementation) that maximise benefit and minimise adverse outcomes in genetically diverse human populations (Stover & Caudill 2008).

Nutritional genomics will also revolutionise the conduct and interpretation of clinical trials and epidemiological studies that investigate the associations between diet and/or nutritional supplementation and disease. This knowledge can be used to distinguish between responders and non-responders, and to determine which populations are most likely to benefit from nutritional intervention and which may be at increased risk of harm.

NUTRITIONAL DEFICIENCY, GENOME DAMAGE AND CLINICAL PRACTICE

There is overwhelming evidence that several micronutrients (vitamins and minerals) are required as co-factors for enzymes or as part of the structure of proteins (metalloenzymes) involved in DNA synthesis and repair, prevention of oxidative damage to DNA as well as maintenance methylation of DNA. The main point is that genome damage caused by moderate micronutrient deficiency is of the same order of magnitude as the genome damage levels caused by exposure to significant doses of environmental genotoxins such as chemical carcinogens, ultraviolet radiation and ionising radiation (Fenech 2008). For example, deficiency of vitamins B_{12}, folic acid, B_6, C, E, or iron or zinc appears to damage DNA in the same way as radiation, by causing single- and double-strand breaks, oxidative lesions or both. Half of the population may be deficient in at least one of these micronutrients (Ames 2004). If moderate deficiency in just one micronutrient can cause significant DNA damage, it is possible that multiple moderate deficiencies may have additive or synergistic effects on genome stability.

Current research indicates that the amount of micronutrients that appear to be protective against genome damage varies greatly between foods, and careful choice is needed to design dietary patterns optimised for genome health maintenance. Because dietary choices vary between individuals, several interventional options are required, and nutritional supplements may be necessary to fill in gaps not met by food intake, or to elevate intake levels beyond dietary intake to influence key metabolic pathways.

As the field of nutritional genomics matures, healthcare practitioners will have the opportunity to make genetically individualised dietary recommendations aimed at improving human health and preventing disease (Milner 2008). It is possible to envisage preventative medicine being practised in 'genome health clinics', where clinicians would diagnose and nutritionally prevent the most fundamental initiating cause of developmental and degenerative disease — genome damage itself (Fenech 2008).

NUTRITIONAL SUPPLEMENTATION

Nutritional supplements have traditionally been recommended only in cases of established deficiency; however, scientific evidence is accumulating to suggest they may be an important extension of healthy eating and necessary to achieve a level of health and disease prevention beyond what is possible through diet alone. As a consequence, many conservative medical bodies are being forced to re-assess their long-established views.

Clinical note — Taking a multivitamin may save billions of dollars

In October 2003, the first ever report to quantify the preventative health benefits of multivitamin supplementation using the US health insurance model was released (DaVanzo et al 2003). After an extensive review of the scientific literature combined with an analysis of Medicare claims and Congressional Budget Office accounting methods, it was established that multivitamin use by older adults could lead to Medicare cost savings of more than US$1.6 billion over the next 5 years. Significant cost savings were based on improved immune function and a reduction in relative risk of coronary artery disease achievable with daily multivitamin supplementation in people over 65 years old. The Lewin Report states that these findings are conservative, as they do not take into account cost savings from decreased ambulatory care and the assumption was that only one-third of adults will experience benefits. Additionally, reductions in the incidence of other diseases were not considered. In conclusion, researchers found that a daily multivitamin supplement is a safe, relatively inexpensive and yet potentially powerful way of improving one's health.

In Australia and New Zealand, the situation is different. Local medical journals include information about nutritional research from time to time, but there is still a sense that a balanced diet will be adequate for most healthy people.

In 2002, a review in the *Journal of the American Medical Association* of both the clinical and the scientific literature on vitamins and their relationship to health and disease came to a conclusion vastly different from medical profession's traditional view (Fairfield & Fletcher 2002). This comprehensive review of 30 years of scientific research supported the concept of suboptimal nutrition, finding it was relatively common and associated with many major chronic diseases. As a result, it was recommended that clinicians counsel patients to improve their diets, and that all adults should take a daily multivitamin (Fletcher & Fairfield 2002).

Evidence supporting the use of multivitamin/mineral supplements as nutritional insurance has continued to accumulate. The consistent finding is that such an intervention would markedly improve health — for example, in cases of heart disease, cancer, immune function and cataracts, particularly for the poor, the young, the obese and the elderly (Ames 2004). The caveat is, of course, that too much of a supplement may be toxic.

SAFETY ISSUES

Nutritional supplements can be viewed as medicines that have both subtherapeutic and toxic doses, as well as the potential to induce adverse reactions and interactions.

Adverse reactions and interactions

The same subpopulations that have been identified to be at greater risk of adverse reactions to pharmaceutical medicines may be used for the safety assessment of nutritional supplements. These groups are the elderly, atopic patients, people with compromised liver or kidney function, anxiety or depression, or serious illness, and those already taking many medicines. In clinical practice, the risk-versus-benefit decision of recommending a supplement or not is always considered and should be discussed with patients. In many cases, the risk of experiencing a minor adverse reaction that is short-lived and not serious may be an acceptable risk, whereas the risk of a more serious adverse reaction is not.

Toxicity

If a toxic dose is defined as one that is capable of causing death or a serious adverse reaction, then only a few nutrients are of special concern. In everyday practice, vitamins A, D and B_6 require special attention, as do the minerals iron, zinc, copper and selenium. Obviously, effects are dose-related and, in some cases, the doses are so large that they cannot practically be achieved in real life (see Appendix 6).

Natural versus synthetic

It is often asked whether natural and synthetic vitamins differ, and whether one is superior to and safer than the other. At this stage, very little research has been conducted to compare natural and synthetic forms, but some investigation into vitamin E has been undertaken.

The biological activity of vitamin E is based on the 'fetal resorption–gestation' method in rats. Using this test, the minimum amount of vitamin E required to sustain fetal growth in pregnant rats is determined. In the case of

D-alpha tocopherol (RRR-alpha), which is considered to be the natural form, the highest activity is observed and therefore valued at 100%, whereas the biological activity of other vitamin E isomers has been estimated to be as low as 21% (Acuff et al 1998). Studies in humans have indicated that natural vitamin E has roughly twice the bioavailability of synthetic vitamin E; however, whether this also means that it has greater efficacy has yet to be clarified (Burton et al 1998).

It has also been speculated that the natural beta-carotene used in supplements, which is derived from algae and contains a mixture of carotenoids, may be safer and possibly more effective than synthetic beta-carotene.

RATIONAL USE OF SUPPLEMENTS

Nutritional supplements can never take the place of a balanced diet or provide all the health benefits of a whole food, but they can provide nutritional assistance and therapeutic effects in three different ways:

1. **Supplementation to correct a gross deficiency.** A patient presenting with clinical signs and symptoms of a nutritional deficiency will require nutritional counselling and possibly supplementation to quickly redress the situation (e.g. vitamin C supplementation and dietary education for patients with scurvy).
2. **Supplementation to address a subclinical deficiency.** A patient may not be presenting with overt clinical signs or symptoms of deficiency but may benefit from an increased intake of certain nutrients or food components to prevent disease or reduce the incidence of other adverse outcomes (e.g. maternal folic acid supplementation and gestational health and development).
3. **Supplementation to address symptoms not associated with nutrient deficiency.** A patient presents with symptoms or disease unrelated to nutritional deficiency, but evidence indicates that nutritional supplementation can provide health benefits. This describes the use of nutritional supplements in pharmacological doses to achieve a specific health-related purpose, much like a therapeutic drug (e.g. high-dose riboflavin supplementation for migraine prophylaxis or coenzyme Q10 supplementation in hypertension). Many more examples are found in the monograph section of this book.

TABLE 3.3 The Rational Use of Nutritional Supplements

Be informed and seek out unbiased information — do not rely on label claims, product information manuals or other commercial sources of information alone.
Know the common nutrient deficiency signs and symptoms.
Know the RDIs and where relevant suggested dietary targets.
Know the benefits and risks of nutrients at levels beyond RDI and upper-limit levels (ULs) that increase the risk of adverse effects.
Be able to detect inadequate dietary intakes or refer to a healthcare professional who can do so.
Ensure that all healthcare professionals involved in a patient's care remain informed of nutritional supplement use.
Take care with children, the elderly, and pregnant or lactating women.
Take care when high-risk medicines are being taken.
Take care with HIV, cancer and other serious illnesses. Know the manufacturer or supplier details.
Store medicines appropriately.

Table 3.3 provides a general guide for healthcare professionals when considering nutritional aspects of their patients' situation and nutritional supplementation.

CHAPTER 4
INTRODUCTION TO AROMATHERAPY

The term 'aromatherapy' refers to the use of essential oils and is an aspect of phytotherapy (botanical medicine). Essential oils are volatile liquid substances extracted from plant material by a variety of methods. However, 'aromatherapy' is frequently associated with cosmetic products that often do not contain any essential oils, even though the term 'aromatherapy' is included on the labels and advertising material of such products. There are several definitions of aromatherapy. Hirsch, for example, defines it as 'the use of odorants as inhalants to treat underlying medical or psychiatric symptoms' (Hirsch 2001), but this definition does not mention essential oils or differentiate between essential and fragrant (synthetic) oils, which are not usually recommended for use in healthcare. In addition, for the administration method Hirsch refers only to inhalation. Thus, Hirsch's definition does not accurately define aromatherapy or describe the way it is practised. For the purposes of this chapter, aromatherapy is defined as follows:

> The controlled use of essential oils from named botanical sources using a variety of application (external) or administration (internal) methods to promote and support health and wellbeing using a patient-centred evidence based approach.
> *Dunning 2005*

In this context 'controlled' encompasses:

- quality use of essential oils (QUEO) (Dunning 2005), which is based on the principles of the Quality Use of Medicines (Department of Health and Aged Care 1999)
- qualifications and competence of practitioners
- accurate diagnosis
- appropriate selection of essential oils based on a thorough assessment, stating the botanical name of the plant and plant part from which the oil was extracted and evidence for use where possible, and the administration/application, dose and dose frequency method
- appropriate documentation, including adverse-event reporting when relevant, and monitoring the effects according to the aims of the treatment
- appropriate storage and handling of essential oils to reduce deterioration and oxidation and meet infection control and disposal standards
- regulatory standards, including scheduling, manufacturing and advertising processes.

HISTORICAL OVERVIEW

Use of essential oils is recorded in most ancient civilisations in healthcare, religion and cosmetics, and to enhance the environment. For example, the ancient Egyptians used them to embalm the dead as well as in healthcare. Almost all cultures used odorants, including plant oils, as preventative measures and to fumigate people and environments during illnesses, such as the plague. In the Middle East, Avicenna (AD 980–1037) is credited with developing the original steam distillation process for extracting essential oils. In the late 1800s, Chamerland undertook research into the antiseptic properties of essential oils and in the 20th century Cavel, who studied the antiseptic properties of 35 essential oils in sewerage cultures, extended Chamerland's work.

A great deal of modern research concerns the relationship between odours and emotional states, cognitive performance (Jellinek 1998/99, Svoboda 2002, Van Toller & Dodd 1988) and stress management. It also focuses on the management of common health problems, such as upper respiratory tract infection

(URTI) and acute and chronic pain, in a range of healthcare settings that include aged care, midwifery and acute care such as coronary care units. Often the research is conducted on isolated chemical components of the essential oil, which does not reflect usual aromatherapy practice.

René Gattéfosse is credited with coining the term 'aromatherapy'. After burning his hand in a laboratory fire, he immersed it in a vat of lavender essential oil, which reduced the pain, and his hand subsequently healed without scarring or infection. Gattéfosse went on to use essential oils in military hospitals in World War I. Essential oils also played a major role in wound care during World War II, where Dr Jean Valnet used them in military hospitals in Europe and IndoChina. Marguerite Maury is largely responsible for the popularity of essential oils in modern beauty care. She introduced aromatherapy into the UK in the 1960s, and her technique of using low doses of essential oils dispersed in a carrier oil and applied in a massage strongly influenced aromatherapy practice in the UK and Australia (Price & Price 1995). Research into the therapeutic application of essential oils is continuing in many countries in animal and human subjects.

AROMATHERAPY PRACTICE MODELS

There are three main aromatherapy practice models, which have implications for the administration/application method, dose, dose intervals and safety. Essential oils are often combined with other conventional and complementary therapies such as massage and acupressure.

MEDICAL AROMATHERAPY

This is also known as aromatic medicine or aromatology. It is used in France and increasingly in the UK, and there is growing interest in Australia. An education program encompassing the internal use of essential oils was recently approved by the Australian National Training Authority. Medical aromatherapy utilises the internal administration of essential oils via the oral, rectal and vaginal routes, as well as in dressings, ointments and fumigation. Only steam-distilled and expressed essential oils are used internally. In France prescribing for internal use is regulated and restricted to medically qualified doctors who have the relevant training. A pharmacist often formulates the prescriptions. Aromatherapists may work under the direction of a doctor. In some other countries, other practitioners can prescribe essential oils if they have the relevant qualifications.

SUBTLE AROMATHERAPY OR AROMACOLOGY

This is the German model of practice, which largely uses inhalation to influence psychological and spiritual states.

POPULAR, OR TRADITIONAL, AROMATHERAPY

Largely based on the UK model, this involves inhalation and massage. Touch, an essential aspect of massage, has its own health benefits, and this model uses topical application in massage, gels, creams and lotions, as well as inhalation for physical, psychological and spiritual effects. There are two subgroups: therapeutic aromatherapy, which is used in healthcare, and cosmetic or beauty care aromatherapy. Australian aromatherapists largely follow the UK model, but some incorporate aspects of all three models.

All three models use essential oils as the main medicinal substance. Essential oils are rarely used undiluted, but rather are incorporated into various carrier substances, depending on the administration/application route. Most aromatherapists formulate blends for individual patients, but fixed-formulation blends are available: for example, massage blends for pain relief. Aromatherapy is very popular with the general public and self-prescribing by following the directions in self-care books, magazine articles and short education courses is common. In Australia some health insurance funds reimburse the costs of aromatherapy treatments, provided the aromatherapist is qualified through an approved training facility.

ESSENTIAL OILS

CHEMISTRY

Essential oils are secondary plant metabolites and are complex chemical compounds that have a different composition from the herb extract of the same plant. Essential oils are stored in specific secretory structures in leaves, twigs, seeds, petals, bark and roots, often with resins and gums in oil cells, sacs, resin canals, ducts and hairs, and are extracted from these structures by steam distillation, expression, enfleurage, solvent extraction, maceration and more recently supercritical carbon dioxide

extraction, depending on the plant source (Guba 2002, Price & Price 1995). More than 3000 odour molecules have been identified.

Chemical variations are common in plants of the same genus and these are known as chemotypes. The best known chemotypes occur in the essential oils of *Thymus vulgaris* (thyme), *Rosmarinus officinalis* (rosemary), *Ocimum basilicum* (basil), and *Melaleuca alternifolia* (tea tree). Growing conditions, harvesting, storage and handling are known to affect the chemical composition of essential oils (Guba 2004, Price & Price 1995). Common phytochemicals in essential oils are terpenes, sesquiterpenes, alcohols, phenols, aldehydes, ketones, esters, acids, phenolic ethers, oxides, lactones and coumarins (Bowles 2003, Clarke 2002). It is necessary to understand the chemical composition of essential oils in order to understand their application in healthcare and the safety aspects associated with their use.

Of the many chemicals present, the alcohols, lactones, phenols and sesquiterpenes are considered to have a major impact on the odour of the oil and are of particular significance in the cosmetic and perfumery applications of aromatherapy. Of these chemicals, alcohols are considered to be among the most important for therapeutic effect and pleasant fragrance. They often have antimicrobial properties and low toxicity, and are described as warming, uplifting and good general tonics. Two examples of alcohols found in essential oils are:

- linalool, found in the essential oils of lemon, rosemary, sage, thyme and mandarin, and which has anaesthetic, antiseptic and sedative effects
- terpineol found in the essential oils of frankincense and tea tree, and which has antiseptic activity.

The sesquiterpenes consist of three isoprene units and make up the largest group of terpenes found in the plant world. They tend to have strong odours and a variety of pharmacological effects. Two examples of sesquiterpenes found in essential oils are:

- caryophyllene, found in oil of cloves, eucalyptus, ginger, lavender, marjoram, sage, thyme, ylang ylang and valerian. It has a strong spicy, woody odour and anti-inflammatory, antispasmodic, antibacterial, fungicidal and sedative effects.
- chamazulene, found in German chamomile, which gives it the characteristic blue colour. It has analgesic, anti-inflammatory, antioxidant, antiseptic and antipyretic effects.

Optical isomerism also influences the odour of a substance, so two different oils containing the same specific chemical may have different odours because the chemicals are stereoisomers. For example, *d*-limonene found in citrus oils, pine leaves and peppermint has a citrus odour, whereas its stereoisomer *l*-limonene has a turpentine-like odour and is found in citronella and lemon verbena.

Although the pharmacological effects of many of the constituents found in essential oils have not yet been fully investigated, a few that have been investigated are notable for their significant activity. For example, eugenol is a phenol found in cinnamon, oil of cloves and ylang ylang, giving the oils a spicy, pungent odour and significant antimicrobial activity. Cinnamaldehyde, chiefly found in cinnamon oil, has also been well investigated. It has antispasmodic, antimicrobial and fungicidal activities and is described as having a warm, spicy and balsamic odour.

Most of the essential oils produced are used in the food, cosmetic and, to a lesser extent, medicine industries, where strict composition standards are needed to ensure products meet relevant standards. Organisations such as the International Organisation for Standardisation (ISO), Research Institute for Fragrance Materials (RIFM), International Fragrance Association (IFRA) and Association Française de Normalisation (AFNOR) have developed composition standards for many essential oil products used in the food and perfume industries, and this is an important aspect of quality control. The ISO and AFNOR standards are often accepted as the most reliable indicators of quality.

The need to achieve compositional consistency has led some manufacturers to artificially manipulate chemical composition, using adulteration, substitution and rectification, to ensure essential oils meet the standard and to reduce the cost of expensive oils such as rose and jasmine. Plant conservation issues have also affected aromatherapy practice: for example, the sale of essential oils from some endangered species is banned in Europe. In some cases synthetic products have been developed, which may increase the potential to cause adverse events and bring aromatherapy into disrepute. The European Federation of Essential Oils was formed in 2002 to increase awareness of the need for sustainable harvesting to benefit both local communities and aromatherapy, as well as to conserve endangered plants.

Analytical techniques such as gas chromatography, mass spectrometry, infrared spectroscopy, optical rotation and refractive index are used to assess the composition and purity of essential oils. Frequently mass spectrometry and infrared spectroscopy are considered together. The analytical information, together with other safety information, is detailed in material safety data sheets, which are available from essential oil suppliers and manufacturers. More recently, the cosmetic industry has begun to examine the peroxide value (POV) of both essential and fixed vegetable oil carrier oils. POV is an indicator of the potential of an essential oil to cause skin irritation and sensitivity (Wabner 2002). In addition, the physical appearance (colour and consistency) and odour of the oil are important aspects of quality.

Currently, there is not a standard for 'therapeutic-grade essential oils' (Guba 2004). However, some suppliers undertake independent quality-control tests to ensure essential oils meet aromatherapy requirements and to guarantee that their essential oils are:

- 100% pure, which means they are not adulterated in any way
- 100% natural, which means they are made from plant material and do not contain any synthetic substances
- 100% complete, which means they are single-distilled and have not had any chemical constituents removed or added.

In Australia most essential oils are listed in schedule 14 of the medicines scheduling system of the Therapeutic Goods Administration (TGA). However, TGA listing does not necessarily indicate benefit or efficacy, but does indicate that the risks associated with listed products are low. Manufacturers are not permitted to make therapeutic claims for listed products.

Aromatherapists prefer to use the entire essential oils rather than isolated compounds or synthetic oils, because the chemicals present in individual essential oils and blends have synergistic and quenching properties that enhance the beneficial effects and reduce unwanted effects. These beneficial interactions occur among the individual constituents within an oil and among the essential oils in a blend of oils (Clarke 2002, Price & Price 1995, Opdyke 1976). In most cases a blend of essential oils is used to suit the condition being treated, and the composition of the blend is modified according to the individual's response in much the same way as herbal medicines are used. Common application/administration methods and doses are shown in Table 4.2 at the end of this chapter. Recommended doses are based on a long history of traditional use and the recommendations of experts, rather than on dose-finding trials. A number of factors need to be considered when deciding on an application method, dose and dose interval including:

- the aromatherapy model being used
- the pharmacokinetics and pharmacodynamics of the essential oils
- the mode of administration/application
- the patient's age and gender, presenting health issues and medical history, including allergies
- other conventional and herbal medicines being used
- the qualifications of the practitioner.

Most aromatherapists do not recommend using fragrant oils for therapeutic purposes, although most accept they may have a role as environmental fragrances and may have psychological effects.

CARRIER SUBSTANCES

In most cases essential oils are dispersed in another substance known as a carrier. Carrier substances for massage are usually cold-pressed or fixed vegetable oils, such as sweet almond, grapeseed and macadamia nut oil, depending on the aims of treatment. In massage, the carrier oils primarily provide lubrication for the therapist's hands to allow smooth movement over the skin and to enhance absorption of the essential oils; however, some fixed oils, such as those of calendula (*Calendula officinalis*) or St John's wort (*Hypericum perforatum*), also have therapeutic properties.

Other carriers include honey, *Aloe vera*, shea and cocoa butter, and waxes, which are used for capsules, ointments and suppositories intended for internal use. Purified clays such as bentonite are also used as carriers for essential oils to be applied in compresses, poultices and face and body masks/packs in beauty care. Incipients (dispersants) are usually required if essential oils are added to water to keep them in solution because essential oils are generally insoluble in water.

HYDROSOLS

A hydrosol is the condensed water co-produced with the essential oil during steam distillation (Catty 2001). Each litre of hydrosol contains low doses of essential oils, between 0.05 and 0.02 mL, depending on the solubility

of the constituents in the oil being distilled, the duration of the distillation process and the hydrophilic/lipophilic nature of the constituents. Therefore, the chemical profile is different from the essential oil obtained from the same distillation. Hydrosols can be used as carrier substances or prepared as tinctures, spritzers and compresses; frequently, they can also be drunk (Catty 2001).

PHARMACOKINETICS AND PHARMACODYNAMICS

Essential oils are absorbed, metabolised and excreted in a similar way to fat-soluble medicines (Tisserand & Balacs 1995). They have a short life span in the blood, from where they are distributed to muscle and adipose tissues over a longer period. They may bind to plasma proteins for transportation, and detoxification primarily occurs in the liver. The exact pharmacokinetics and pharmacodynamics depend on many factors, including the route of administration.

Research into the pharmacodynamics and pharmacokinetics of essential oils indicates that they are metabolised and excreted between 72 and 120 hours after administration/application depending on the:

- body size of the subject
- chemical composition of the essential oil/s carrier substance
- carrier substance
- application/administration route
- dose, dose form and dose interval
- individual's health status.

Essential oils are absorbed through the skin, but the absorption rate of the various chemical components in a particular essential oil depends on a number of factors, including the size of the individual molecules, the percentage of essential oils in the blend, total dose applied, the area covered and the state of the circulation. Jager et al (1992) detected linalool and linayl acetate (components of lavender) in the blood at 5 minutes after a 10-minute abdominal massage using 2% *Lavandula angustifolia* in peanut oil.

Likewise, salicylate was detected in subcutaneous tissue within 30 minutes and for up to 60 minutes after the application of 20% methyl salicylate to the forearm (Cross et al 1997). Larger molecules, such as the coumarins, take up to 1 hour to penetrate (Ford et al 2001). Covering the area after applying the essential oils enhances absorption. Absorption is usually rapid from the rectal and buccal mucosa. Gastrointestinal factors such as diarrhoea and vomiting can affect absorption of oral doses.

Research is currently under way to ascertain whether essential oils enhance the absorption of topically applied medicines. Components such as limonene, 1,8-cineole and nerolidol enhance the penetration of both hydrophilic and lipophilic substances (Cornwall et al 1996, Duke 1998). Such research suggests topical application of essential oils may be contraindicated or caution required if conventional topical medicines such as anti-anginal agents, nicotine patches or hormone replacement therapy (HRT) are used at the same time.

SAFE USE

Safe use of essential oils is a complex topic that includes similar issues to those concerning herbal medicine safety. It is largely based on the long history of safe traditional use, case reports and animal studies to determine lethal doses (e.g. LD_{50}). The lethal dose (LD) may not provide useful information about topical applications. Even less is known about effective doses (ED) or the effects of organ disease, such as liver, renal or cardiac disease, on the metabolism and elimination of essential oils, although it is reasonable to expect these would be important considerations for internal dosing, as would the state of the skin for absorption of topical applications. Safety information can be found in the essential oil material data sheets, *The complete German Commission E monographs* (Blumenthal et al 1998) and the *ESCOP monographs: The scientific foundation for herbal medicinal products* (ESCOP 2003), as well as Poisons Information Centres (see Appendix 3).

Common potential risks are:

- skin, eye and mucous membrane irritation to the person using the oils and people in the vicinity (this is also an occupational hazard for practitioners)
- phototoxicity
- local irritation
- allergy (regular use of the same essential oils increases the risk of cumulative effects and allergy)
- odours can trigger respiratory difficulties, asthma or migraines in susceptible individuals
- unwanted psychological effects (e.g. euphoria in people with dementia).

Essential oils that contain aldehydes, phenols and furocoumarins, especially citrus oils such as bergamot (*Citrus bergamia*), are more likely to irritate the eyes, mucous membranes and skin,

and cause sensitisation. Contact sensitisation related to monoterpene oxidation (Tisserand & Balacs 1995) is frequently the result of poor storage conditions (Burfield 2000). If a skin reaction occurs, the area should be blotted with tissue to remove or dilute the oils and a carrier substance applied and removed with tissue. The process may need to be repeated several times. Removing with soap and water may exacerbate the reaction (Bensouilah & Buck 2006). The reaction should be noted in the individual's health history and an adverse event notification filed depending on its severity.

Cross-sensitisation to other essential oil components and foods has also been reported: for example, between Thai food and *Cymbopogon flexuosus* (East Indian lemongrass) (Bleaser et al 2002, Clarke 2002). Perfume and fragrant products found in candles, aerosols, incense and soaps are common irritants and often contain limonene, coumarin, geraniol and cinnamaldehyde (Harris 2005). Some also contain carcinogenic substances such as styrene or naphthalene, and some contain formaldehyde in amounts many times the safe limit, which is < 2 micrograms/m^3 of air (Harris 2005).

Patch testing of susceptible individuals (e.g. those with atopy) is recommended. Allergy from inhaled essential oils is known to occur, but data about exposure levels are limited and many of the reports concern perfumes rather than essential oils (Burfield 2000). Cumulative effects can occur. Essential oils that are not commonly used in aromatherapy have been associated with cancer, neurotoxicity (ketones) and hepatoxicity in large doses in animals, and these adverse events are most likely to occur with internal use (Tisserand & Balacs 1995).

Potentially carcinogenic essential oils

There is no evidence that essential oils cause cancer in humans, although some constituents are potentially carcinogenic, particularly saffrole, iso-saffrole, estragole, methyl chavicol, methyl eugenol, elemicin, asarone and *d*-limonene (Tisserand & Balacs 1995). High doses and prolonged use of essential oils containing these constituents should be avoided; however, most of these are not commonly used in aromatherapy.

Use in pregnancy

Essential oils are widely used in midwifery units in Australia, the UK and USA. Women use them largely to manage backache, nausea, discomfort from varicose veins, prevent or reduce stretch marks, and reduce perineal discomfort. Essential oil massages are often used in the last trimester to relieve backache and to aid relaxation and mental wellbeing. In Australia there is little internal use of aromatherapy oils; however, the practice is starting to attract interest. Internal use of essential oils should be undertaken with caution in pregnancy, as there are a number of reports of adverse effects following oral ingestion or vaginal use. This may be because higher doses achieved with oral dosing are likely to reach the fetus, as the placenta is permeable to essential oils because of their small molecular size (< 500 molecular units). This does not necessarily represent a risk to the fetus, but the fetal liver may not be mature enough to detoxify the oils or their components. In contrast, there are no case reports of topically applied or inhaled essential oils causing harm, but there is also no definitive evidence confirming safety in the first 16 weeks of pregnancy. A low dose, ~ 2%, is therefore recommended for full body massage during pregnancy, based on expert opinion rather than definitive evidence.

Although there is good evidence that fetal organs and tissues are sensitive to different chemicals at different stages of development, no such data is available for essential oils (Tisserand & Balacs 1995). When deciding about the risks and benefits of using essential oils during pregnancy the woman's medical history, obstetric history, weeks of gestation, and current health need to be considered. Table 4.1 (p 42) shows essential oils that should be used with caution, those that should be avoided throughout pregnancy and those generally considered safe to use. Taking a cautious view, aromatherapy experts recommend that essential oils with the potential to cause fetal damage be avoided throughout pregnancy. Essential oils containing sabinyl acetate and apiol represent the greatest risk to the fetus. Essential oils with a high proportion of antheol have mild oestrogenic effects, therefore internal use of these oils is not recommended. Many aromatherapists recommend emmenagogue essential oils be avoided, although there is little scientific evidence to indicate they cause adverse outcomes when used topically or inhaled.

Some of the current recommendations are based on contraindications for the herb extract; however, as has already been pointed out, essential oils and herbs may contain very different chemical components, even when they are derived from the same plant. Until more is known, caution is recommended.

TABLE 4.1 Use of Essential Oils During Pregnancy

Generally considered safe	Generally safe to use externally	Use with caution	Avoid. These contain camphor, apiol, sabinyl acetate or pinocamphone
Cardamom Roman and German chamomile Clary sage Coriander Geranium Ginger Lavender Neroli Palmarosa Patchouli Petitgrain Rose Rosewood Sandalwood Sweet orange or mandarin	Anise Fennel Lavandin Lavender spike *Lavandula stoechas* Rosemary Star anise Yarrow Mace	Artemisia Cangerama Cotton lavender Oakmoss Perilla Rue	Camphor Ho leaf Hyssop Indian dill *Juniperus pfitzeriana* Parsley leaf Plectranthus Spanish sage Savin

INTERACTIONS

It is difficult to determine whether interactions between conventional medicines, herbal medicines and essential oils occur. Most texts focus on interactions with conventional medicines, and there is little information about interactions with herbal medicines. Interactions between topically applied essential oils and medicines are most likely if they are both applied to the same local site. Only very small amounts are absorbed from topical application, so clinically significant interactions are unlikely, but the potential for interactions increases with internal use (see Table 4.2 at the end of this chapter). The exact mechanism of actual or potential interactions is difficult to define. Most are theoretical, largely based on animal studies, and most are not thoroughly researched.

SAFETY PRECAUTIONS

Most available essential oils are considered safe and present few risks when used appropriately.

- Most essential oils should not be applied undiluted to the skin.
- Susceptible individuals, such as those with a history of allergies or eczema, can develop a sensitivity to any essential oil.
- The risk of serious adverse events is higher with internal administration methods, especially oral.
- Essential oils containing aldehydes and phenols are more likely to cause allergic reactions. Patch testing before using essential oils for the first time may be indicated, especially in at-risk individuals.
- Using the same essential oils for long periods may lead to cumulative effects and cause sensitivity after a period of time. After 3 weeks of use, cessation for at least 24 hours is recommended.
- Although there is not any quality evidence to support recommendations for the use of essential oils in certain groups of people, traditional precautions and contraindications concerning pregnancy and lactation, epilepsy, asthma, people with alcohol or other addictions, certain age groups and disease states should be considered.
- Use traditional doses and dose intervals. Most aromatherapists use low doses, although effective therapeutic doses and dose ranges for specific situations are unclear.
- Some essential oils are not used in aromatherapy because of their known toxicity: for example, wormwood, rue, camphor, bitter almond and sassafras. Oil of wintergreen is sometimes on the exclusion list, but if it is used appropriately, it is an effective analgesic in a massage blend for muscular aches and arthritic pain.
- Essential oils must be appropriately stored and kept out of the reach of children, the cognitively impaired or suicidal patients to avoid inadvertent or deliberate overdose. Vaporisers should also be placed out of reach.
- Essential oils are highly flammable. Products must be used and disposed of appropriately to reduce the fire risk.
- Educating patients who self-apply essential oils is an important aspect of safe use.

For safety and medicolegal reasons healthcare professionals and the general public are advised to buy essential oils from reputable sources that label and store their products correctly. Labels are an important source of information and should contain the following information:

- botanical name, species, and if relevant the chemotype of the plant from which the oil was extracted or, in the case of a blend, for all the oils in the blend
- part or parts of the plant from which the essential oil was extracted
- country where the plants were grown (country of origin)
- extraction method
- statement of purity (However, this is not a regulatory requirement and not all suppliers make such statements.)
- batch number, so that the batch can be identified if an adverse event occurs to determine whether the reaction was idiosyncratic or occurred because of the manufacturing process
- expiry date and storage precautions
- in some cases specific warnings: for example, phototoxicity risk in Australia
- supplier details.

STORAGE

Essential oils are volatile and readily evaporate, so they should be stored in airtight amber glass bottles to protect them from light and air. Plastic is usually avoided because there can be transference of chemicals in the oil to the plastic and vice versa, thereby changing the chemical composition of the oil. Essential oils should also be stored in a cool place, preferably away from direct sunlight. Some aromatherapists store oils in a refrigerator. The 'top notes' of the oil have the lowest boiling points and are highly volatile and evaporate first, thereby altering the aroma of the oil. In general, oils should be used within 1 year of opening; however, their shelf life can be extended with careful use and storage.

AROMATHERAPY IN PRACTICE

The level of evidence for aromatherapy use is an important aspect given the current focus on evidence-based care. The level of evidence is judged according to the quality of the research, considering factors such as statistical power, study design, accuracy of the measurements, and the outcomes. Overall, most clinical aromatherapy research is low-level evidence (DANA-Farber Cancer Institute 2008). In addition, individual practice varies considerably, which means that the management of specific health conditions varies considerably.

As with all clinical practice, it is important to be clear about the goals of treatment and decide what treatment/s and forms of administration will achieve those goals. For aromatherapy, this means choosing the correct essential oils and whether the topical and/or inhaled method of administration is suitable. Psychological, physical and practical requirements are also assessed, together with relevant safety information. When using oils topically in children, the elderly or allergenic people, it is recommended that a skin test be performed first. One drop of oil applied with a cotton ball or swab to the inside of the elbow or wrist is usually sufficient. The application area should be marked and left unwashed for 24 hours. If a reaction occurs (redness and itch) the offending oil should be avoided. See Table 4.2 at the end of this chapter for more information about using oils in practice.

CHOOSING AN AROMATHERAPIST

Aromatherapy may be particularly beneficial for managing stress and inducing relaxation. It can also be useful in skin care, for managing topical fungal and bacterial infections, to relieve respiratory symptoms, as topical analgesia, and to reduce muscle spasm, especially when combined with massage. A key aspect of safe, effective aromatherapy treatment is choosing a knowledgeable and competent aromatherapist.

Education and competence

The aromatherapist should belong to a professional association, such as the International Federation of Aromatherapists (IFA) or the Australian Aromatic Medicine Association (AAMA), that has defined membership criteria, including the expectation that the aromatherapy training curriculum was approved by the Australian National Training Authority and/or state training authorities, whose competencies are consistent with national competency standards for aromatherapy, continuing professional development requirements and a code of professional conduct. These associations maintain membership lists and can be accessed via the telephone directory or their respective websites. Aromatherapists in Australia are not regulated, but membership of such

TABLE 4.2 Common Application Methods, Recommended Doses and Safety Tips for Essential Oils

Application method	Doses (using a standard essential oil dropper top)	Safety tips
Massage	*Adults* The recommended dose is between 3.5% and 5% of an essential oil blend in a carrier oil. However, larger doses can be used safely (e.g. 15% in an aqueous cream, 10% in a gel). The dose also depends on the presenting problem (e.g. undiluted tea tree or lavender oil might be applied to an insect bite or a small burn, whereas lower doses would be used for chronic diseases). *Children* Children > 7 years and the elderly: 1–1.5%. Children 2–7 years: 0.5%. *Babies* 0–1 year: no essential oils. Approximately 25–30 mL of a carrier substance is needed for a full adult body massage, depending on size of the individual, skin condition and amount of body hair.	• To avoid cumulative effects and reduce the likelihood of sensitivity developing over time, the same essential oils should not used for long periods. • Essential oils containing aldehydes, phenols and furocoumarins, especially cinnamon (or cassia) and citrus oils such as bergamot (*Citrus bergamia*), are more likely to irritate the eyes, mucous membranes and skin, and cause sensitisation. • Geranium, ginger, pine and citronella should be avoided by people with sensitive skin or a history of dermatitis. • Essential oils are not recommended for use on babies.
Bath	4–7 drops of essential oils added to a warm bath directly or first mixed in a carrier substance and agitated into the bath water.	• Take care that bath water with oils is not ingested and does not enter eyes. • The oil must be mixed into the water before the person gets into the bath, not left floating on the surface.
Vaporiser	4–7 drops applied onto the surface of the water that is to be vaporised.	Keep vaporisers out of the reach of children and confused people who might drink from them. Poisoning has been reported in children drinking from vaporisers.
On a tissue, cotton ball, pillowcase or clothing	1–2 drops applied directly and inhaled from these items.	
Steam inhalation	Fill a bowl with 2 cups of almost boiling water and add 2–4 drops of essential oils. The scented steam should be inhaled for 5–10 minutes. Low doses of essential oils should be used to reduce the risk of irritating the respiratory mucous membranes and the eyes, especially when the oils are highly volatile (i.e. top notes). Five drops of essential oil yields approximately 35 mg of essential oil from a nebuliser.	• Take care with people who have asthma because some oils can exacerbate symptoms. • High doses, and some essential oils such as eucalyptus, can irritate the eyes.
Unscented lotions, creams or ointments	4–5 drops/60 mL of vehicle such as aqueous cream, white soft paraffin or vitamin E cream.	
Gargle and mouth wash	2–3 drops in 30 mL of distilled or spring water; for children, 1 drop mixed in honey before adding to water. Hydrosols can be used as mouthwashes and gargles.	Not to be ingested orally.
Room sprays and spritzers	8–10 drops in 500 mL of distilled water. Spritzers are useful when the person cannot be massaged (e.g. for herpes zoster 15–20 drops in 50 mL can be used to relieve pain and itch). Hydrosols can be used as spritzers.	• Use glass bottles or stainless steel spray cans, not plastic containers. • Do not spray into the eyes.

Continued

TABLE 4.2 Common Application Methods, Recommended Doses and Safety Tips for Essential Oils *continued*

Application method	Doses (using a standard essential oil dropper top)	Safety tips
Poultice	2–3 drops in ½ cup of chopped up solid or semi-solid medium, e.g. clay, oatmeal, linseeds, chopped comfrey. Hot water can be added to the mixture to make a paste, which is then spread onto a piece of gauze and covered with a second piece of gauze. Fold over the ends to secure the contents and apply warm to the affected area.	
Compress — hot or cold Cold compresses are used when there is inflammation, swelling or headache; hot compresses for muscle aches and pains, menstrual pain or boils.	2–6 drops, depending on the size of the area to be covered by the compress: 2–3 drops for a finger; 5–6 drops for a knee. A soft piece of fabric (e.g. flannel, towelling) is sufficient for both types. Put 6–10 drops of essential oil into 0.5 litre of water (ice-cold or hot) and place the fabric on top of the water. Squeeze the fabric to prevent it from dripping when lifted out; however, don't allow the fabric to become too dry. Place the compress on the area to be treated and reapply when it has warmed or cooled to body temperature.	
Undiluted on the skin (tea tree, lavender)	1–2 drops onto a cotton bud and applied directly to the affected area.	• Essential oils should not be applied directly to the skin unless under the direction of an aromatherapist. • Some low-irritant essential oils, such as lavender and rosewood, are generally safe.
Oral, buccal (not generally used in Australia or New Zealand)	30 mg/dose for adults in a gel, capsule or lozenge. *Acute conditions* 60 mg three times daily for 3 days. *Chronic conditions* 30–45 mg three times daily for 15 days.	• Essential oils should be used orally only under the direction of an aromatherapist qualified in this method of use. • Many essential oils irritate mucous membranes.
Rectal suppositories (not generally used in Australia or New Zealand)	*Adults* 150–450 mg/day three times daily for 3 days. *Chronic conditions* 150 mg/day for 15 days.	• Essential oils should be used only under the direction of an aromatherapist qualified in this method of use. • Many essential oils irritate mucous membranes.
Vaginal suppositories (not generally used in Australia or New Zealand)	150 mg on 1 g suppository. 1–5% with an excipient in a douche. Up to 10% in a carrier substance on tampons.	• Essential oils should be used only under the direction of an aromatherapist qualified in this method of use. • Many essential oils irritate mucus membranes.

an association suggests self-regulatory processes are in place. Undertaking short courses is adequate for self-care, but not for the therapeutic application of essential oils, even by healthcare professionals such as doctors and nurses.

Professional courtesy

The aromatherapist should communicate with other relevant healthcare providers, document the care provided, including monitoring outcomes and adverse events, provide advice that includes the benefits and risks of using essential oils, and recommend that people with serious conditions seek medical advice.

Safety

The aromatherapist should adhere to relevant occupational health and safety standards and other relevant Acts and regulations: although aromatherapists are not regulated, regulations apply to the products they use and their premises.

Clarity of outcome

The aromatherapist should be clear about what aromatherapy can offer and their personal competencies.

CHAPTER 5
INTRODUCTION TO FOOD AS MEDICINE

Let food be your medicine and medicine be your food. (Hippocrates)

The maxim coined by Hippocrates, the father of Western medicine, around the 5th century BC, is as true today as it was then. Hippocrates observed that certain foods had the potential to both prevent and treat disease, and recognised the effects of nutritional deficiencies and excesses on health (Jensen 1993). Hippocrates' axiom went largely ignored in the evolution of Western medicine, but the pioneering work of researchers such as Linus Pauling and Victor Rocine in the early 20th century created a renewed interest in the therapeutic value of food and its influence, both positive and negative, on health.

Over the last 100 years a number of significant developments have been made in nutritional science, including:

- identifying essential nutrients and documenting their associated biochemical pathways
- defining nutrient reference values and RDI required to prevent nutritional deficiencies
- establishing dietary guidelines that include increasing consumption of fruits, vegetables and fibre, and reducing fat
- developing food guides, such as food pyramids, that can be used for daily meal planning.

Nutritional science has also led to the recognition that diet plays a major role in the chronic diseases that cause the bulk of morbidity and mortality in modern societies, such as heart disease, diabetes, hypertension and cancer.

Together with an increasing understanding of the potential benefits and negative consequences of food choices comes an unprecedented availability of different foods. Yet despite this, a problem of oversupply has arisen in developed countries and many Australians are consuming vast amounts of kilojoule-laden, yet nutrient-deficient, foods resulting in nutritional depletion and suboptimal nutrition. Largely as a result of this phenomenon, nutrition research has shifted from focusing exclusively on deficiency states to investigating the association between disease prevention, healthy ageing and adequate dietary intake in order to optimise quality of life and long-term health (Kennedy 2006).

FUNCTIONAL FOODS

The foods and substances we ingest affect us even at the most basic cellular level. In recent years scientists have discovered many thousands of previously unidentified substances in food and described their therapeutic actions. Currently around 50,000 (of a likely 200,000 substances) have been identified and described, yet for the most part we know very little about their functions (Hounsome 2008). These substances are known as phytonutrients, phytochemicals or a-nutrients. They impart colour, taste and smell, as well as possessing therapeutic properties such as antioxidant, anticarcinogenic, antimicrobial, antihypertensive, anti-inflammatory and cholesterol lowering properties. Major classes of phytonutrients include phenolic and polyphenolic compounds (flavonoids, phenolic acids, lignins), terpenoids (carotenoids, tocopherols and tocotrienols, quinines, sterols), alkaloids (including saponins), and sulfur-containing compounds (glucosinolates) (Goldberg 2003). A brief summary of some of the better known phytonutrients, their major actions and therapeutic uses is shown in Table 5.1 (pp 48–50). Although thousands of studies have already been conducted to identify phytonutrients in foods and understand their properties and influence on human health, much remains unknown.

TABLE 5.1 Examples of Phytonutrients Found in Functional Foods and Their Main Actions and Uses

Class/Phytonutrient	Main food sources	Main actions	Clinical use
Carotenoids			
Beta-carotene	Carrots, sweet potatoes, spinach, pumpkin, apricots, rockmelon (cantaloupe)	Anticarcinogenic Antioxidant	May reduce the risk of lung cancer in smokers. May protect against UV radiation (Stahl et al 2006).
Lutein, zeaxanthin	Green leafy vegetables such as kale, chard, spinach Egg yolk	Antioxidant Antitumour (breast, colon)	May reduce the risk of macular degeneration and cataracts, cardiovascular disease and some cancers (Ribaya-Mercado & Blumberg 2004).
Lycopene	Tomatoes cooked with oil, watermelon, guava, pink grapefruit, papaya	Antioxidant Anticarcinogenic (bladder, breast, cervix, prostate) Anti-inflammatory Hypocholesterolaemic	May reduce the risk of some cancers (especially prostate) and atherosclerosis (Bhuvaneswari & Nagini 2005).
Thiols/dithiols			
Alpha-lipoic acid (dithiol)	Potato, spinach Liver	Hypoglycaemic Antioxidant (water & lipid soluble) Hypotensive	May assist in the prevention of diabetic complications and cardiovascular disease. Recycles other antioxidants (Eddey 2005, Smith et al 2004, Wollin & Jones 2003).
Glutathione (thiol)	Garlic, fruits, vegetables Meat (found in all cells of plants and animals)	Antioxidant Chemoprotective	Important endogenous antioxidant
Phenolic compounds (including flavonoids)			
Phenolic acids	Most fruits and vegetables, especially the cruciferous (cabbage) family, tomatoes, berries	Antioxidant Anti-inflammatory Inhibits platelet activity	
Polyphenols	Fruits and vegetables Wine Green tea Extra-virgin olive oil Dark chocolate and other cocoa products	Anti-allergenic Antioxidant Anti-inflammatory	
Anthocyans (anthocyanins, glycosides, and their aglycons, anthocyanidins)	Fruits and berries	Anticarcinogenic Antioxidant	May reduce the risk of cancer (Cooke et al 2005).
Caffeic acid (phenolic acid)	Fruits (apples, pears, citrus) Some grains and vegetables	Antioxidant Antihypertensive Antithrombotic Antitumour Antiviral	May contribute to maintenance of healthy vision and cardiovascular health (Jiang et al 2005).
Ellagic acid (polyphenol)	Fruits, nuts and vegetables (e.g. strawberries, raspberries, grape seeds, onions)	Aldose reductase inhibitor (Duke 2003) Anticarcinogenic (cervix, colon, oesophagus, mouth) Antioxidant	Counteracts synthetic and naturally occurring carcinogens (Stoner & Mukhtar 1995).

TABLE 5.1 Examples of Phytonutrients Found in Functional Foods and Their Main Actions and Uses *continued*

Class/Phytonutrient	Main food sources	Main actions	Clinical use
Phenolic compounds (including flavonoids) *continued*			
Proanthocyanidins (catechin and epicatechin)	Fruits (e.g. apples, pears, grape seeds and peaches) Vegetables, nuts, beans Seeds, flowers and bark (e.g. pine) Tea Cocoa, chocolate	Antioxidant	May stabilise capillary walls and enhance wound healing. May assist in the treatment of pancreatitis.
Quercetin	Onions, beans Red wine Green tea, black tea Apples, berries	Anti-allergic Anti-inflammatory Antioxidant Antiviral	May assist in the treatment of allergies. May prevent diabetic complications.
Resveratrol	Red wine and red grape juice	Anticarcinogenic (breast, prostate, skin (Duke 2003)) Antifungal Anti-inflammatory Antioxidant Antithrombotic	May reduce risk of cardiovascular disease and cancer (Fremont 2000).
Diphenols (phyto-oestrogens)			
Isoflavones (daidzein, genistein, glycitein)	Soybeans and soy-based products	Anticarcinogenic (breast) (Duke 2003) Antioxidant Phyto-oestrogenic	May ameliorate menopausal symptoms and contribute to the maintenance of bone and cardiovascular health.
Lignans	Flax/linseed Some legumes and grains	Anticarcinogenic Antioxidant Phyto-oestrogenic	May contribute to maintenance of cardiovascular and immune function. May reduce risk of breast and prostate cancers.
Isothiocyanates			
Sulforaphane	Broccoli (especially young), broccoli sprouts, cauliflower, cabbage, kale, horseradish	Anti-apoptotic Anticarcinogenic Antioxidant	May reduce the risk of cancer (Fimognari et al 2005, Gills et al 2005).
Indoles			
Cruciferous indoles (indole-3-carbinol)	Cabbage, broccoli, Brussels sprouts, Chinese cabbage, Chinese greens, kale	Anticarcinogenic	May induce the metabolism of a cancer-preventative form of oestrogen and reduce the risk of cancer.
Fatty acids			
Conjugated linoleic acid	Dairy products and cooked meats	Anticarcinogenic Anti-inflammatory	May assist with fat loss and cardiovascular disease prevention (Eddey 2005).
Monounsaturated fatty acids	Olives, olive oil Canola oil	Anti-atherogenic Antihypertensive Anti-inflammatory	May reduce risk of cardiovascular disease and diabetes (Eddey 2005).
Omega-3 PUFAs (ALA, DHA, EPA)	Fish (deep sea/cold water) Flax/linseed, walnuts	Anti-arrhythmic Anticarcinogenic Antihypertensive Anti-inflammatory Cardioprotective	May reduce risk of cardiovascular disease (Eddey 2005). May contribute to maintenance of mental and visual function. Has many other uses.

Continued

TABLE 5.1 Examples of Phytonutrients Found in Functional Foods and Their Main Actions and Uses *continued*

Class/Phytonutrient	Main food sources	Main actions	Clinical use
Dietary fibre			
Beta-glucan	Oat bran, wholegrain oats	Antihypertensive Hypocholesterolaemic	May reduce risk of cardiovascular disease. Reduces GI of meal.
Insoluble fibre	Wheat bran, celery, dried beans	Anticarcinogenic	May contribute to the maintenance of a healthy digestive tract. May reduce the risk of colon, lung, breast, cervical cancers.
Soluble fibre	Psyllium seed husk, pectin, oat bran, broccoli	Hypocholesterolaemic Modulates bowel function.	May lower cholesterol and reduce risk of cardiovascular disease. May improve gastrointestinal health.
Prebiotics/probiotics			
Inulin, oligofructose	Globe artichoke, garlic, onions, leeks, asparagus Whole grains Some fruits Honey	Anti-inflammatory Modulates immune function. Prebiotic	Stimulates colonic production of short-chain fatty acids and favours the growth of lactobacilli and/or bifidobacteria (Guarner 2005). Increases calcium and magnesium absorption. Influences blood glucose levels and reduces the levels of cholesterol and serum lipids (Lopez-Molina et al 2005).
Lactobacilli/bifidobacteria	Yoghurt; some other fermented foods	Probiotic	May reduce diarrhoea (Bergonzelli et al 2005). Improves gastrointestinal health and systemic immunity.

Note: Data adapted from International Food Information Council 2005 and Duke 2003. See respective monographs for more detail.

In parallel with the advances in nutritional science, there has been growing consumer interest in food's potential to have a positive impact on health and wellbeing, as well as in developments in food technology that allow foods to be produced, processed, preserved and fortified so as to maximise their nutritional values. This has led to changes in food-labelling laws that permit certain foods to make claims about health benefits and has given rise to the development of functional foods.

The concept of a 'functional' food originated in Japan and is now being further developed, mainly in Japan, the United States and Europe. Functional foods are foods or dietary components that provide a health benefit that goes beyond their nutritional value, such as improving wellbeing and/or reducing the risk of disease. These may include traditional foods that have been shown to impart a positive biological effect or foods that have been modified to impart health benefits. Other terms that are used for functional foods are super foods, designer foods, fortified foods, nutraceuticals, cosmaceuticals, medifoods, vitalfoods and Foods for Specified Health Use (FOSHU) (Ashwell 2002).

Functional foods can be foods in which a component has been enhanced through special growing conditions or foods in which a component has been added, removed, modified or had its bioavailability increased. Functional foods cannot be marketed as medicines because they cannot make therapeutic claims for treating specific diseases; rather they are designed to be marketed to healthy consumers to enhance health and prevent disease (Ashwell 2002). As such, functional foods are distinct from dietetic foods, which are designed for treating illness and are marketed to health professionals.

Examples of functional foods include yoghurt and probiotics, vitamin- and mineral-fortified breakfast cereals, iodised salt and sports drinks (which are proven to promote rapid gastric emptying and fast intestinal absorption, to improve water retention, thermal regulation and physical performance, and to delay fatigue)

(Ashwell 2002). Many commonly prescribed 'herbal medicines' can also be considered as functional foods and are commonly used for both medicinal and culinary purposes. Many of these foods and food derivatives are included in the monographs in this book: for example, celery seed, chamomile, cloves, cranberry, dandelion, fenugreek, fish oils, garlic, ginger, green tea, honey, horseradish, lemon balm, liquorice, linseeds, noni, oats, peppermint, probiotics, raspberry, rosemary, sage, stinging nettle, thyme and turmeric.

Although functional foods retain their identity as foods and do not include pills, the line between food and medicine is a fine one and the line between food and herbal medicine even finer. In Australia, foods (including herbal medicines) are regulated according to their intended use either by the TGA or by Food Standards Australia New Zealand (FSANZ 2006). Recently, recognition of the therapeutic value of foods has led to a review of the extension of permissible health claims, substantiated by scientific evidence, that are allowed on food packaging. Regulations currently allow for nutrient-content claims (e.g. 'high in fibre') and some health-maintenance claims. Other types of health claims, with the exception of claims about the benefit of maternal consumption of folate, are prohibited (FSANZ 2006).

Although the primary aim of altering foods to make them 'functional' is to promote their beneficial effects, consideration should also be given to the potentially negative implications of manipulating foods, such as altering the natural synergy of nutrients, the introduction of synthetic nutrients and the possibility of detrimental effects. In the USA, for example, mandatory fortification of cereal and grain products with folic acid has raised concerns about masking the haematological abnormalities of vitamin B_{12} deficiency, thereby allowing the progression of neurological complications to continue undetected (Rothenberg 1999), as well as placing some individuals at risk of exceeding the recommended safe upper limit of 1000 micrograms synthetic folate daily (Jamison 2005), while still failing to meet the peri-conceptual requirements of others (see *Monographs: Folate*).

SUPPLEMENTS VERSUS FOOD

The actions of a whole food cannot be completely understood by studying its various components in isolation, because phytonutrients often interact with one another and, when used together, can produce different outcomes from those predicted for an isolated compound. Thus supplementation with individual food components may produce different effects from those produced by the consumption of the whole food. For example, epidemiological studies supporting the use of foods containing beta-carotene for the prevention of lung cancer in smokers have not been supported by clinical trials of supplementation with synthetic beta-carotene (Ziegler et al 1996) (see *Monographs: Beta-carotene*). Similarly, there is strong evidence to suggest that eating a variety of fibre-rich foods is beneficial in the prevention and management of diabetes; however, studies using fibre supplements have produced contradictory results (Venn & Mann 2004).

The results of these and other studies substantiate the value of 'whole foods' as medicine and suggest that epidemiological studies supporting the use of certain foods cannot necessarily be extrapolated to confirm the benefits of isolated supplementary nutrients. Furthermore, the practice of refining foods and then enriching them with synthetic versions of some of the lost nutrients cannot be deemed to be the equivalent of the whole food. Additionally, some nutritional supplements may not produce the desired or anticipated effect because of the absence of significant but as yet unidentified co-factors that are important for bioavailability, pharmacological activity or safety of the individual constituent.

Alternatively, nutritional supplements may prove life saving in an overt deficiency state and may enhance the individual's nutritional status when dietary intake is insufficient to meet physiological requirements, such as during periods of increased biological demand. Many of the isolated nutritional supplements discussed in this book are not only used to correct a deficiency state, but also have direct pharmacological activity at doses unattainable through dietary modification alone.

INDIVIDUALISING FOOD

An old Chinese proverb states 'Whatsoever was the father of disease, an ill diet was the mother'. Traditional medicine systems such as traditional Chinese medicine (TCM) and Ayurvedic medicine continue to understand and practise using food as medicine, and view food within a conceptual framework that includes the energetic value of food in addition

to its physical qualities. An assessment of different foods may be based on the food's 'vitality' or 'life force', otherwise known as 'chi' in TCM and 'prana' in Ayurvedic medicine. The type of food and its biological, nutritional and sensual properties, together with the many agricultural practices, production processes and preparation methods, make a contribution to this force. Every step in the process of producing a food may potentially affect the energetic value, net nutritional content and overall therapeutic benefits.

In traditional medicine systems, foods may be classified as having properties such as 'heating', 'cooling', 'drying' or 'moistening', and may be considered to be energetically aligned with one or more of five phases of transformation, or 'elements', that correspond to the different organ systems and tissues within the body, as well as to the different emotions, seasons, colours and so on. These properties, as well as constitutional typing of the patient, may be used to make a sophisticated assessment of an individual and to design dietary prescriptions that are based on an individual's constitution, propensities for disease development and/or responses to different foods. Thus traditional medicine systems can be seen to practise 'nutriphenomics', whereby a food is used as a medicine based on a person's phenotype.

Biomedical science has not matched the same degree of sophistication in individualising diet as traditional medicines; however, it is moving in this direction. Just as in pharmaceutical medicine the emerging science of pharmacogenomics promises to provide drugs best suited to a person's genetic makeup, the emerging science of nutrigenomics promises to deliver an understanding of how different nutrients affect genes to cause specific conditions and the ability to design foods and dietary recommendations based on an assessment of an individual's genotype (see also Chapter 3).

The increasing individualisation, complexity and knowledge base of nutritional science has led to research into 'Point-Of-Sale Individualised Foods' (POSIFoods), which integrate advances in nutritional science, innovative food processing and formulation processes and state-of-the-art vending technology to deliver fast, palatable and nutritious foods, tailored to an individual's dietary needs and taste preferences at the touch of a button (Decision News Media 2004). The success of such developments and their impact in human health, however, are yet to be determined.

FOOD QUALITY ISSUES

The health benefits of different foods must be considered in relation to the many agricultural farming practices and production processes that are involved. As soon as produce is picked or an animal is killed, it starts to decompose and lose nutritional value. When a ripe organic apple is picked in season directly from the tree and eaten immediately, its nutritional value is at its maximum. How does this compare to the apple grown in nutritionally depleted soil, using pesticides and herbicides, out of season, picked before ripening and kept in cold storage to extend its shelf life, potentially for months, even years?

Every step in the process, from paddock to plate and beyond, may potentially affect the nutrients, as well as the 'energetic' quality and therapeutic benefits of the food. Thus food quality can be affected by multiple factors:

- farming conditions, which include genetic variety, chemical exposure, maturity at harvest, location, water availability, soil composition, climate, seasons, aspect and sunlight exposure
- transport conditions and processing, such as milling, refining and enriching
- preservation methods, which may include chemical additives, cold storage, drying, salting, irradiation
- the conditions and length of storage
- meal preparation methods, such as cutting, crushing or tossing
- cooking methods, such as no cooking (i.e. food is raw), steaming, frying, microwaving
- how food is consumed, which includes duration of mastication, food combinations and the biochemical individuality of the person consuming the food (Gliszczynska-Swiglo et al 2005, Jeffery et al 2003, Podsedek 2005).

PESTICIDE RESIDUES

The creation of a global food industry and the emergence of agribusiness have led to the increasing use of pesticides in food production. At the same time there is growing worldwide public concern about the impact of these pesticides on human health. Currently, it is reasonable to expect that most animals on the planet have accumulated pesticide residues through water, air or the food chain and, although acute effects of pesticides are well documented, the chronic effects of pesticide exposure are more difficult to assess. A recent systematic review examined

the peer-reviewed literature published between 1992 and 2003 on currently used pesticides (the 'older' organochlorine pesticides were excluded) and their effect on human health. The review found that there is a high level of consistency across multiple studies to indicate a wide range of pesticide-related clinical and subclinical health effects, including significant positive associations between pesticide exposure and solid tumours (such as cancers of the brain, breast, kidney, prostate and pancreas) and haematological cancers (such as non-Hodgkins lymphoma and leukaemia); genotoxic effects; as well as effects on mental and emotional functioning, the nervous system, neurodegenerative diseases and reproduction (including birth defects, fecundity, fetal death and intrauterine growth retardation) (Sanborn et al 2004). A further review of the effects of pesticides on children indicates that pesticide residues have been implicated in causing reproductive problems, including miscarriages and spontaneous abortion, birth defects, childhood cancer, and neurological, neurobehavioural and endocrine effects (Garry 2004).

Children appear to be particularly vulnerable to the effects of pesticides because they eat and drink more per kilogram of body weight than adults, and their diets are often rich in foods that contain higher levels of pesticides, such as fresh fruits, vegetables and juices. It should be noted that such contaminants are often bio-accumulated in the fatty tissue of animals, and that concerns over pesticide exposure should not lead to the removal of nutrient-rich foods from the diet but rather to minimising exposure by choosing organic foods whenever possible.

Children's exposure to pesticides may also be increased through breastmilk. This provides many immunological, physiological, nutritional and psychological advantages, but is nevertheless commonly contaminated with high levels of pesticides. For example, it has been found that serum concentrations of organochloride compounds are significantly higher ($P < 0.0001$) in breastfed infants than in bottle-fed infants (Lackmann et al 2004), and that an infant's measured intake of organochlorines from breastmilk may greatly exceed the adult acceptable daily intake (ADI) (Quinsey et al 1995, 1996). In addition, children have less developed detoxification pathways; for example, newborn infants have low levels of the enzyme paraoxonase–1, which detoxifies organophosphate pesticides (Chen et al 2003). The fact that children born today have a longer life expectancy in which to develop diseases with long latency periods places them at further risk (Sanborn et al 2004). These factors led to the 1996 revision of the US Federal Fungicide, Insecticide and Rodenticide Act to include an additional 10-fold margin of safety for exposure to pesticide chemical residues in infants and children (Makris & Rowe 1998).

The dietary exposure of the Australian population to pesticides and other food contaminants was previously monitored every 2 years via the Australia Total Diet Survey (ATDS) conducted by Food Standards Australia New Zealand (FSANZ). The most recent surveys, however, have not included pesticides. The most recent to do so was the twentieth survey in 2003, which concluded that the levels of pesticide residues and contaminants found in Australian food sources were very low and within acceptable safety limits (FSANZ 2003a). The survey selected specific 'contaminants' for study and therefore cannot demonstrate broad effects on public health. Residue testing is also conducted on fresh produce in Australia (e.g. FreshTest and the National Residue Survey), but this is largely funded and directed by industry bodies.

Although safety assessments are conducted on pesticides and guidelines are set for maximum residue levels (MRLs), this does not necessarily guarantee food safety as numerous other factors need to be considered. Safety assessments usually examine only single chemicals at high doses and often only in animals, which may lead to a significant underestimation of the potential risk associated with the numerous mixtures of compounds that consumers are typically exposed to. The combined toxic effect of multiple chemicals is not necessarily predictable by adding up the toxic potential of each chemical; mixtures of chemicals can also interact to produce synergistic toxic effects. Thus it is possible that there may be greatly enhanced toxicity of these compounds when they are combined, and this is supported by research documenting reproductive, immune and nervous system effects not expected from the individual compounds acting alone (Boyd et al 1990, Porter et al 1993, 1999, Thiruchelvam et al 2000). Pregnant and lactating women require specific consideration to minimise exposure of the fetus or infant during critical periods of development, and children do not metabolise chemicals as efficiently as adults (Sanborn et al 2004).

GENETIC MODIFICATION (TRANSGENIC FOODS)

Conventional methods of selective breeding and cross-breeding have been used for centuries to alter the genetic makeup of the foods we consume; for example, the wheat that we consume today is significantly different from the wheat consumed by our ancestors. However, these methods allow only for the selective enhancement of characteristics that already exist within a species or compatible species. In recent years transgenic technology, commonly (if not entirely accurately) known as 'genetic engineering', has been developed. This allows for the introduction of genetic material from unrelated species, which would not be possible using conventional methods.

While advocates maintain that there is the potential for biotechnology to have a positive impact on the nutritional properties of transgenic foods and to allow for their cultivation in areas where farming is difficult, it has been argued that most transgenic foods have so far produced greater benefits for producers than consumers. Currently, only six countries (Argentina, Brazil, Canada, China, South Africa and the USA), four crops (corn, canola, cotton and soy) and two traits (herbicide tolerance and insect resistance) represent 99 per cent of the transgenic crops planted worldwide (FAO 2004): 'The so-called "orphan crops" such as cowpea, millet, sorghum and teff that are critical for the food supply and livelihoods of the world's poorest people' and 'traits of interest to the poor; drought and salinity tolerance, disease resistance, or enhanced nutrition' are receiving little attention (FAO 2004). The prospect that transgenic crops could be used for mass medication and vaccination programs also raises concern in some circles.

The long-term safety implications of genetic engineering, a self-regulated industry, are being hotly debated by activists and the public alike. Some of the issues under discussion focus on:

- the consequences of introducing into the food chain questionable genetic material that may produce unpredictable results
- the introduction of lectins, causing immunological effects such as allergic reactions
- the use of bacteria and viruses to introduce foreign material into cells
- the use and potential spread of antibiotic-resistant genes
- the greater use of pesticides and herbicides with transgenic crops
- the contamination of non-transgenic crops with modified genes
- the use of terminator genes and prevention of seed-saving.

Consequently many communities are divided as to whether transgenic foods should be allowed in their country.

Currently, six genetically modified (GM) foods have been approved for sale in Australia and New Zealand: all are derived from soybeans, sugar beet, corn, cottonseed oil, canola and potatoes. In Australia, to enable consumer choice, food producers are required to label foods that contain a GM-derived component or a GM protein introduced through genetic engineering; however, the genetic material that has been used is not specified. The introduction of these transgenic foods has been criticised, with claims that there is insufficient evidence of safety and that safety test technology is inadequate to assess potential harms (Pusztai 2001). It has also been suggested that a precautionary principle should be applied and that further research needs to be conducted on the possible health risks of transgenic foods before they are introduced (BMA 1999). In reality, the ultimate benefits and detriments of genetic engineering are unlikely to be known for several generations.

ANTIBIOTIC RESISTANCE

Approximately one-third of the antibiotics used in Australia are for human use. Two-thirds are used in intensive animal production, of which the majority is mixed into stock-feed to act as a growth promoter (JETACAR 1999). Furthermore, antibiotic resistance genes are sometimes added as marker genes to GM food. This has led to the fear that widespread antibiotic-resistant bacteria have emerged that can cause disease in humans and animals that will be difficult to treat. The British Medical Association has warned that antibiotic resistance is 'one of the major public health threats that will be faced in the 21st century' (BMA 1999), while the World Health Organization has called for a reduction in their use in agriculture (WHO 2001).

FOOD ADDITIVES AND IRRADIATION

Additives are listed as either numbers, known as additive codes, or by name; 'de-coders' are readily available in many bookstores. Up-to-date lists of the food additives used in

Australian and New Zealand food products are freely available from FSANZ (2009). Additives include preservatives, artificial sweeteners, colourings and flavourings, monosodium glutamate, hydrogenated fats and phosphoric acid. Artificial colourings and preservatives in food and drink are thought to contribute to hyperactivity in some preschool children; although many still contest this issue, a recent study in the UK found that the proportion of hyperactive children halved when additives were removed from their diets (Bateman et al 2004).

A further concern is the long-term safety of consuming irradiated foods. Currently irradiation is used for the purpose of food preservation, to control microbes and to protect against critical quarantine pests. Irradiated food is exposed to gamma rays from a radioactive source, which kill insects, eggs, larvae and pathogenic microorganisms. This is an expensive procedure and thus is not extensively used in Australia at present. Currently the *Food Standards Code* in Australia allows for the irradiation of spices, herbs and herbal infusions, and tropical fruits (breadfruit, carambola, custard apple, lychee, longan, mango, mangosteen, papaya and rambutan) as a disinfestation measure for pests such as the fruit fly (FSANZ 2003b).

PROCESSING AND PREPARATION

While production and preservation methods may affect food quality, processing techniques may also significantly affect the therapeutic value of a food, and both benefits and detrimental effects are possible. For example, as both fibre and other nutrients are concentrated in the outer part of the grain, significant losses of not only fibre but also of B vitamins, fat-soluble vitamins and other nutrients occur when grain is refined (Jamison 2006). Similarly, food preparation methods can significantly affect a food's therapeutic qualities. Consider the potentially different nutritional and energetic effects of the same food consumed raw, juiced, steamed, boiled, fried, barbecued or microwaved. The microwaving of broccoli, for instance, has been found to destroy 97% of the flavonoids; conventional boiling destroys 66% and high-pressure boiling causes considerable leaching into the cooking water, whereas steaming produces minimal loss (Vallejo et al 2003).

Cooking does not always have detrimental effects and can sometimes increase the bioavailability of bioactive compounds; for example, the lycopene in tomatoes is more bioavailable when tomatoes are cooked in oil. The concentration of phenolic compounds in a food may also be increased by thermal processing, resulting in a significant increase in overall antioxidant status, despite some loss of heat-sensitive antioxidant nutrients such as vitamin C (Jamison 2006).

Food combination is another factor that influences the therapeutic value of a meal; for instance, consuming red meat with leafy greens and a citrus salad dressing synergistically improves iron absorption. The consumption of antioxidants in the diet, such as the tocopherols, coenzyme Q10, carotenoids, vitamin A, ascorbic acid, reduced glutathione, selenomethionine, flavonoids and other polyphenolic compounds, together with spices and synthetic antioxidants added to food, counteract the effects of pro-oxidants found in food and the environment. Applying this concept, it could be suggested that foods containing high levels of pro-oxidants (e.g. meat) should be served with plenty of antioxidant-containing vegetables, together with sauces, juices, fruits and teas high in antioxidants (Surai et al 2004). This is supported by a study of 2814 male smokers who participated in the Belgian Interuniversity Research on Nutrition and Health study. This found that men with the highest oxidative balance score had a higher relative risk of all-cause mortality (RR = 1.44, 95% confidence interval [CI]: 1.13, 1.82) and of total cancer mortality (RR = 1.62, 95% CI: 1.07, 2.45), compared with men in the lowest-score group (Van Hoydonck et al 2002).

Glycaemic index™

The glycaemic index™ (GI) ranks carbohydrates on their immediate effects on blood glucose levels. Carbohydrate-containing foods that cause a rapid rise in blood glucose are said to have a high GI (> 70), whereas those that cause a slow, steady rise in blood glucose, a more ideal situation, have a low GI (< 55). As insulin is released in response to circulating glucose levels, foods with a high GI will cause a rapid rise in insulin levels. In the presence of chronically elevated levels of circulating glucose and insulin, cells begin to shut down receptor sites, resulting in insulin resistance. Foods that have a low GI rating cause a much slower rise in blood glucose levels and therefore less insulin is secreted in response.

Observational studies indicate that a low-GI diet reduces elevated low-density lipoprotein (LDL) and triglyceride levels, raises

high-density lipoprotein (HDL) levels (Dushay & Abrahamson 2005), and improves fasting glucose and glycated protein values (Anderson et al 2004).

As some foods have a low GI because of their fat content, the GI rating should not be used in isolation, but form part of a sensible approach that limits the amount of saturated and *trans*-fatty acids in the diet. Additionally, other foods that have a high GI, such as potatoes, may also contain substances such as lipoic acid, which is beneficial for the prevention of the long-term complications of diabetes. As such, it is more important to consider the GI or glycaemic load (GL) of the *entire* meal than to eliminate all foods that have a high GI. The GL is calculated by multiplying the number of grams of carbohydrate in a serving of food by the GI value, and is expressed as a percentage: GL = GI (%) × grams of carbohydrate per serving.

Social, cultural and environmental aspects

In addition to being influenced by physicochemical properties, the therapeutic qualities of food may further be affected by a person's psychological state and/or intention while preparing and eating food, as well as by the social, cultural, economic, ethical, religious and environmental impact of the food. It has been said that 'eating is essentially an act of communion with the living forces of nature' (Robbins 1992). Indeed, most cultures and traditions have developed mealtime rituals that acknowledge the source of their food and attempt to align mind and body with the greater forces of nature. Food also features prominently in many spiritual traditions and practices. Thus, the idea of saying grace before meals and then eating 'gracefully' and mindfully, without rushing, may make significant contributions to psychological and spiritual health.

Food and health are both multidimensional and interrelated. Food choices not only influence physiological functioning, but have much broader social, economic, ethical and environmental ramifications, which may in turn affect personal health and wellbeing. Some of these aspects are becoming acknowledged in wider food-related social movements, such as the Fair Trade Federation (see www.fairtradefederation.org), International Slow Food Movement (see www.slowfood.com) and Food Miles (see Sustainable Agriculture–Food and Environment Alliance (SAFE), (see www.sustainweb.org).

Food is not just a means of providing nutrition and sustaining health, it is also a global industry that affects everyone. In the new global economy, there is a fear that the production, trade and retailing of most goods and services are being increasingly concentrated under the control of a small number of corporations that have enormous influence. It is questionable whether all corporations take sufficiently seriously the responsibility of providing quality foods while protecting workers and their environment, and whether free-trade agreements do any more than just offer global protection for a company's intellectual and property rights. For example, global trade in coffee and cocoa has led to social disruption, environmental damage and the mistreatment of workers, including children, who earn meagre wages while corporations make huge profits (Cavanagh 2002).

To counter this trend, the Fair Trade Federation (www.fairtradefederation.org) sets standards for commodities, such as coffee, tea, sugar, cocoa and fruits, that will support living wages and safe, healthy conditions for workers in the developing world. Fair Trade standards stipulate that traders must pay a price to cover the costs of sustainable production and living, and the organisation attempts to support food-producing communities by paying a premium that producers can invest in development, making partial advance payments when requested by producers and signing contracts that allow for long-term planning and sustainable production practices.

The environmental, economic, social and health consequences of the global trade in food are not only influenced by how food is produced but also by its transportation. Nutrients have their best chance to develop under certain climatic conditions; this means that foods grown and harvested seasonally have an advantage and are also more appropriate for eating at those times of year. The ability to transport food around the world allows seasonal food to be eaten year round and creates an enormous economic, social and environmental burden. The environmental and social implications of the rapid escalation in 'food miles', which is the distance that food travels before being consumed, has been reviewed by SAFE, which also considers the effects of food on behaviour and mental health.

The interests of the food industry and agribusiness are not always aligned with the interests and needs of consumers; for example, the

widespread availability of fast foods and their enormous popularity threatens gastronomic traditions, traditional cultivation and processing techniques, while standardising taste. The Slow Food Movement is an international movement that originated in Italy; it attempts to address these concerns by:

- promoting regional food and wine cultures, while defending food and agricultural biodiversity worldwide
- opposing the standardisation of taste
- defending the need for consumer information
- protecting cultural identities tied to food and gastronomic traditions
- safeguarding traditional foods.

Unfortunately the exploitation of natural and human resources comes at a cost. For too long, the external costs of agribusiness have been delayed, resulting in the availability of artificially 'cheap' but nutritionally depleted food. The food production industry is now faced with new challenges: the results of years of hyperintensive farming practices (soil erosion, contamination of water sources, superbugs), the effects of climate change, water shortages; rising oil prices (required for transportation, food processing and the production of pesticides and fertilisers); the diversion of food grain for ethanol production; and the loss of arable land to urbanisation. All these challenges must be met with nutritionally, socially and environmentally responsible solutions.

PRINCIPLES OF USING FOOD AS MEDICINE

It is often said that 'you are what you eat'; however, it may be more accurate to say that 'you are what you absorb from what you eat'. Food choices can exert a profound positive or negative influence on individual health, as well as on the health of communities and the environment. While the research community establishes the mechanisms by which foods exert their biological effects, there are some general recommendations that can enhance the positive impact of food, summarised by the mnemonic SLOW: consume food that is

- **S** **S**easonal
- **L** **L**ocally produced with lots of colour and variety
- **O** **O**rganic
- **W** **W**hole, fresh and with minimal processing.

THERAPEUTIC POTENTIAL OF COMMON FOODS

When consuming or prescribing functional foods, consideration should be given not only to the selection of foods for their potential therapeutic benefits, but also to the quality of the food consumed (as discussed earlier), and to the digestive function and health status of the individual. It should be noted that no single food should be eaten to the exclusion of others, and the inclusion of functional foods should form part of an otherwise balanced diet. Several examples of foods that may be incorporated into the diet for physiological benefit are discussed here, but a range of foods are covered in greater depth in the monographs.

Blueberries (and other berries)

A growing body of research suggests that the dietary intake of berry fruits has a 'positive and profound impact on human health, performance, and disease' (Seeram 2008). Berry cousins blueberry (*Vaccinium corymbosum*), cranberry (*Vaccinium macrocarpon*) and bilberry (*Vaccinium myrtillus*) have demonstrated significant benefits in the past, and there has recently been increased interest in other berry-type fruits such as pomegranate (*Punica granatum*), goji berry (*Lycium barbarum*), mangosteen (*Garcinia mangostana*) and the Brazilian acai berry (*Euterpe oleraceae*).

Blueberries, native to East Asia and the USA (Natoli 2005), are readily available fresh during the warmer months and frozen or juiced year round. They were traditionally used by the North American Indians for the treatment of diarrhoea and labour pains (Pratt & Matthews 2004a) and are an excellent source of antioxidant nutrients and phenolic compounds that work synergistically within the body (including vitamin C, beta-carotene, flavonoids, anthocyanins and resveratrol) (Natoli 2005, Pratt & Matthews 2004a). The anthocyanins are powerful antioxidant and anti-inflammatory agents, responsible for the deep blue-purple colour of blueberries; the deeper the colour, the greater the anthocyanin content (Pratt & Matthews 2004a).

The majority of studies to date rely on in vitro, animal and epidemiological evidence. Blueberry and its cousins appear to 'limit the development and severity of certain cancers and vascular diseases including atherosclerosis, ischemic stroke, and neurodegenerative

diseases of aging' (Neto 2007). The antioxidant and anti-inflammatory effects of blueberries have been associated with an improvement in age-related cognitive and motor deficits, spatial working memory tasks and neurodegenerative disorders such as Alzheimer's dementia (Bickford et al 1999, 2000, de Rivera et al 2005, Galli et al 2006, Lau et al 2005, Ramirez et al 2005, Wang et al 2005, Williams 2008) and reduced risk of cardiovascular disease (Kalea et al 2006, Youdim et al 2002). Recent animal studies suggest improved growth capacity in neural transplants (Willis 2008); a reduction in total and LDL cholesterol (Kalt 2008) and prevention of bone loss (Devareddy et al 2008). Anticarcinogenic properties have also been demonstrated in prostate cell lines, and blueberry extracts have been shown to suppress tumour growth, protect the integrity of DNA (Natoli 2005), reduce angiogenesis (Atalay et al 2003), inhibit the proliferation of androgen-dependent prostate cancer cells (Schmidt et al 2006), prevent oestrogen-induced mammary tumors (Aiyer 2008), and reduce the risk of metastasis (Matchett et al 2006). Blueberry may also act synergistically with cranberry to inhibit *Helicobacter pylori* (Vattem et al 2005) and human clinical trials have demonstrated improved exercise capacity in hot environments (McAnulty et al 2004).

Choose dark blue-purple berries that move freely in the container. Damaged berries will inhibit movement and be prone to mould and should be discarded before storage. Organic fruit is preferable because it has higher concentrations of malic acid, phenolics, anthocyanins, and overall higher antioxidant activity (Wang et al 2008). Although the vitamin C content degrades rapidly during heating and storage, many of the phenolic compounds may actually become more bioavailable, improving the overall antioxidant capacity (Wehrmeister et al 2005). Frozen berries maintain the phenolic compounds and provide an excellent source for year-round availability (Srivastava 2007). As blueberries contain salicylates, those with a known sensitivity should be cautious about consuming them (Natoli 2005).

Broccoli (and cruciferous vegetables)

Broccoli, originally grown in the Mediterranean region and cultivated by the ancient Romans, belongs to the cruciferous family of vegetables (Brassicaceae), so called because of the cross-shaped structure of the leaves and flowers (Pratt & Matthews 2004b). The family also includes cauliflower, Brussels sprouts, cabbage and kale, which have also demonstrated significant therapeutic potential. Broccoli is low in kilojoules and an excellent source of fibre; calcium; folate; vitamins C, E and K; coenzyme Q10; iron; sulforophane; indoles; phenolic compounds (quercetin, kaempferol, hydroxycinnamoyl acids); and the carotenoids beta-carotene, cryptozanthin, lutein and zeaxanthin (Damon et al 2005, Lucarini et al 1999, Podsedek 2005, Pratt & Matthews 2004b). The antioxidant nutrients in broccoli work in synergy to reduce reactive oxygen species and recycle each other (Podsedek 2005); however, significant variations occur in nutrient levels because of differences in variety, maturity at harvest, soil quality, sunlight exposure, growing environment, processing and storage conditions (Jeffery et al 2003, Gliszczynska-Swiglo et al 2005, Podsedek 2005).

Numerous epidemiological studies have established an inverse association between the consumption of cruciferous vegetables and the incidence of cancer (especially lung, colon, stomach, rectal, bladder and premenopausal breast cancers) (Brennan et al 2005, Cortizo & Vitetta 2004, Kim et al 2003, Pratt & Matthews 2004b, Tang 2008). When broccoli is crushed or chewed, glucoraphanin (a glucosinolate) is converted by the action of myrosinase into isothiocyanates, the most studied of which is the powerful anticarcinogenic compound known as sulforophane (Matusheski et al 2004). Young broccoli shoots are the best source of the chemoprotective glucosinolates, containing 20–50-fold the content of the more mature vegetable (Cortizo & Vitetta 2004). In animal and in vitro studies, isothiocyanates have demonstrated chemoprotective activity against different types of tumours, enhancing detoxification of carcinogens, blocking the initiation of chemically induced carcinogens, inducing apoptosis and modulating cell-cycle progression in highly proliferative cancer cells (Cortizo & Vitetta 2004, Fimognari et al 2005, Gills et al 2005, Hintze et al 2003, Rose et al 2005, Jadhav et al 2007). Indoles, such as indole-3-carbinol, have also been shown to exert chemopreventive effects in liver, colon and mammary tissue (Kang et al 2001) and to arrest human tumour cells in the G1 phase of the cell cycle (Matsuzaki et al 2004); they may also block oestrogen receptors in breast cancer cells (Pratt & Matthews 2004b).

Although the anticarcinogenic, antioxidant and anti-inflammatory benefits of broccoli compounds help to explain their therapeutic

effects, the exact mechanisms are still unclear and contradictory evidence exists for a role in inhibiting phase I and inducing phase II enzymes (Cortizo & Vitetta 2004, Knize et al 2002, Myzak & Dashwood 2005, Perocco et al 2006, Steinkellner et al 2001, Vang et al 2001). Furthermore, several authors warn of potential risks resulting from uncontrolled use of isolated compounds from broccoli (Fimognari et al 2005, Perocco et al 2006, Wiseman 2005); therefore, consumption of the plant itself is currently more advisable than isolated extracts.

Human clinical trials demonstrated a reduction in LDL-cholesterol in 77 hypercholesterolaemic patients (Takai et al 2003). Additional benefits for cardiovascular health are suggested by in vitro evidence indicating that broccoli compounds may bind to bile acids (Kahlon et al 2007) and have an ACE inhibitor activity (Lee et al 2005). Broccoli contains high amounts of selenium and glucosinolates, which can exert a cardioprotective effect (Mukherjee et al 2008). Because of its known nutrient content, broccoli may support the immune system; it may also reduce the risk of cataracts, osteoporosis and neural tube birth defects (Podsedek 2005, Pratt & Matthews 2004b).

Choose young plants or shoots with a dark-green–purplish colour. As broccoli is prone to infestation and has a large surface area, agricultural chemical residue can be an issue, and ideally organic broccoli should be purchased and inspected for pests. Broccoli will store at 5°C (non-packaged) for 1–3 weeks without significant nutrient loss (Favell 1998, Leja et al 2001), although processing methods may affect nutrient quality (Podsedek 2005). Although cooking degrades the vitamin C and isothiocyanate content, the carotenoids may become more bioavailable, increasing the potential overall antioxidant activity (Bernhardt & Schlich 2005, Pratt & Matthews 2004b, Turkmen et al 2005, Tang et al 2008). Light steaming (approximately 1 minute) of raw broccoli is likely to maintain the best nutritional profile. Despite concerns that goitrogenic compounds in broccoli may increase the risk of thyroid cancer, a meta-analysis found no correlation (Cortizo & Vitetta 2004); nevertheless broccoli should not be consumed in excess by those with known thyroid disease. A serving size of half to 1 cup per day is associated with a significant reduction in cancer risk (Pratt & Matthews 2004b).

Single-cell foods

Microalgae are both single cells and whole plants that are at the bottom of the food chain and are the most productive organisms on the planet, using light approximately three times more efficiently than higher plants (Pirt 1980). Gram for gram microalgae may also be the most nutrient-dense food on earth (Passwater & Solomon 1997), with minimal indigestible structures in contrast to higher plants or animals, in which less than half their dry weight is typically nutritionally useful (Bruno 2001).

Microalgae, which include *Spirulina* and *Chlorella* species, and the 'red-orange' algae *Dunaliella salina*, contain a range of macro- and micronutrients, such as chlorophyll, carotenoids, phytonutrients, amino acids, polysaccharides, essential fatty acids, carbohydrates and vitamins, and bioavailable minerals (Cases et al 1999, Chamorro et al 2002, Kay 1991). They may also promote the growth of lactic acid bacteria in the gastrointestinal tract (Parada et al 1998).

These organisms can be considered to be a mix of food, supplement and medicine. As single-cell plants, they represent 'whole' foods; however, they are often marketed in capsules and can be taken as supplements and/or medicines. In contrast to the reductionist approach to nutrition, which leads to supplementation with only a few specific nutrients, microalgae provide a complex mix of nutrients developed over millions of years of evolution. Although accumulating research suggests that microalgae have many health benefits, further research is required to determine their clinical applications.

The cyanobacteria *Spirulina* spp (usually *Spirulina platensis* or *S. maxima*) contains pigments, called phycobilins or phycobiliproteins (including phycocyanin and allophycocyanin), that are similar in structure to bile pigments (Pinero Estrada et al 2001). *Spirulina* spp are said to possess antiviral, hypocholesterolaemic, antioxidant, anti-inflammatory, hepatoprotective, anti-allergic and immunomodulatory activities and have been used to treat certain allergies, anaemia, cancer, viruses, cardiovascular diseases, hyperlipidaemia, immune deficiency, and inflammatory processes (Chamorro et al 2002, Hirahashi et al 2002).

In vitro studies of spirulina suggest antiviral and antiretroviral activity by inhibiting the penetration of viruses into host cells and also the replication of several enveloped viruses, including human cytomegalovirus,

measles virus, mumps virus, influenza A virus and HIV-1 (Ayehunie et al 1998, Hayashi & Hayashi 1996, Hernandez-Corona et al 2002).

Spirulina extracts enhance macrophage activity (Quereshi & Ali 1996), and humoral and cell-mediated immune functions in animal studies (Quereshi et al 1996), and may also act as anticlastogenic (Ruiz Flores et al 2003) and antitumour agents (Li et al 2005). They inhibit mast-cell-mediated immediate-type allergic reactions in vivo and in vitro (Kim et al 1998), possibly by inhibiting mast-cell degranulation.

Animal studies have demonstrated that spirulina reduces vascular reactivity (Mascher et al 2006), possesses hypocholesterolaemic (Devi & Venkataraman 1983), anti-atherogenic (Kaji et al 2002, 2004) and antioxidant activity (Pinero Estrada et al 2001), reduces chromosomal damage and lipid peroxidation, and increases liver enzymes and non-enzymatic antioxidants (Premkumar et al 2004). The hepatoprotective effects are likely caused by the antioxidant activity. Although some green foods are touted as being a good source of vitamin B_{12} for vegetarians, and this is true of chlorella, the B_{12} in spirulina appears to be in a largely inactive form (Watanabe et al 2002). Spirulina extract is an excellent selenium carrier and therefore enriched sources can provide a highly bioavailable source of selenium (Cases et al 1999).

Chlorella (usually *Chlorella vulgaris* or *C. pyrenoidosa*) has been promoted as an anticarcinogenic, immunomodulatory, hypolipidaemic and gastric mucosa-protective agent. As with other green foods, the antitumour activity is thought to be mediated by an immunopotentiation mechanism (Noda et al 1996), and extracts of chlorella have demonstrated antitumour activity against both spontaneous and experimentally induced metastasis in the lymphoid organs of mice (Tanaka et al 1998). Based on animal studies, chlorella may also ameliorate some of the side effects of 5-fluorouracil chemotherapy treatment (Konishi et al 1996).

Chlorella vulgaris extract enhances resistance to *Listeria monocytogenes* through augmentation of Th1 responses, producing gamma-interferon (Hasegawa et al 1999). It may be useful for the prevention of allergic diseases (Kralovec et al 2005), especially in those people with a predominantly Th2 response (Hasegawa et al 1999).

In some animal experiments, chlorella appears to possess hypolipidaemic (Sano et al 1988) and anti-atherogenic effects (Sano & Tanaka 1987). It may prevent dyslipidaemia in animals chronically fed a high-fat diet by preventing intestinal absorption of redundant lipids and thus reducing triglyceride, and total and LDL-cholesterol levels (Cherng & Shih 2005). In addition, inhibition of advanced glycation end products in vitro suggests a possible role for reducing atherogenesis, diabetic microangiopathy and Alzheimer's dementia (Yamagishi et al 2005).

Chlorella may also exhibit hypoglycaemic activity (Cherng & Shih 2006), improve insulin sensitivity (Jong-Yuh & Mei-Fen 2005) and prevent stress-induced ulcers (Tanaka et al 1997), according to animal studies.

Although it has been suggested that a diet high in spirulina may be a risk for kidney stones, this may be the case only with a high or excessive intake of oxalic acid (e.g. beetroot leaves or rhubarb) (Farooq et al 2005), as the antioxidant activity of phycocyanin appears to aid in the prevention of calcium oxalate stones (Farooq et al 2004). Occasional gastrointestinal symptoms and allergic reactions have been reported for spirulina and chlorella, and those taking warfarin should avoid chlorella, which can be high in vitamin K.

Doses of spirulina range from 250 mg to 5 g daily (PDR Health 2006). High doses of chlorella (10 g/day) have been used successfully in clinical trials for fibromyalgia (Holdcraft et al 2003, Merchant & Andre 2001), but the standard dose is usually 200–500 mg/day (PDR Health 2006).

Dunaliella salina is a soft-celled microalga found in many coastal waters and saltwater lakes (see the monograph on Dunaliella). It is one of the most salt-tolerant life forms known, and is adapted to extremely high UV radiation. To cope with these extreme environments, *Dunaliella* produces very high levels of antioxidant molecules. On a per-gram basis, *Dunaliella* has more than twice the chlorophyll, five times the mineral content and more than 6000 times the carotenoid antioxidants content of spirulina (Table 5.2), with the carotenoids giving it an orange rather than a green colour. Furthermore, *Dunaliella*'s soft-cell membrane makes it easily digestible, compared with other microalgae that have hard cell walls (Ben-Amotz & Avron 1983). To date, most of the clinical research on *Dunaliella* has been on beta-carotene-containing extracts rather than on the whole organism, but recent advances in production technology have allowed the whole, dried *Dunaliella* biomass with its full range of nutrients and minerals to become commercially available (Table 5.3) (Tracton & Bobrov 2005), and more studies

TABLE 5.2 Nutrient Content of *Dunaliella* Compared with *Spirulina* and Carrots (per 100 g)

Nutrient	*Dunaliella*	*Spirulina*	*Carrots*
Protein	7.4 g	57 g	1 g
Fat (total)	7 g	8 g	0
Carbohydrates	29.7 g	24 g	10 g
Energy	893 kJ	1214 kJ	180 kJ
Fibre	0.4 g	4 g	3 g
Chlorophyll	2210 mg	1000 mg	NA
Minerals	49 g	6.2 g	1 g
Beta-carotene	2100 mg	0.34 mg	8.3 mg
Alpha-carotene	53 mg	0.0 mg	3.5 mg
Lutein/zeaxanthin	97.6 mg	0.0 mg	0.26 mg
Cryptoxanthin	46.5 mg	0.0 mg	0.1 mg

are likely to include the whole organism in future.

Medicinal mushrooms (reishi, shiitake)

Mushrooms such as shiitake (*Lentinus edodes*), reishi (*Ganoderma lucidum*), oyster (*Pleurotus ostreatus*) and maitake (*Grifola frondosa*), to name only a few, have also been used as medicinal agents in Asia for thousands of years (Chang 1996, Sliva 2004). More recently the benefits of the common button mushroom (*Agaricus bisporus*), widely cultivated in the West, have also begun to be elucidated (Beelman et al 2004). Although the nutritional and medicinal potential of mushrooms may differ because of variations in species, cultivation techniques, maturity at harvest and other factors, numerous common features arise.

In general, mushrooms contain significant amounts of water (>90%) and, as a result, nutrients measured on the fresh-weight values may appear to be quite low. Nevertheless, they are low in kilojoules and a good source of fibre (including glucans and chitin), amino acids, B vitamins, copper, selenium, potassium, germanium, ergosterol (Beelman et al 2004) and lipids, especially linoleic acid (Yilmaz et al 2005).

The immunostimulatory properties of a variety of polysaccharides found in mushrooms are thought to contribute to their anticancer effects, and other biologically active substances, including triterpenes, cerebrosides and phenols, have been identified and characterised in the medicinal mushrooms in particular (Sliva 2004). Mushrooms may also protect against oxidative damage to DNA (Beelman et al 2004)

Shiitake mushrooms (*Lentinus edodes*) possess immunomodulating, antitumour, hypolipidaemic, antibacterial (Hirasawa et al 1999) and antioxidant properties (Cheung et al 2003), and may help to reduce dental caries, according to in vitro and animal studies (Shouji et al 2000). They have been traditionally used for exhaustion, colds, intestinal parasites, poor circulation and liver problems (PDRHealth 2006).

Lentinan, which is a biologically active beta-glucan in shiitake mushrooms, modulates the immune system (including T-lymphocytes and cytokines); suppresses hepatic expression of cytochrome P1A (Okamoto et al 2004); and has demonstrated antitumour and antimetastatic activity against chemical and viral carcinogens (Mitamura et al 2000, Ng & Yap 2002, Zheng et al 2005). However, clinical trials using shiitake extract in men with prostate cancer were not successful in reducing levels of prostate-specific antigen (White et al 2002), although other compounds may also contribute to the antitumour effects (Sia & Candlish 1999). Lentinan is antifungal and may also exert an inhibitory effect on HIV-1 reverse transcriptase and proliferation of leukaemia cells (Ngai & Ng 2003).

Lentinus edodes mycelia inhibit atherosclerotic development in rabbits (van Nevel et al 2003) and contains eritadenine, a hypocholesterolaemic compound that also acts as an immunomodulator and tumour-inhibitor in animal models (Beelman et al 2004, Yamada et al 2002). Extracts from shiitake mushrooms have been shown to elevate plasma insulin and reduce plasma glucose, total cholesterol and triglyceride levels in rats (Yang et al 2002).

Ganoderma lucidum (reishi) has been used in TCM for thousands of years for the treatment of asthma, cough, fatigue, insomnia and weakness, and was popular as a cancer chemotherapy agent in ancient China (Sliva 2003). There is some confusion about the taxonomical classification of reishi mushrooms and, as a result, a variety of different medicinally active compounds with significantly different pharmacological effects may be attributed to different strains, adding confusion to the body of evidence available (Szedlay 2002).

The anticancer activity may be due to direct cytotoxic effects against tumour cells, inhibition of angiogenesis (Lin & Zhang 2004), and the effects of immunomodulatory polysaccharides (Chen et al 2004), which act by stimulating the expression of cytokines (especially IL-1, IL-2 and IFN-gamma) (Wang et al 2002) and modulating humoral and cellular immunity (Lin 2005).

Agaricus bisporus may modulate aromatase activity and function, resulting in chemoprevention of the deleterious effects of in situ oestrogen in breast cancer (Grube et al 2001). It has also been suggested as a potential agent for preventing scarring and promoting healthy wound-healing (Batterbury et al 2002, Kent et al 2003). The browns strains (Swiss browns, portabellas) harvested when fully mature, with open caps, appear to be the most useful (Beelman et al 2004).

High doses of shiitake mushrooms may cause rash, diarrhoea and bloating, and consumption of 4 g shiitake powder has been associated with marked eosinophilia (Levy et al 1998). Reishi mushrooms should not be consumed daily in the long term (> 3–6 months), as they may cause dizziness, dry mouth, nose bleeds and gastrointestinal upset, and may potentially produce additive effects with anticoagulant medications (PDRHealth 2006).

Agaricus bisporus contains agaratine, a hydrazine compound with suspected carcinogenic potential (Hashida et al 1990). To date, animal studies have demonstrated different outcomes between species and no conclusive evidence exists for a cause–effect relationship between mushroom intake and cancer prevalence in humans. In addition, the potential anticarcinogenic properties of other compounds in mushrooms may provide protection (Beelman et al 2004). Although there are concerns about heavy metal toxicity in wild *Agaricus* mushrooms, levels of mercury and cadmium in

commercially cultivated mushrooms have been found to be very low (Kalac & Svoboda 2000, Vetter & Berta 2005).

Agaricus mushrooms (including Swiss browns and portabellas) and shiitake mushrooms are readily available fresh or dried, and dried reishi mushrooms can sometimes be found in Asian grocery stores. Dried mushrooms can be reconstituted in warm water for use in cooking. Cooking mushrooms may increase free polyphenolic compounds (Choi et al 2006) but can make them tough and result in losses of manganese, zinc and iron (Coskuner & Ozdemir 1997).

FUTURE DIRECTIONS

Despite advancements in medicine and pharmaceutical drug development, dietary choices remain the cornerstone of preventative medicine and enhance the health of individuals and societies. Emerging research indicates exceptional potential for the benefits of using 'food as medicine'. Recognising the inherent therapeutic value of foods or their potential to induce harmful health consequences means that we can tailor the diet to produce better health outcomes.

CHAPTER 6
INTRODUCTION TO THE PRACTICE OF INTEGRATIVE MEDICINE

Throughout history, every civilisation and culture has developed its own form of medicine. The rise of modern technology and scientific enquiry has added new therapeutic techniques, products and services to the range of traditional therapies. Thus, within today's pluralistic, multicultural and increasingly globalised societies, the wisdom and therapeutic interventions of many different traditions are becoming available. While it is impossible for any practitioner to have access to, or even know something about, the many hundreds of therapeutic interventions available, it is possible to incorporate some of the key principles into today's conventional healthcare practice. This leads to the practice of integrative medicine (IM), which attempts to define and embrace these principles.

The practice of IM is more than simply an expansion of conventional medical practice to include 'complementary therapies' such as mind–body techniques, acupuncture, herbs, nutrients and body work (for example, massage and manipulation). It involves:

- a focus on the whole person: the interplay between the physical, emotional, spiritual and psychological states
- highly individualised treatment plans that are tailored to meet the needs of the person
- development of a therapeutic partnership between the patient and practitioner as a fundamental part of the healing process
- a primary focus on prevention, health enhancement and addressing predisposing, exacerbating and sustaining causes of disease
- integration of the best available, evidence-based, safe and ethical therapies from different traditions.

As such, IM implements principles that form the basis for clinical decision making and improving patient outcomes, by providing each patient with effective and compassionate care and healing on many levels. IM is increasingly being acknowledged as 'best practice'; however, it requires some fundamental shifts in the way in which healthcare is delivered and has not yet become widely implemented (Cohen 2005a). For example, the use of complementary medicines is an integral part of IM practice, yet this use raises many issues for medical practitioners, particularly those who have not received training in how to use them. Some of the questions are:

- What can be reasonably expected by providing integrative care?
- What are the safety issues?
- Which therapies are cost-effective?
- What advice should be given to patients in the absence of definitive evidence?
- Which therapies or products are useful for which conditions and which patients?
- Where can high-quality complementary and alternative medicine (CAM) products be obtained?
- Which specially trained practitioners should patients be referred to, and when, how and for what reasons should referrals be made?
- Where can reliable information about CAM be found, and what pathways are there for further study?

These are core issues in any healthcare practice and are not specific to the use of complementary medicines or even to the practice of IM. The practice of IM, however, poses additional challenges to medical practitioners, both professionally and personally. It requires being prepared to learn about new

and different treatment systems, traditions and ways of thinking, and recognising the advantages and limitations of both complementary and conventional medicine and the potential benefits of combining them. It also requires adopting a collaborative approach with patients and a variety of different healthcare professionals, while allowing old beliefs to be challenged and re-evaluated. Furthermore, the practice of IM challenges medical practitioners to develop their intuition, empathy and compassion, address their own health and personal growth, and become role models for their patients and the wider community. From a practical perspective, developing IM takes extra time. Time is needed to keep up to date with the changing evidence base, as well as to establish a holistic understanding of patients and then apply the principles of IM to address their needs.

HOLISM AND THE INDIVIDUAL

In their professional training, medical practitioners study the biological, psychological and social aspects of health, as well as the signs, symptoms and pathophysiology of specific illnesses, to achieve an understanding of health and disease in a clinical context. This knowledge base must be updated and modified with new knowledge provided by new scientific evidence and cumulative clinical experience. Although consideration of the best available evidence is an important dimension of clinical practice, scientific data are often based on a group of observations that give statistical information about research populations, but which may not provide definitive information about what will happen to any individual patient in certain circumstances.

Each human being is unique and presents in a specific clinical context, in which the outcome will be determined by personal attributes such as attitudes, education and understanding, as well as by genetics, physiology, past experiences, socioeconomic and cultural circumstances, available resources and lifestyle. Accounting for individual differences is an essential aspect of the art of medicine and is a cornerstone of many ancient systems of medicine.

Chinese medicine, Ayurvedic medicine and Western herbal medicine all have sophisticated systems of categorising people according to their different physiological and psychological characteristics in order to guide treatment selection. In comparison, modern Western medicine has been slow to accept and use this individualistic approach, preferring to standardise treatment approaches through clinical guidelines and protocols. The fields of pharmacogenomics and nutrigenomics, which have emerged out of the Human Genome Project, are beginning to provide a scientific rationale for individualising treatments. These new fields emphasise two factors: individualised response to medicines and nutrients, and the roles of dietary and genetic interactions in patient health.

The practice of IM combines both ancient and modern knowledge, and takes a holistic perspective that recognises that health involves physical, psychological, social, spiritual and environmental dimensions. This is in line with increasing patient expectations to have the accompanying social and psychological aspects of their illness addressed, not just their presenting symptoms (Jonas 2001). Thus the practice of IM requires careful history taking and physical examination, which may include obtaining information from different philosophical perspectives, together with astute and appropriate investigations and obtaining other information from relatives or carers.

Accounting for individual factors takes considerable time, yet this time is well spent because there is mounting evidence to suggest a direct relationship between consultation length and the quality of care. Longer consultations are likely to result in better health outcomes and better handling of psychosocial problems, fewer prescriptions, more lifestyle advice and lower costs, less litigation and more patient and doctor satisfaction (Cohen et al 2002).

THERAPEUTIC RELATIONSHIPS

Although amassing personal information about a patient is a time-consuming process, it is an extremely valuable one, not only for the information gleaned but also because it facilitates the development of rapport, respect and trust, thus laying the foundation for the therapeutic relationship. The development of close and meaningful relationships with people in a clinical context is one of the great challenges of holistic or integrative practice. It is also one of the most powerful therapeutic tools clinicians have and may be more important than any specific treatment modality.

The therapeutic relationship is a profound and sacred one, acknowledged since ancient

times and codified in the Hippocratic oath, which has specific phrases that dictate the principle of doctor–patient confidentiality, as well as the responsibility of clinicians to exercise a duty of care. A therapeutic relationship is established with the specific intention of healing, and the act of establishing such a relationship, in which intuition and empathy are valued alongside information and evidence, may be therapeutic in itself. Simply articulating one's personal story and expressing traumatic experiences to a sympathetic listener can help people make connections and better understand the causes and implications of their disease, as well as providing much needed psychosocial support.

Healthcare professionals commonly see people at their worst: when they are in pain and/or feeling sick, scared, sleep deprived and fearful of the possible implications of an illness. The constant stream of 'sick people' can make it easy to start differentiating patients by their illnesses; however, thinking of people in terms of their highest level of functioning may be more productive. To this end, some of the most important questions a practitioner can ask are: 'What makes you happy?' or 'What makes you feel alive?' The answers to these questions can provide valuable insight into an individual and form the basis for a more meaningful relationship than the answer to the question: 'What is the problem?'

Developing rapport, trust and a holistic understanding of patients' lives is one of the most important elements in IM, because it places practitioners in a better position to allay their patients' fears, adequately address the issues of most concern, and help to reduce the burden of stress that accompanies virtually all illness. A holistic understanding of a person also enables clinicians to recommend treatments that are more likely to be successfully integrated into a patient's social and cultural environment, thus improving efficacy and compliance. Furthermore, a sound therapeutic relationship provides the camaraderie and sense of therapeutic adventure necessary to underpin a partnership model of health and provides a solid foundation for clinical decision making.

PRACTITIONER WELLBEING

Healthcare professionals experience significant mental, physical and spiritual demands during the course of everyday practice. In addition, personal stress can influence the ability to deliver effective care, establish therapeutic relationships and maintain good health. Over time, exposure to multiple stressors can lead to physical and emotional exhaustion, or burn out, with its accompanying physical and psychological burden (Dunning 2005).

For some practitioners, there is a perceived pressure to symbolise perfect health and be invulnerable to disease. As a result, there is the temptation to avoid indications of ill health in themselves and their colleagues and a failure to see the need for self-care.

The practice of IM compels clinicians to address their own health and lifestyle, explore their emotional life and develop self-care routines to maintain wellbeing and prevent disease. In addition, the therapeutic relationship developed with patients can be nurturing for the practitioner, with rewards that flow in both directions (Cohen 2005b).

In advocating a holistic view of health, the practice of IM can motivate practitioners to become more involved in broader community, public health and global issues, such as social justice, fair trade, environmental preservation, regeneration and sustainability, as well as spiritual, ethical and philosophical debates and pursuits.

INTUITION, BEDSIDE MANNER AND PLACEBO

Medicine is an art informed by science, yet with so much recent attention being given to scientific evidence, it is easy to forget the importance of intuition and clinical experience. A holistic understanding of a patient, together with empathy and compassion for a patient's circumstances, adds important information to any clinical encounter. It is likely that the best and most inspired practice occurs when the practitioner's academic knowledge, clinical experience and intuitive understanding of the individual merge to provide a picture of the clinical situation as a coherent whole, known as the 'Gestalt' approach.

Developing an intimate therapeutic relationship and integrating rational and intuitive knowledge enlists the full capacity of the practitioner. It may also be the best way to tap into patients' unconscious healing processes and elicit the 'placebo response'. The placebo effect is often considered a source of bias and a scientific distraction that research methodology must minimise; however, the placebo response is ubiquitous and cannot be avoided in the clinical setting. All interventions have a

non-specific therapeutic action, in addition to their purported activity, and the best clinicians will always use their 'bedside manner' to harness the 'placebo response' and enhance the therapeutic benefits of any specific intervention. Herbert Benson suggested that the placebo response is based on a good therapeutic relationship, as well as positive beliefs and expectations on the part of the patient and practitioner and furthermore can yield beneficial clinical results and be a powerful adjunct to therapy. Benson, who coined the term 'the relaxation response' in reference to meditation, further suggested that the placebo response should be renamed 'remembered wellness', and that it may be one of medicine's most potent assets because it is safe, inexpensive and accessible to many people (Benson & Friedman 1996).

In addition to the use of rapport, empathy, compassion, trust, confidence and intimacy, an integral part of a good bedside manner is the appropriate and thoughtful use of touch. Touch pulls together psychological and bodily experiences and is important in relationships between people in general, and the therapeutic relationship in particular. It is a basic human need that enhances communication and builds up trust. A simple handshake to acknowledge each other's presence or hand-holding when bad news is delivered can provide important and reassuring support that goes beyond words. The therapeutic power of touch has been recognised and practised throughout history: for example, through the art of massage, which, when provided by trained practitioners, can produce substantial therapeutic effects, enhance a person's sense of wellbeing and promote a sense of calm and peace.

BIAS IN MEDICAL DECISION MAKING

How do people make decisions and how do they choose between different treatment options? Decisions are made using 'heuristics', or general rules of thumb, which reduce the time and effort required. Normally this method yields fairly good results; however, there are times when they lead to systematic biases (Plous 1993). In these situations, assumptions are made and information is neglected, downplayed or overplayed, or based on what is easily recalled. In healthcare, unrecognised bias of this nature can have dire repercussions, affecting a clinician's ability to diagnose and treat effectively and a patient's ability to make good choices.

It is both normal and human to have a range of biases that influence the types of treatments that are considered appropriate, based on the individual's personal, ideological, religious, ethical, cultural, educational and philosophical ideals and experiences. Good clinicians are aware of their personal biases and will openly disclose those that may influence a patient's care. In some cases, this is easier said than done. Stating known or potential bias can be particularly sensitive when the practitioner has strongly held religious beliefs that may limit their practice or determine their attitudes to different therapies, as well as when it comes to declaring commercial interests.

Healing is a human vocation that arises from the desire to do the best for humanity. The patient–practitioner relationship, however, is not only a therapeutic one, it is commonly a commercial one. Healing is a business that sustains the personal lives of individual practitioners and drives the pharmaceutical industry. In 2002 the combined profits for the top 10 drug companies in the Fortune 500 list were greater than those of all the other 490 companies combined (Angell 2004).

One important source of bias that is becoming increasingly recognised concerns the millions of dollars spent by the pharmaceutical industry in a bid to influence doctors' decision making. The seemingly unlimited marketing budgets and provision of gifts, luxuries and educational events has forced the medical profession to attempt to limit these sorts of inducements (Studdert et al 2004). The extent of the industry's influence is vast and has not always been obvious. In her book on the pharmaceutical industry, Marcia Angell, a former editor-in chief of the *New England Journal of Medicine*, states:

> Over the past two decades the pharmaceutical industry has moved very far from its original high purpose of discovering and producing useful new drugs. Now primarily a marketing machine to sell drugs of dubious benefit, this industry uses its wealth and power to co-opt every institution that might stand in its way, including the US Congress, the FDA, academic medical centers, and the medical profession itself.
> *Angell 2004*

Not only are doctors subject to the influence of the pharmaceutical industry, they may also have other pecuniary interests that

could bias their clinical decision making, such as commercial interests in pathology companies and their own clinical dispensaries.

COMPLEMENTARY MEDICINE PRODUCTS

Several thousand complementary medicine products are now available on the market, the vast majority of which are available without prescription. Choosing the best product, correct dose and time frame for use, and having realistic expectations of the treatment are just some of the factors that healthcare practitioners must consider before recommending a specific product (Table 6.1). These factors, which are addressed in further detail in the monographs and chapters of this book, must be considered in the light of each individual patient's circumstances, including their condition and co-morbidities, renal and hepatic function, personal preferences, financial resources and their ability to self-monitor their condition.

Complementary medicines in Australia are regulated in the same way as pharmaceutical medicines and are evaluated for quality and safety; however, seemingly similar products will vary with respect to their efficacy and supporting scientific evidence. Most complementary medicines are available over the counter (OTC) through pharmacies, health food stores and supermarkets; however, there are also certain complementary medicines that are available as practitioner-only products. These are prescribed and dispensed only by a CAM practitioner; they can have different potencies and formulations from those available OTC and include extemporaneously compounded herbs that require time, specific knowledge and expertise to dispense. Clearly, making product choices can be confusing, and clinicians should be encouraged to become familiar with

TABLE 6.1 Factors to Consider When Recommending a Complementary Medicine

Product factors	Comments
Mechanism/s of action	How well established are these? Do they seem plausible?
Evidence and expectations	Is it likely to achieve treatment goals? In what time frame? Do not rely on label claims alone. Consider the type of evidence available for this particular indication. For herbs also consider: extract and plant part/s tested. For nutrients: consider chemical form and bioavailability.
Dose and administration route	Ensure these are correct for the specific indication.
Frequency, timing and ease of use	Reduced frequency improves compliance. Consider timing, such as before, during or after meals.
Quality control standards	Not all countries impose high quality control standards on the manufacture of complementary medicines; e.g. the USA. In Australia, only use products with AUST L or AUST R numbers on the label.
Combination products or single entities	For combination products, consider dosage and potential synergy of individual ingredients.
Potential to induce adverse reactions	Consider potential likelihood of adverse reaction and consequence (see Chapter 7 for more information).
Potential to induce interactions	Are harmful, beneficial or neutral interactions possible? Should the product be avoided, used only under professional supervision, or actively prescribed? (Use METOPIA algorithm in Chapter 8.)
Contraindications	Take special care with high risk groups (see Chapters 7 and 10 for more information).
Storage	Consider sensitivity to light and heat, need for refrigeration, and shelf life.
Cost	Compare cost with that of other treatments — medicinal and non-medicinal.
Availability	Is it available OTC or only from a practitioner?

the products available and eventually identify a group of favoured products they feel confident in prescribing.

There are many good reasons for including complementary medicines into routine practice (Table 6.2). Medicines that are supported by good evidence of efficacy and safety, or which offer advantages over conventional medicines in terms of cost-effectiveness, should be considered an essential part of routine clinical practice. Indeed, there could be seen to be an ethical imperative for considering the use of such complementary medicines, as not to do so would deprive patients of potentially safe and effective treatments (see Table 6.3 and specific monographs for further details).

THE ROLE OF CAM IN THE NHS

In October of 2005, a report entitled *The role of CAM in the NHS* was published. This report examined whether other treatment approaches that are not funded by the National Health Service (UK) can provide some financial relief, while retaining good quality patient care (Smallwood 2005). The report was commissioned by HRH Prince Charles, who engaged a leading economist to investigate the potential contribution of mainstream complementary therapies to healthcare in the United Kingdom. The enquiry took more than 9 months and involved an assessment of the scientific evidence, interviews with experts, such as researchers, policy makers and healthcare professionals, and case studies to draw together published and experiential information, financial data and economic forecasting.

One area that was evaluated was acupuncture, as it is widely available through private and NHS-funded clinics. The studies examined by the enquiry suggest that acupuncture may have advantages in terms of costs and benefits in general practice for musculoskeletal conditions

TABLE 6.2 Reasons for Using Complementary Medicines

Efficacy — will alleviate symptoms of disease, reduce exacerbation or present a cure.

Safety — present a safer treatment option than other therapies.

Cost — when they provide lower cost treatment options.

Adjunct — if the efficacy and/or safety of other interventions can be improved with adjunctive use.

Prevention — when they provide safe prevention strategies in at-risk populations.

Enhance health — increase sense of wellbeing and quality of life.

Enlists patients' involvement in their own healthcare.

TABLE 6.3 Examples of Herbs and Natural Supplements with Proven Efficacy

Herb/natural supplement	Proven efficacy
Chaste tree	Premenstrual syndrome
Cranberry	Urinary tract infection prophylaxis
Fish oils	Cardiovascular disease prevention; lipid-lowering
St John's wort	Depression
Ginkgo biloba	Dementia
Glucosamine sulphate	Osteoarthritis: symptoms and disease progression
Hawthorn	Chronic heart failure (New York Heart Association classes I–II)
Honey	Infection control/wound healing
Horse chestnut	Chronic venous insufficiency
Kava kava	Anxiety
Peppermint	Irritable bowel syndrome
Probiotics	Preventing antibiotic-induced diarrhoea
Pygeum	Benign prostatic hypertrophy (BPH)
Saw palmetto	BPH
Tea tree oil	Topical infections

and when used as an adjunct to conventional treatment for lower back pain, migraine and stroke rehabilitation. With regard to herbal medicine, the enquiry identified several OTC herbal medicines that provide potential cost savings to the government, while offering similar or greater benefits than pharmaceutical treatments. Although many herbal medicines were not evaluated because of insufficient time, those named in the report are St John's wort, phytodolor, *Echinacea*, *Ginkgo biloba*, devil's claw, hawthorn, horse chestnut and saw palmetto.

DISPENSING PRODUCTS

The choice whether or not to stock and dispense products is a complex one, with ethical, commercial and practical issues to be considered. Many medical practitioners may feel it is unethical to profit from the sale of products they prescribe (Cohen et al 2005), but the direct dispensing and selling of complementary medicines by doctors is in line with the sale of products by other registered healthcare professionals such as veterinary surgeons, pharmacists, podiatrists, physiotherapists and optometrists. These healthcare professionals dispense advice and sell products in the same consultation, as do CAM practitioners such as naturopaths, herbalists and traditional Chinese medicine (TCM) practitioners.

The direct dispensing of products provides practitioners with some assurance of patient compliance and promotes the use of correct dosage, administration forms and extracts. This may be particularly important for herbal products. Direct dispensing is convenient for patients and gives them the confidence that a practitioner who is aware of their history and current needs has directed them to the best treatment. If a decision to dispense products is made, this should obviously be done in an ethical manner, and treatment plans must always be dictated by what is in the best interests of the patient.

Ethical conduct

The issues of ethical practitioner conduct have their basis in the Hippocratic oath, which acknowledges the inherent inequality of the practitioner–patient relationship and the responsibility of the doctor to use this to improve the health of their patients who may be vulnerable and who entrust themselves to medical care.

The ethical conduct of doctors has since been explored by various professional associations and colleges such as the Australian Medical Association and Royal Australian College of General Practitioners. The standards of ethical conduct (AMA 2004) include:

- always acting in the best interests of patients
- not exploiting patients for any reason
- respecting patients' right to make their own decisions and to accept or reject advice about treatment or procedures
- ensuring patients are aware of fees, and that healthcare costs are openly discussed and direct financial interests disclosed.

These standards also apply to IM, and the sale of complementary medicines must conform with these principles, insofar as the interests of the patient are the foremost consideration and patients are fully informed about the nature, benefits, risks and costs of any proposed treatment, as well as any financial interests of the practitioner. Patients also need to be aware that they have the right to accept or reject any advice (AMA 2004).

INFORMED CONSENT

The ethical precepts of informed consent and the respect for patient autonomy compel healthcare practitioners to inform their patients about the range of appropriate treatments available, their associated costs and risks, and to respect the right of patients to make their own decisions. In practice, this can be problematic, as it remains unclear how much information practitioners are expected to know themselves and how much patients require.

This issue has been addressed recently by the joint position statement on complementary medicine put out by the Royal Australian College of General Practitioners (RACGP) and the Australasian Integrative Medicine Association (AIMA):

> General practitioners require a basic understanding of natural and complementary medicine and should receive sufficient training in their undergraduate, vocational and further education to enable them to include natural/complementary medicines with proven safety and efficacy in their practice, and to discuss issues with their patients on an informed basis.
>
> The key principle of evidence based medicine should be the basis of evaluating natural and complementary medicines and their use by the medical profession. It should also be the basis of any collaborative relationships between general practitioners and complementary therapists.
>
> *RACGP/AIMA 2004*

Based on this statement it would seem reasonable that all general practitioners need to know enough about reasonably available complementary therapies to use safe and effective, evidence-based therapies where appropriate and to avoid predictable adverse events and interactions induced by commonly used complementary therapies. It has further been argued that doctors have an ethical and even a legal obligation to become familiar with this area and open a dialogue with their patients about complementary treatments to provide quality care and address safety concerns (Brophy 2003).

Unfortunately this is a difficult task, as most medical schools give little or no time to teaching about evidence-based complementary therapies, and the opportunities for vocational and postgraduate medical education about CAM remain limited. As a result, having ready access to quality, evidence-based, independent information sources is essential to guide clinicians when making healthcare decisions or faced with patient enquiries about CAM.

EVIDENCE-BASED MEDICINE

The idea that practitioners need to refer to evidence is the basis of evidence-based medicine (EBM), which has been described by Sackett et al (1996) as: 'the conscientious, explicit, and judicious use of current best evidence in making decisions about the care of individual patients'. These authors go on to state:

> The practice of evidence-based medicine means integrating individual clinical expertise with the best available external clinical evidence from systematic research. By individual clinical expertise we mean the proficiency and judgment that individual clinicians acquire through clinical experience and clinical practice. Increased expertise is reflected in many ways, but especially in more effective and efficient diagnosis and in the more thoughtful identification and compassionate use of individual patients' predicaments, rights, and preferences in making clinical decisions about their care.

This statement acknowledges that, in practice, for most treatment decisions the conclusive evidence simply does not yet exist, and the best available evidence may simply be clinical experience or anecdotal reports. It is also clear that each practitioner and patient must seek out the necessary information they require and interpret this evidence in the light of each individual situation.

EVIDENCE IN PRACTICE

EBM adds another dimension to the art of medicine and requires clinicians to review the evidence of safety and efficacy for the therapy under consideration, as well as to understand the inherent limitations of the available evidence and its relevance to a specific situation. It also involves weighing up the evidence for a number of different therapies, which includes an assessment of their costs and risks versus their potential benefits (see PEACE mnemonic in Chapter 1).

In the specific case of CAM, a growing number of treatments have been subject to scientific investigation, with over 6000 RCTs identified and made available through the central Cochrane Library. Although this is encouraging, many therapies do not yet have established evidence and some remain difficult to assess under controlled conditions (e.g. massage). In practice this should not preclude them from being viable treatment options, but can place some limitations on use. Ultimately, clinical decision making should be guided by the evidence available (Fig. 6.1).

- When there is evidence of efficacy and safety for CAM, it should be recommended to patients where appropriate and included as part of standard care.
- When the efficacy of a treatment is unknown, due to insufficient investigation or inconclusive results, and there are no apparent safety concerns, patients deciding to use these therapies should be supported and supervised. It is prudent to set specific therapeutic objectives and time frames, and to monitor for potential adverse outcomes.

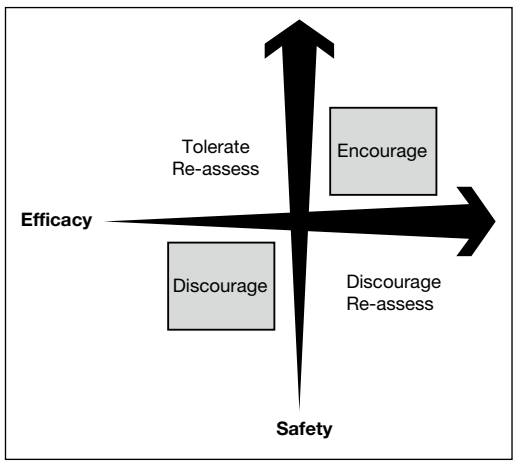

FIGURE 6.1 Paradigm of clinical decision making (Based on Renella & Fanconi 2006, adapted from Cohen & Eisenberg 2002)

- When there is evidence for a lack of effect, use should be discouraged, especially if there is the potential to induce adverse effects.

This approach is summarised by the four Ps: **P**rotect, **P**ermit, **P**romote and **P**artner (Jonas et al 1999). Thus practitioners need to protect their patients by ensuring the safety and cost effectiveness of treatments, permit therapies that are safe and inexpensive, even if their efficacy has not been conclusively proven, promote proven practices and partner with patients and other complementary therapists (Jonas 2001) (Table 6.4).

Complementary therapies with rigorous evidence for efficacy and safety that do not require specialised skills or expertise to implement should be considered part of mainstream practice and used by all healthcare practitioners, whereas other therapies/medicines with less rigorous evidence or requiring specific expertise may be more appropriately used by those with a special interest and/or appropriate training. Therapies that have evidence for a lack of efficacy and safety should be abandoned to the long list of therapies that have been discontinued throughout medical history.

A MULTIDISCIPLINARY, COLLABORATIVE APPROACH

While it remains unclear which therapies should be considered within the domain of every doctor and which should be considered areas of special interest or the exclusive domain of CAM practitioners, it is clear that the practice of IM requires a multidisciplinary approach with collaboration and communication between the different practitioners with declared interests and expertise who are aware of their own limitations. It is also clear that whether or not doctors are prepared to personally use CAM, all doctors need to be prepared to discuss their use and inform patients of viable evidence-based options, as well as assess the likelihood of safety issues or interactions.

OPEN COMMUNICATION

Effective communication and teamwork is essential for the delivery of high-quality, safe patient care: communication failure is an extremely common cause of inadvertent patient harm.

Numerous surveys have shown that patients commonly combine CAM with conventional medical treatments, outside the knowledge of their various healthcare providers. This may be particularly true in hospitals, where it has been found that while almost 50% of surgical patients take complementary medicines in the peri-operative period, 80% are not asked about this use (Braun et al 2006). It is also estimated that more than 50% of users of CAM do not disclose this use to either their hospital doctors (Braun et al 2006) or their GPs (MacLennan et al 2002). In addition, many treatments are patient-initiated without professional advice.

According to a review of 12 studies, patients do not disclose use of CAM to their medical practitioner for reasons that can be grouped

TABLE 6.4 Principles for Advising the use of Complementary Therapies

Status of evidence	Special skill/training required	Special skill/training not required
Strong evidence for quality, safety and cost-effectiveness	*Promote & partner with therapist* Encourage/recommend/implement therapy. *OR* Refer to appropriate practitioner and/or consider obtaining required skills (e.g. acupuncture).	*Promote & partner with patient* Encourage/recommend/implement therapy. Consider as part of standard practice (e.g. dietary modification).
Insufficient or inconclusive evidence for quality, safety and cost-effectiveness	*Permit & partner with therapist* Continue therapy with caution and monitor patient in collaboration with other practitioner if necessary. *OR* Consider more appropriate therapies.	*Permit and partner with patient* Continue therapy with caution and monitor patient. *OR* Consider more appropriate therapies.
Strong evidence against quality, safety and cost-effectiveness	*Protect & partner with patient* Discourage use. Discuss reasons and desired outcomes and consider more appropriate therapies.	

into three main themes (Robinson & McGrail 2004).

1. Concerns about eliciting a negative response, disapproval and rejection. Patients fear they will be persuaded to cease use and the practitioner will not continue to provide patient care.
2. Patients believed that the practitioner does not need to know about CAM use because it was irrelevant to the biomedical model of treatment; their practitioner was ignorant about CAM and would not be able to understand why it was being used or be able to contribute useful information about it.
3. Not being asked about CAM use or perceiving practitioner disinterest in the topic. (This has proved to be more significant in preventing discussion than previously thought [Braun et al 2006].)

It is therefore not unusual for there to be little coordination between patient-initiated and clinician-initiated treatments, which can result in suboptimal 'integrative care' and potentially unsafe outcomes.

As the popularity of CAM continues, medical practitioners in the community and hospital settings will continue to come into contact with patients who are using, or considering using, these treatments, making the issue of communication and competence in dealing with CAM-related issues more urgent. Asking patients about possible use of complementary medicines may seem daunting; however, it is a necessary measure to promote patient safety. It also provides an opportunity to gain insight into patients' beliefs and attitudes, as well as their willingness to be involved in their own healthcare.

Although discussions about complementary therapies may enhance the therapeutic relationship, non-disclosure can indicate a serious deficiency in this relationship, for if patients are unwilling to discuss their use, it is also possible that they will not discuss other personal information that may have an impact on their health and medical treatment. Non-disclosure also refers to a lack of interdisciplinary communication. Although many patients would like to benefit from treatment and advice from both doctors and natural therapists, effective collaboration between these groups appears to be limited and it has been estimated that of the 44% of Australians who visit natural therapists, only 13% do so on the advice of their doctors.

INTERDISCIPLINARY COLLABORATION

True collaboration can occur only in an environment of shared respect and trust, and knowledge of what can be offered. In reality, both medical and CAM practitioners have several concerns about each other's practice, which must be addressed in order to achieve a good working partnership.

For medical doctors, there are concerns that CAM practitioners may put patients at risk of delayed or missed diagnosis and/or delay the use of more effective therapies (Cohen et al 2005). There is also concern that CAM practitioners might encourage patients to refuse use of 'proven' treatments in preference for 'unproven' ones, particularly in serious diseases such as cancer or HIV-AIDS. The promotion of implausible or untrue claims or unsafe complementary therapies that waste patients' time and money, or induce adverse events, is another source of apprehension.

Complementary therapists on the other hand may be concerned that medical doctors too readily prescribe symptom-suppressing drugs, yet do little to address underlying causes and support natural homeostasis through diet, lifestyle and preventive approaches. There is concern that patients may waste their time and money on treatments that exert significant side effects while providing limited benefits, and that medical practitioners may advise against the use of natural therapies because of fear, ignorance or arrogance. Furthermore, natural therapists may be concerned that their positions are being usurped by doctors who take on the use of natural and complementary therapies with little specific training and little consideration for their underlying philosophies and holistic considerations (Cohen 2001).

Many of these concerns are based on ignorance and misunderstanding between the practitioner groups and can be addressed through open and honest communication and formalised communication strategies, one of the most important of which is through the provision of formal correspondence in referral letters.

Referral letters

Referral letters are a standardised method of professional communication between practitioners. They can be outgoing to another practitioner or incoming from another practitioner; they set out what has been done to date and any specific requests. Referral letters may request a second opinion, ask for help in patient management through a collaborative approach or transfer patient care (Table 6.5). Upon

receiving a referral letter, a practitioner is expected to send return correspondence, thanking the referring practitioner for the referral and stating the details of any procedures undertaken, new findings, clinical impressions or recommendations, as well as their rationale, and arrangements for follow-up. Such correspondence forms an essential part of professional collaboration and may also have legal status as part of the medical record and/or eligibility for funding or patient reimbursement. It also ensures that practitioners understand each other's expectations and goes far towards fostering goodwill and mutual respect.

Although effective communication is vital, there are still many issues that need to be resolved before interdisciplinary collaboration between complementary and conventional practitioners becomes the norm. These include the credentialling and regulation of CAM practitioners, differences in nomenclature between disciplines, equity of access in different healthcare settings, the requirements for evidence-based practice, appropriate funding models and medico-legal issues including referrals and vicarious liability (Cohen 2004). Despite these obstacles the fruits of interdisciplinary collaboration are becoming evident with the emergence of clinics in which doctors and natural therapists share premises and work together for the benefit of their patients. Currently this collaboration and drive towards IM seems to be in response to patient demand rather than driven by professional associations, government policy or the accumulation of supportive scientific evidence.

Patients' responsibility

Patients now have unprecedented access to healthcare information, as well as unprecedented power to choose the type of services they receive. This power is further supported by the ethical principle of informed consent and respect for patient autonomy. With power, however, comes responsibility. Patients must therefore begin to accept the responsibility to become more informed and to be active participants in the decision making process and the implementation of their healthcare. This responsibility also extends to implementing lifestyle interventions as summarised by the SENSE approach (see Chapter 1). Thus in every encounter, whether patients are currently well, at risk of disease or have an established disease, practitioners should take the opportunity to enlist patients' cooperation in implementing their own healthcare and discussing interventions that can be used to enhance health, prevent disease and complement the use of any disease-specific interventions.

PERSONAL AND PROFESSIONAL SATISFACTION

The role of the IM practitioner is particularly challenging and rewarding. It compels practitioners to develop multiple skills, be informed

TABLE 6.5 Elements of a Referral Letter

Element	Details
Professional letterhead	Referring practitioner's name Qualifications Practice address Phone number/fax/email Provider number if appropriate Date of referral
Practitioner and patient identification	Details of practitioner to whom referral is being made Patient identifying details: full name, date of birth, address, hospital UR (patient) number etc
Patient's history	Brief patient history including background, any special considerations, past history and present complaints Investigations, treatment to date, including current and/or proposed treatments pharmaceutical or complementary, rationale and expected outcomes including involvement of other practitioners Any psychosocial concerns
Reasons for referral	Detailed reasons for referral, including expected actions of other practitioner (e.g. second opinion, further investigation, specific intervention, help in case management, transfer of care etc)
Conclusion	Arrangements for follow up Referring practitioner's signature

about many therapies, navigate between different information sources and practitioners, and keep an open mind. It also broadens the capacity of practitioners to deal with a great variety of patient issues from a number of perspectives, thus providing continuous intellectual stimulation and both professional and personal satisfaction. To have people's confidence as a practitioner and to participate in their most emotionally charged moments, which may include both the beginning and the end of their life, is a great privilege. Sharing the triumphs and tragedies of individuals from different walks of life is a great reward and practitioners' personal lives are undoubtedly enriched.

Our knowledge of health and disease is far from complete, and healthcare practitioners regularly deal with uncertainty. The implementation of IM, however, recognises that compassion is always helpful and healing is always possible, even when curing is not (Rakel & Weil 2003); it also recognises that practitioners endeavour always to do their best with what they have from their perspective and to be comfortable in the knowledge that their best will continually get better.

SUMMARY POINTS

- Taking time to develop a good therapeutic relationship may be therapeutic in itself and provides the best foundation for any other therapy.
- The integrative approach compels practitioners to develop an intimate understanding of their patients' lives, and to provide social support, understanding and compassion.
- The widespread use of complementary therapies compels doctors to discuss their use with patients and to do so on an informed basis and in a non-judgmental manner.
- All healthcare practitioners should have access to appropriate and independent information, so that they can provide sound advice and detect predictable interactions and safety issues.
- Healthcare practitioners need to be aware of their particular biases, limitations and financial interests, and to clearly state these to patients when patient care may be affected.
- Healthcare practitioners should attempt to make patients active participants in the decision-making process and the implementation of their own healthcare.
- Healthcare practitioners need to liaise with different practitioners in order to advise on and implement the most appropriate interventions.
- Complementary therapies/medicines with rigorous evidence for efficacy and safety that do not require specialised skill or expertise to implement should be considered as part of mainstream practice.
- When efficacy of treatment is unknown and there are no apparent safety concerns, patients deciding to use these therapies should be supported and supervised.
- Therapies/medicines with less rigorous evidence or requiring specific expertise may be more appropriately used by healthcare practitioners with a special interest and/or appropriate training.
- When there are differences in the supporting evidence and quality of different herbal extracts and other CAM, the recommendation of specific brands of CAM products may be appropriate.
- Compassion is always helpful and healing is always possible, even when curing is not.

> By fostering interaction, cross-disciplinary research, and collaborative care, redefined standards of care will emerge that are scientifically based and interdisciplinary in nature. The outgrowth of such a paradigm shift will change the legal and practice environment from one of fear to freedom.

CHAPTER 7
SAFETY OF COMPLEMENTARY MEDICINES

Complementary medicines (CMs) are widely used by the public, who assume they are a safe, non-pharmaceutical option that can be used to prevent, treat and manage disease (MacLennan et al 2002). The perception that CMs are safe is largely based on the assumption that if something is 'natural' it is inherently safe, a view encouraged by many in the health food industry. Unfortunately the 'natural' argument is simplistic and not well thought out, because nature provides many examples of unsafe substances, such as the naturally occurring poisons hemlock, jimsonweed and oleander. There is also an assumption that possible side effects and toxicities will be listed on product labels and therefore, if the information is absent, the product must be well tolerated. In Australia, some warnings are required on labels; however, CMs are not accompanied by comprehensive consumer product information (CPI) in the same way as many pharmaceutical medicines; many CMs are self-selected without professional advice, which means that much-needed information is not delivered with the product (Jamison 2003, MacLennan et al 2002).

Importantly, people who use CMs tend to have poorer health than the general community (MacLennan et al 2006) and are not necessarily dissatisfied with their conventional care (Astin 1998), which raises the possibility of dual care by complementary and conventional medical practitioners. This situation is not necessarily dangerous and can produce significant benefits when well coordinated; however, if communication is poor, and complementary and conventional practitioners remain unaware of what the other has recommended, a potentially unsafe situation can arise. The prospect of interactions or adverse drug reactions leading to misdiagnosis, induction of withdrawal effects and misleading pathology test results are examples of unwanted outcomes when combined care is not coordinated.

In the real world, people are exposed to risk whenever they actively choose to undertake a treatment or choose to do without. Some risks are identifiable, while others are unknown. In practice, in order for patients to make an informed decision, these risks must be classified into those that are acceptable and those that are unacceptable, and then considered against the potential benefit, Over-the-counter (OTC) CMs offer a lower-risk and potentially more cost-effective option than other treatments for some indications and are generally considered safe when used appropriately under 'normal' circumstances; however, they are not entirely devoid of risk.

A BRIEF HISTORY OF MEDICATION SAFETY

The potential for medical care to cause harm has been appreciated throughout history. In ancient times, knowledge of medicine, pharmacology and the healing arts developed through trial and error, with many adverse outcomes and deaths along the way. Although both practitioners and patients were aware that health could be compromised by the 'cures' used to alleviate disease, it was in ancient Greece that patient safety was formally acknowledged as the highest priority. The maxim *primum non nocere* (First, do no harm) is attributed by some historians to Galen (AD 131–201) and is still a basic tenet of modern medical practice (Ilan & Fowler 2005).

As societies developed over the centuries, so too did their systems of medicine and healing — particularly the Vedic system of medicine, which originated more than 3000 years ago in India, and Chinese medicine, which has an appreciation of the importance of dosage. Persian medicine had a major influence on the development of medicine in the Middle East and Europe, most notably with *The canon of medicine* written by the Persian scientist Avicenna (AD 980–1037) in the 11th century. This major work documented 760 medicines, made comments about their use and effectiveness, and remained a standard medical text in western Europe for seven centuries. Avicenna recommended the testing of new medicines on animals and humans before general use, no doubt in recognition of their potential to have both beneficial and harmful effects.

In medieval Europe, there was a mixture of scientific and spiritual influences on the practice of medicine, so factors such as destiny, sin and astrology played a role in perceptions of health and disease. Two major trends appeared during this period, as the practice of medicine developed among both physicians of the upper classes and folk healers who lived in the villages. From the 14th to the 17th centuries, monasteries played a major role in the provision of medicine and developed great expertise in pharmacognosy. At the same time, the Christian church was instrumental in eliminating much of the practice of folk medicine through its witch-hunts, which many believe retarded the development of medicine.

In the 16th century, Paracelsus (1493–1541) was one of the first physicians to believe that chemicals could cure and cause certain illnesses. He determined that specific chemicals were responsible for the toxicity of a plant or animal poison, and documented the body's responses to those chemicals. Paracelsus then concluded that the body's response was influenced by the dose received. He further discovered that a small dose of a substance may be harmless, or even beneficial, whereas a larger dose can be toxic. In essence, he started expounding the concept of a dose–response relationship. Paracelsus made an enormous contribution to medicine when he stated plainly, 'What is there that is not poison? All things are poison and nothing (is) without poison. Solely the dose determines that a thing is not a poison' (Watson 2005). As a result, he is sometimes referred to as the 'Father of Toxicology'.

In practice, this refers to the biological effect of chemicals that can be either beneficial or deleterious. Which of these effects occurs depends on the amount of active material present at the site of action (internal dose), and the concentration of the amount present relates to the amount of substance administered (external dose).

During the 18th and 19th centuries deliberate clinical testing of medicines began, and the study of dose–response relationships led to the safer use of medicines. From the 19th century onwards, developments in pharmacology, physiology and chemistry meant that drugs could be artificially synthesised and be produced by large-scale manufacturing. During this time, animal- and plant-based medicines began to be replaced in clinical use by mass-produced pharmaceutical medicines that were being newly created in laboratories or synthesised from traditional medicines (e.g. morphine from *Papaver somniferum*).

Up to this point, Western herbalism had been intrinsically linked to the practice of medicine, and herbal products were an important source of treatment. Empirical knowledge accumulated and formed a body of evidence now referred to as 'traditional evidence', a knowledge base built on the basic tenets of good clinical practice (i.e. careful observation of the patient, the environment and the diseases). This huge and diverse store of learning includes not only prescriptions for health, but also safety information. The traditional evidence base is still expanding and becoming more accessible as researchers investigate and document various healing practices worldwide. Although traditional evidence provides a valuable starting point, it has many limitations, especially with regard to issues of safety. Careful patient observation is likely to detect immediate or serious adverse effects, but is less likely to identify slow-onset responses or mild to moderate side effects that could be considered symptoms of a new disease. Additionally, many medicinal preparations contained multiple ingredients, making it difficult to identify which one might be responsible for inducing an adverse reaction.

More recently, the traditional evidence base has been joined by a scientific evidence base, which provides additional information about pharmacological actions, clinical effects and safety; however, much still remains unknown.

Clinical note — History of poisons

The history of poisons dates back to the earliest times, when humans observed toxic effects in nature, most likely by chance. By 1500 BC, written records indicate that the poisons hemlock, opium and certain metals were used in warfare and in facilitating executions. Over time, poisons were used with greater sophistication; notable poisoning victims include Socrates, Cleopatra and Claudius. Today, the 'science of poisons' is known as toxicology. This field of learning investigates the chemical and physical properties of poisons and their physiological or behavioural effects on living organisms, and uses qualitative and quantitative methods for analysis and for the development of procedures to treat poisoning (Langman & Kapur 2006). The 20th century was marked by an advanced understanding of toxicology; DNA and various biochemicals that maintain cellular functions were discovered, so that today we are discovering the toxic effects on organs and cells at the molecular level.

This is particularly true regarding the safety of CMs in children and in women who are pregnant or lactating, and concerning drug interactions, which is a relatively new phenomenon. Just as Galen pronounced hundreds of years ago, 'First, do no harm' should remain the practitioner's guide.

WHAT IS SAFETY?

Safety is a complex issue that is determined by considering the interaction between 'likelihood' and 'consequence'. These two variables will differ for each medicine and individual. The likelihood can be graded from 'near impossible' to 'certainly likely', and the severity of consequence can be graded from 'negligible' to 'serious and life-threatening', with many outcomes lying somewhere between these extremes (Fig 7.1).

With regard to medication safety, avoidance of an adverse drug reaction (ADR) is paramount. Several factors are associated with an increased likelihood of developing an ADR, such as advanced age and polypharmacy, but most ADRs occur in people who are prescribed treatment within the limits of accepted clinical practice (Burgess et al 2005).

BENEFITS, RISK AND HARM

Many different sources of risk are associated with therapeutic products:

- **The product itself** — side effects and toxicity of ingredients, administration form, potential harm through excessive dosage and length of time used.
- **Manufacturing factors** — poor manufacturing process, which introduces contaminants, uses unsafe excipients or incorrect ingredients etc.
- **Prescribing faults** — incorrect product prescribed, based on insufficient information about it, the patient or the disease, or simply negligence.

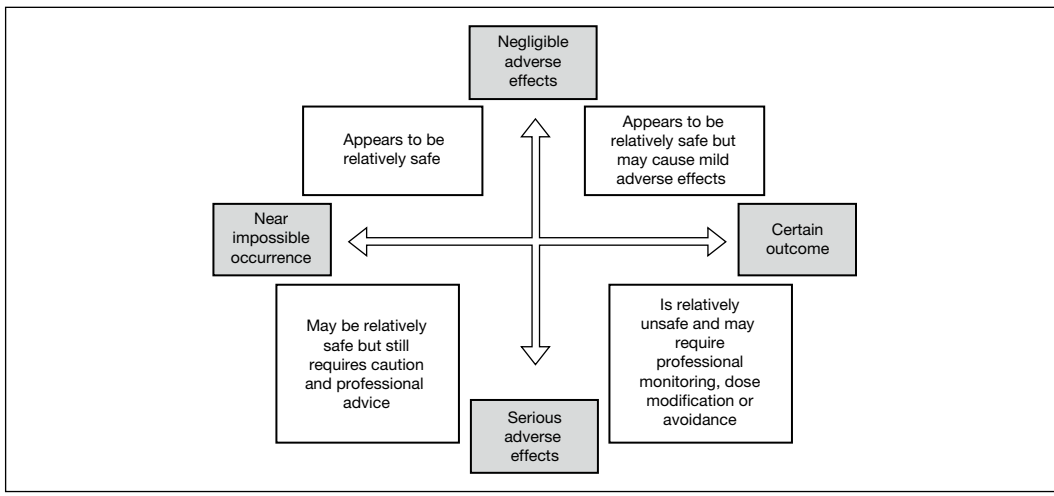

FIGURE 7.1 Interaction between the two variables of 'likelihood' and 'severity of consequence' with regard to medication safety

- **Patient factors** — incorrect use of a product when information for appropriate use is poorly understood, or insufficient or inappropriate self-diagnosis and treatment.

Whenever a treatment is chosen, it is done so in the belief that its potential benefit will outweigh its potential to cause harm. Practice guidelines and traditions provide guidance when making risk–benefit evaluations and are based on common treatment decisions made many times before by many clinicians, together with the available evidence. The safety information tends to come from a variety of sources, such as post-marketing surveillance and spontaneous reporting schemes, laboratory and animal studies, anecdotal reports, theoretical reasoning and, increasingly, formal studies.

The amount of safety literature published on pharmaceutical medicines is overwhelming. It has been estimated that 30% of the primary published literature about ADR appears in anecdotal reports and 35% as formal studies or randomised controlled trials (Aronson et al 2002). As regards the safety of complementary medicines, traditional evidence and theoretical reasoning are heavily relied upon to provide guidance because relatively little reliable information has been published in the peer-reviewed literature. This poses a challenge for practitioners when making a rational decision about the relative risks of treatment and is one of the great difficulties of CAM practice. For the public who are interested in using OTC products, it is just as difficult to find reliable and understandable information about their safety and efficacy.

ADVERSE DRUG REACTIONS (ADRs)

The World Health Organization defines an ADR as a 'response to a medicine which is noxious and unintended that occurs at doses normally used in humans'. When two medicines interact in a way that produces an unwanted effect, this is also referred to as an ADR. Adverse reactions have been classified into different types depending on severity and likelihood or onset of reaction, and do not always result in serious outcomes; however, an ADR is considered serious when it is suspected of causing death, danger to life, admission to hospital, prolongation of hospital stay, absence from productive activity, increased investigational or treatment costs, or birth defects.

Adverse reactions can arise from either an intrinsic or an extrinsic effect. An intrinsic effect refers to the active ingredient itself, such as the herbal medicine present within a product, whereas an extrinsic effect relates to product characteristics resulting from poor manufacturing processes or quality control, such as contamination and adulteration. Intrinsic adverse effects can be categorised in a similar way to pharmaceutical medicines and are mainly type A or type B reactions.

Type A reactions

Type A reactions are the most common form and are typically dose-related, predictable from the known pharmacology of the medicine, associated with high morbidity but low mortality, and potentially avoidable (Routledge et al 2004). People most at risk of a type

TABLE 7.1 Potential Risks Associated With the Use of Complementary Medicines

Type of harm	Circumstances
Delay in diagnosis	When a patient has avoided or delayed seeking medical advice because they are self-treating with CMs. When a complementary medicine practitioner has not referred a patient to a medical practitioner for early diagnosis.
Adverse effects	Increased risk of adverse reactions with inappropriate use of CM products or when patients self-select CM products without professional advice. Increased risk if products used are not manufactured to pharmaceutical grade quality.
Drug interactions	Increased risk of drug interactions when patients: (a) self-select CM products without professional advice; (b) do not disclose use of CM products to their pharmacist or medical physician; (c) do not disclose use of pharmaceutical drugs to their CM practitioner.
Financial cost	If an expensive medicine or therapy is not providing benefits and a patient continues to use it, this presents an unnecessary financial burden.
Lost opportunity to treat	Failure to undertake a different treatment with proven benefits, when the current treatment is ineffective but is being used to the exclusion of others.
False hope of a cure	When cure is unlikely, the use of any medicine or therapy that is associated with false hope may delay important considerations, such as attending to 'unfinished business'.

A reaction are frail, older patients who are also likely to be receiving a combination of medicines and those with altered hepatic or renal function. There is now mounting evidence to indicate that some type A adverse reactions are due to genetic polymorphisms, which affect an individual's drug clearance rate and therefore toxicological response. This may explain why certain individuals taking medicines in the recommended doses experience adverse reactions, whereas the majority of the population does not. Examples related to pharmaceutical medicine are bleeding with anticoagulants and hypoglycaemia with the use of insulin. An example for herbal medicine is licorice-associated hypertension, which is thought to be caused by increased renal sodium retention. The glycyrrhetinic acid in licorice inhibits renal 11-beta-hydroxysteroid dehydrogenase type 2 and, by that mechanism, increases the access of cortisol to the mineralocorticoid receptor that causes renal sodium retention and potassium loss. If continued for sufficient time, clinically significant changes in blood pressure and potassium status develop, which can be avoided by recommending that high-dose licorice herbal products not be used for longer than 2 weeks (Heilmann et al 1999). In recognition of this adverse effect, some manufacturers produce licorice products that do not contain glycyrrhetinic acid, so that they can be used more safely in the long term.

Table 7.2 gives some examples of known or suspected type A adverse reactions to herbs and natural supplements. For many herbal and natural medicines, there is insufficient reliable information about possible adverse reactions; where available, evidence from clinical trials, case reports and post-marketing surveillance systems are the main sources of information used in this book.

Type B reactions

Type B reactions are idiosyncratic and uncommon, difficult to predict and not dose related. They tend to have higher morbidity and mortality than type A reactions and are often immunologically mediated (Myers & Cheras 2004). Other factors contributing to type B reactions are receptor or drug metabolism abnormalities and the unmasking of a biological deficiency (e.g. glucose-6-phosphate dehydrogenase deficiency) (Bryant et al 2003). They do not appear to relate to genetic polymorphisms.

An example of a type B reaction to a pharmaceutical drug is interstitial nephritis with the use of NSAIDs. With regard to CMs, *Asteracaea* dermatitis provides a good example of a type B hypersensitivity reaction — specifically, an allergic contact dermatitis caused by exposure to allergens from the Asteraceae family or the daisy group of plants and plant extracts. Some examples of common plants that belong to this family are arnica (*Arnica montana*), chamomile (*Chamomilla recucita*), marigold (*Calendula officinalis*), echinacea (*Echinacea* spp), tansy (*Tanacetum vulgare*), feverfew (*Tanacetum parthenium*) and yarrow (*Achillea millefolium*). The most important allergens in the Asteraceae family are the sesquiterpene lactones, which are present in the oleoresin fraction of the leaves, stems, flowers and possibly pollen (Gordon 1999). The condition is most frequently seen

TABLE 7.2 Examples of Known or Suspected Type A Adverse Reactions to Herbs and Natural Supplements

Herb or natural supplement	Adverse effect/s
Andrographis paniculata	Vomiting, anorexia and gastrointestinal discomfort
Creatine	Nausea, vomiting, cramping, dehydration, fluid retention
Trigonella foenum (fenugreek)	Diarrhoea, flatulence
Fish oils	Gastrointestinal discomfort, diarrhoea
Allium sativum (garlic)	Breath and body odour, nausea, dyspepsia, flatulence, diarrhoea, increased bleeding
Zingiber officinale (ginger)	Gastric irritation, dyspepsia
Camellia sinensis (green or black tea)	CNS stimulation
Gymnema sylvestre	Hypoglycaemia
Paullinia cupana (guarana)	CNS stimulation
Selenium	Nausea, vomiting, irritability, fatigue, nail changes

TABLE 7.3 Examples of Known or Suspected Type B Adverse Reactions to Herbs and Natural Supplements

Herb or natural supplement	Adverse effect/s
Andrographis paniculata	Urticaria
Aloe vera	Hypersensitivity and contact dermatitis
Chamomilla recutita	Asteraceae dermatitis
Echinacea spp	Asteraceae dermatitis and anaphylaxis
Tanacetum parthenium (feverfew)	Asteraceae dermatitis — lip swelling, mouth ulceration and soreness when the leaves are chewed
Zingiber officinale (ginger)	Contact dermatitis with topical use
Thymus vulgaris (thyme)	Contact dermatitis with topical use of the oil

in middle-aged and elderly people; it typically starts in summer and disappears in the autumn or winter. The dermatitis manifests as eczema and can develop from exposure to airborne particles, direct topical application (such as cosmetics, perfumes, essential oils) or oral ingestion of allergenic components. The diagnosis of allergy can be difficult to establish, because there are few completely reliable laboratory tests and sometimes symptoms can mimic infectious disease symptoms. Table 7.3 gives examples of known or suspected type B adverse reactions.

Extrinsic factors

Extrinsic factors are also a consideration and of particular relevance when medicinal products are not manufactured according to the standards of good manufacturing practice, such as some produced in the USA and various Asian countries.

REGULATION AND PRODUCT INFORMATION

Numerous regulations are in place in Australia and New Zealand to protect people from potentially unsafe and dubious therapeutic products. Both countries have an international best-practice, risk-based regulatory system that encompasses both complementary and pharmaceutical medicines. Currently the Therapeutic Goods Administration (TGA) regulates the system in Australia, and aims to ensure the safety and quality of products and the truthful labelling of therapeutic goods. All products are entered onto the Australian Register of Therapeutic Goods (ARTG) and allocated an AUST L number if considered low risk (most CM products) or AUST R number if considered high risk, or low risk with a high-level claim (prescription drugs and many OTC pharmaceutical medicines). Products with either an Aust L or an Aust R number have been evaluated for safety and quality, whereas those with an AUST R number have also been evaluated for efficacy. Importantly, the TGA does not undertake the evaluation itself but relies on sponsors to provide the evidence.

The TGA also acts to ensure that all therapeutic products (complementary and pharmaceutical) are produced according to the code of Good Manufacturing Practice (GMP), and both licenses and audits manufacturers. Since the Pan Pharmaceuticals debacle in 2003, when more than 1000 CM products were recalled owing to quality control concerns, there have been calls for more frequent auditing of manufacturers in order to maintain closer control over product quality.

It appears that many people are unclear about the TGA's role in this regard and think it has a greater capacity to monitor product quality than actually occurs. According to a recent survey of more than 3000 people living in South Australia, approximately half assumed that CMs were independently tested by a government agency (MacLennan et al 2006).

It is important to note that the regulation of therapeutic goods varies greatly between countries and is influenced by ethnological, medical and historical factors. For instance, CM products are treated as foods by the Food and Drug Administration in the USA and not required to be manufactured to the same quality-control standards as pharmaceutical medicines (Brownie 2005).

RELIABLE INFORMATION SOURCES

When it comes to sources of information about herbal and natural medicines, a 1999 Australian consumer report found that 51% of people surveyed ask their friends or relatives for advice, with their mothers ranked as number one for healthcare advice (and it is open to debate as to where the mothers get their information from). In 2001, an Australian rural survey produced similar results, finding that

64.5% of people first ask family and friends for advice (Wilkinson & Simpson 2001). Interestingly, 78% of nursing, pharmacy or biomedical science students had used CAM in the previous 12 months, and 56% had visited a CAM practitioner. They, too, cited friends and family as their main sources of information (Wilkinson & Simpson 2001).

In recent years information technology has revolutionised the availability of health information for both practitioners and their patients. Besides relying on traditional sources of health information, such as healthcare providers, family and friends, people now have easy access to a variety of sources, particularly since the advent of the internet, email and text messaging.

Advertising plays a role in informing consumers about therapeutic products and is regulated by the government. Advertisements must comply with the Therapeutic Products Advertising Code and Therapeutic Product Act(s) and Rules, which state that advertising must be truthful, balanced and not misleading, and promote responsible use, and that the claims must be substantiated. The regulations relate to advertisements disseminated in all forms of media, including emails, websites and SMS messages. However, some information routes are exempt: bona fide news, editorial, public interest or entertainment programs are not restricted by the code, allowing for freedom of speech, but also allowing for sensationalism and inaccuracies.

In 2000, a study published in the *New England Journal of Medicine* found that media coverage of new drugs often exaggerates their benefits and downplays the associated risks (Moynihan et al 2000). The study analysed a sample of 207 stories released by 40 media outlets (36 newspapers, 4 television networks) that appeared between 1994 and 1998. Of the stories reviewed, 40% did not report benefits quantitatively and, of those that did, 83% used statistics to exaggerate the beneficial effect of the drug. Potential harm associated with use of the drug was not mentioned in 53% of stories, and 70% failed to mention costs. Based on the results of this study, it was concluded that news-media stories about medicines may be inadequate or incomplete regarding benefits, risks and costs, and may fail to disclose financial ties between researchers and pharmaceutical companies.

It is clear that a number of factors influence the way journalists report health issues in the news media. One important factor relates to the information provided (or not provided) to the journalist by a medical journal, researcher or company in a press release. The following case about the safety of *Echinacea* provides a local example. In 2002, an article entitled 'Adverse reactions associated with Echinacea — the Australian experience' was published in a scientific journal. It described in detail five allergic reactions to different *Echinacea* preparations, further stating that 51 adverse reaction reports involving *Echinacea* had been reported to the Adverse Drug Reactions Advisory Committee (ADRAC) (Mullins & Heddle 2002). This was then reported in the news media as alarming and drew much debate about the safety of herbal medicines in general. Inspection of the original article reveals that the reports were collected over a 21-year period, an important fact that failed to be included in the original press release (Flinders Medical Centre 2006).

A study published in the *Journal of the American Medical Association* suggests that incomplete or inaccurate press releases may be more common than once thought (Woloshin & Schwartz 2002). The study assessed the quality of press releases from seven high-profile journals, which were selected for their professional influence and because they are frequently cited by the news media. It was identified that for 544 articles published in the journals over the study period, 127 press releases were issued. Of these press releases, only 23% reported study limitations, 65% quantified study results and only 22% reported the source of funding.

Ideally, journalists, program researchers and writers involved in the media need to be able to assess the scientific information provided to them, and then present it accurately to consumers in a way that is easy to understand, unambiguous and not misleading, so that they can make better personal health decisions. Inaccurate, incomplete and inconsistent information not only confuses consumers, it also confuses healthcare providers and makes it difficult for them to determine which resource is useful and reliable.

A recent study by the National Prescribing Service in Australia found that both general practitioners (GPs) and pharmacists seek or need information regarding complementary medicines, and are particularly interested in information about drug interactions, adverse effects, contraindications and evidence of effectiveness. GPs tend to refer to trade journals, MIMS, the internet in general, and

peer-reviewed medical journals for information about CMs. Pharmacists' most common sources were the internet, MIMS and the Australian Pharmaceutical Products (APP) guide, colleagues and complementary medicine textbooks (Brown et al 2008). Interestingly, when asked which information sources were considered moderately or highly useful, CM textbooks came out on top for both groups of healthcare professionals. This implies that practitioners who only used standard drug information sources were not accessing the most useful resources available. Another consequence is the assumption by these practitioners that either little evidence exists (because little is available in standard pharmaceutical or medical texts or journals), or that there are no good resources.

Similarly, a study funded by the Department of Health and Ageing and the Pharmacy Guild that investigated the quality use of medicines in relation to complementary medicines found that pharmacists have trouble locating information they consider credible, and are keen for standardised information to be endorsed by a reputable organisation and made widely available.

MEDICAL DATABASES AND TEXTS: INCONSISTENCY

Unfortunately, some medical databases and textbooks that are widely used in the hospital system and universities are not always up to date; authors don't critically examine the evidence from primary sources and sometimes overstate the safety issues without considering the wider perspective. This makes it extremely difficult for a busy clinician to find accurate information in a timely manner.

An example presented here is the purported interaction between ginkgo biloba and warfarin. Ginkgolides found in ginkgo leaf inhibit platelet aggregation according to in vitro and ex vivo studies. As a result, it has been assumed that the effect is clinically relevant, and ginkgo has been implicated as the causative factor in case reports where haemorrhage has been described in association with ginkgo use (Koch 2005). It has also led many writers and clinicians to assume that a pharmacodynamic interaction exists between ginkgo and drugs affecting haemostasis at the platelet level (Bone 2008). Evidence from multiple controlled studies published over the last 5 years casts doubt on the clinical significance of this theoretical interaction, indicating it is unsubstantiated (see monograph on *Ginkgo biloba* for further details). Major databases and textbooks on complementary medicines provide quite different information to readers about this issue, adding to the confusion (Table 7.4, p 88).

ADR INCIDENCE

Alarmingly, the rates of ADR-related hospital admissions are rising and account for considerable morbidity, mortality and costs. One recent Australian study found that one in ten patients who visited a GP had experienced a significant ADR within the previous 6 months, and almost 50% of these were assessed as moderate to severe by the GP (Miller et al 2006). An ADR is more likely to be experienced with increasing age, peaking at 65 years and older, and by females rather than males. Children aged between 1 and 4 years are three times more likely to have an ADR than children in other age groups. At this rate, ADRs rank as one of the most important causes of morbidity. Anticoagulants, NSAIDs and cardiovascular medicines feature prominently as preventable, high-impact problems in Australia and other countries (Pirmohamed et al 2004, Runciman et al 2003).

Although ADRs also occur with CMs, relatively few reports have been collected through spontaneous post-marketing surveillance systems. The most extensive database of ADRs to herbal medicines is held by the Uppsala Monitoring Centre, which is the coordinating centre for the WHO Programme for International Drug Monitoring (see www.who-umc.org). It receives data from national centres in 72 countries and, over the past 20 years, 11,716 case reports of suspected herbal ADR have been collected. The most commonly reported non-critical effects were (from higher to lower incidence): pruritis, urticaria, rash, erythematous rash, nausea, vomiting, diarrhoea, fever, abdominal pain and dyspnoea. The most common critical effects were: facial oedema, hepatitis, angio-oedema, thrombocytopenia, hypertension, chest pain, convulsions, purpurea, dermatitis and death.

In Australia, the ADRAC database holds reports of suspected ADRs. From 1 November 1972 to 19 April 2005, it has only 1112 reports related solely to CMs. This is reassuring, when one considers that in 2004 approximately 52% of the population were identified as users of at least one non-medically prescribed CM product in the previous 12 months (MacLennan

TABLE 7.4 Examples of Current Databases and Textbooks Reporting on the Purported Ginkgo–Warfarin Interaction

Resource	Interaction information	Comments
MIMS on CD	'Warfarin interacts with a wide range of complementary medicines, including vitamin and herbal preparations, e.g. Gingko biloba … have confirmed or potential interactions with warfarin.'	Accessed 10 July 2008 Ginkgo spelt incorrectly Insufficient information provided

et al 2006). The relatively small number of case reports can be interpreted as indicative of the comparative safety of CMs and the effectiveness of pre-market checks; however, the impact of under-reporting should not be dismissed.

Research on under-reporting of serious ADRs in the USA and Canada suggests that formal reporting rates may be as low as 1.5% of total ADRs (Miller et al 2006). In the specific case of CMs, CAM practitioners and retail staff may not report such events because:

- they are unaware of ADR schemes
- they are not qualified or trained to consider the possibility of ADRs
- they are not motivated to report any ADR that comes to their notice.

In addition, herbal medicine consumers may not be motivated to report ADRs to their physician, as one British study suggests (Barnes et al 1998), or they may not consider the possibility that their symptoms may be related to the CM products they use.

CASE REPORTS AND POST-MARKETING SURVEILLANCE SYSTEMS

Given that current knowledge about CMs is incomplete and that controlled studies are often lacking for CAM, well-documented case reports can serve as a critical early warning system until further research is undertaken, whereas poorly documented case reports can be misleading. Unfortunately, reports of ADRs with herbal medicines often cause some controversy and contain incomplete data; for example, one systematic review, which assessed information from four electronic databases, located 108 cases of suspected medicine–herb interactions. Of these, 68.5% were classified as 'unable to be evaluated' and only 13% were described as 'well-documented' (Fugh-Berman & Ernst 2001). Table 7.5 lists the elements that should be included in a report of an adverse reaction.

Besides improving the quality of reporting, the ideal would be to chemically analyse the product to authenticate the ingredients and

TABLE 7.5 Important Components of an Adverse Reaction Report

Patient demographics: male/female, age, social history if relevant
Suspected product details: formula as stated on label, batch number, expiry date and Aust L or Aust R number
Details of the person making the report
Manufacturer's details
Relevant medical history
Other medicines and treatments being used (including other complementary medicines)
Dose used, duration of use and administration form
Date and time of onset
Adverse effects: description of signs and symptoms
Outcome of event
Information regarding re-challenge, if applicable Presence of confounding variables: e.g. additives

make sure that quality control issues are not involved. This is particularly important when the implicated product has not been manufactured under a strict GMP code.

Much of the information obtained from the current spontaneous post-marketing surveillance systems about CM safety is of limited value, as it does not provide an estimate of the incidence of adverse reactions. Without understanding the level of incidence, case reports can easily be interpreted as cause for alarm or alternatively dismissed as irrelevant. Additionally, authorities discourage reporting of less severe ADRs, so many mild-to-moderate side effects remain undetected and are a hidden source of patient morbidity.

Post-marketing surveillance systems aim to detect trends in ADR and become useful when a large number of reports relating to a specific medicine are received. When evidence gathers to suggest a significant problem, the TGA may issue an alert on its website, impose new conditions on the product's listing or registration, suspend or cancel listing or registration, impose new manufacturing conditions and, if considered sufficiently serious, issue a mandatory product recall. Alerts in recent years have included warnings about drug interactions with St John's wort (*Hypericum perforatum*), suspected hepatotoxicity with products containing kava kava and renal toxicity with Chinese herbal medicines containing the herb *Aristolochia*. The Complementary Medicines Evaluation Committee (CMEC) advises the TGA on matters regarding CMs and is made up of people considered expert in this area.

The two cases involving black cohosh and kava kava provide recent examples. On 9 February 2006 the TGA announced that it had reviewed local and international reports and concluded that, although some reports were confounded by the presence of multiple ingredients, there was sufficient evidence of a causal relationship between black cohosh and serious hepatitis. As a result, the TGA decided that products containing black cohosh must be accompanied by a warning statement on the label:

'Warning: black cohosh may harm the liver in some individuals. Use under the supervision of a healthcare professional.'

A few years earlier, local and international reports suggesting a link between kava kava and hepatotoxicity were received by the TGA. This eventually led to a voluntary recall of kava-containing products by the CM industry and a recommendation in August 2002 that people discontinue use of these products.

The conclusion and recommendations of the TGA have not always been met with agreement from CAM practitioners. In both of the above instances, the initial warnings were considered overly cautious, as the case reports tended to be of poor quality. Based on the high consumption of these medicines and the relative lack of ADRs reported in clinical trials and collected by surveillance systems in general, calls were made for further investigation.

Largely in response to these issues, the Kava Evaluation Group was established in January 2003 to review the accumulating safety data, and by August 2003 CMEC had recommended to the TGA that certain forms of kava could be considered safe. The TGA accepted these recommendations and amended the regulations accordingly. Currently, there is a limit of 125 mg kavalactones allowable per tablet or capsule, and no product must provide more than 250 mg kavalactones in the recommended daily dose.

With regard to the safety of black cohosh, a wait-and-see approach has been adopted.

FACTORS THAT MAKE AN ADR MORE LIKELY

Although little investigation has been conducted into what factors influence the likelihood of ADRs with CMs, it can be assumed that most factors that increase the risk of ADRs with pharmaceutical medicine will also apply to CMs. These factors can be grouped as patient-related or therapeutic.

Patient-related factors

- Older age. Declining liver and kidney function as a result of ageing can increase sensitivity to both therapeutic and adverse effects. During times of ill health, the elderly can experience a further loss of homeostatic reserve, once again increasing sensitivity to the effects of medicines and interactions (Atkinson et al 2001).
- Females appear to be more susceptible to ADRs.
- Concurrent disease, acute and/or severe.
- History of atopic disease.
- Confusion.
- Genetic factors: for example, variations in liver enzymes.
- Reduced renal or hepatic function. Altered metabolism or excretion of a medicine can increase the risk of toxicity
- Self-medication. Prudent self-care can offer numerous benefits to the individual, society and the healthcare system if there is access to quality services, products and information. However, when people at higher risk of adverse effects self-medicate with OTC medicines, it can be potentially harmful. Additionally, interactions that do not produce a clinically obvious change, such as elevation in blood pressure, serum cholesterol or warfarin INR, can remain undetected and uncorrected unless professional advice is sought.
- Use of multiple healthcare practitioners. This is of concern when practitioners fail to communicate effectively with one another to ensure that interactions are avoided and identified.

Therapeutic factors

- Dose. Most ADRs are dose related, with higher doses increasing risk.
- Route of administration (e.g. topical application) can cause delayed hypersensitivity.
- Prolonged and/or frequent therapy.
- Medicines not manufactured under a code of good manufacturing practice (GMP) have an increased risk of extrinsic effects.
- Use of concurrent high-risk medicines; for example, those with a narrow therapeutic index (NTI) such as warfarin, digoxin, lithium, cyclosporin, phenytoin, barbiturates, theophylline, many HIV medicines (e.g. saquinavir), antineoplastic agents (e.g. methotrexate) and anti-arrhythmic agents (e.g. quinidine). These medicines are particularly sensitive to pharmacokinetic alterations in which small changes to blood concentrations can cause a clinically significant change to drug activity. Depending on whether drug concentrations are reduced or increased, there is the potential to cause a loss of efficacy or induce toxic effects, respectively.
- Polypharmacy. This is of particular concern in the elderly, who may have chronic diseases and are known to use more medicines than any other age group, increasing the risk of interactions. Additionally, in many serious diseases such as cancer and HIV, multidrug treatment is the standard of care.
- Use of medicines known to induce or inhibit cytochrome (CYP) enzymes, particularly CYP 3A4, which is responsible for the metabolism of many common pharmaceutical medicines.

STRATEGIES FOR PREVENTING AND LIMITING ADRs

Many countries are trying to cope with the growing problem of ADRs and their associated morbidity and mortality. Currently in Australia and New Zealand there are many structures and initiatives in place, such as regulatory agencies, the CMEC, 'quality use of medicines' organisations and information providers, safety and quality organisations and professional bodies; however, it is ultimately the practitioner and the patient who play the definitive roles.

Strategies for clinicians

- Encourage open and honest communication — between patient, carer and practitioner, and between fellow practitioners about treatments prescribed. One way of achieving this is for CM practitioners to label all dispensed herbal medicines with the botanical names of the herbs included in the product, together with suggested dosage, date of manufacture and practitioner's contact details.
- Take a careful medical and medicines history, including previous allergies and adverse effects.
- Consider non-medicinal treatments.
- Avoid polypharmacy and complicated treatment regimens.
- Become familiar with the potential safety issues associated with a medicine to avoid unnecessarily inducing an ADR or misdiagnosing one as a symptom of a new disease. An important adjunct to this is having access to reliable medical and CM information,

and having a network of experts or informed colleagues to consult. Computer-generated prescriptions and decision-support systems are frequently advocated as possible solutions and can be useful if their information is accurate and updated frequently.
- Regularly review therapeutic goals and medicines being used. This provides an opportunity to promote patient compliance and ensure that the appropriate medicines are being taken safely.
- When problems do arise, practitioners need to be aware of their professional responsibility to report a suspected ADR to one of the following:
  - Adverse Drug Reactions Advisory Committee (Reporting is confidential, open to everyone and is now possible online at www.tga.gov.au.)
  - Relevant herbal and natural medicine associations such as the National Herbalists Association of Australia, (www.nhaa.org.au)
  - Relevant manufacturer (Manufacturers keep their own records and are formally obliged to inform the TGA Prescriber, if applicable.)

Strategies for patients

Patients also play an important role in promoting a beneficial and harm-free outcome. They should ensure that they understand the benefits and potential risks associated with their treatment and be confident that they know how to take/use it appropriately. The Australian Commission on Safety and Quality in Health Care has produced a patient information booklet entitled *10 tips for safer health care* (ACSQHC 2006) to encourage patients to become more active in their own healthcare while in hospital. Many of the steps outlined in the booklet are relevant to people taking CMs in the community or in hospital.

Below is a summary of recommendations for patients choosing to use or currently using CM, adapted from *10 tips for safer health care*.
- Choose a suitably experienced and qualified CM practitioner or ask for referral from a trusted medical practitioner, pharmacist or other source.
- Become an active member of your own healthcare team. Help clinicians reach an accurate diagnosis, discuss appropriate management strategies, ensure treatment is administered and adhered to, identify side effects quickly and take appropriate action.
- Tell all healthcare practitioners about all the medicines being used (complementary and conventional). This includes telling doctors about complementary medicines and telling naturopaths and herbalists about pharmaceutical medicines.
- Make sure information given by the healthcare practitioner about the condition and the treatment options available is understood. In the case of lengthy explanations or recommendations, ask the practitioner to provide written information that can be taken home.
- Ask questions when you need more information because you are uncertain or the information provided is unclear.
- Be motivated to learn about the health condition being addressed, treatments being used and ways to improve wellbeing, by referring to reliable information sources.

THE RATIONAL USE OF HERBAL AND NATURAL MEDICINES

Overall, when manufactured, prescribed and used appropriately, the safety of OTC CMs is high. Serious adverse effects and dangerous interactions are rare, particularly in comparison with the thousands of reports attributed to pharmaceutical medicines. Even so, the assessment of likely adverse reactions or interactions should remain integral to patient management.

Currently, there are few large-scale clinical studies confirming and clarifying the clinical significance of most suspected adverse reactions and interactions associated with CMs, and much remains unknown. It is important to recognise that the information presented in this book requires individual interpretation, because the clinical effects of any medicine or any potential interaction, no matter how well documented, will not occur consistently in each patient, each time or to the same degree of intensity.

Ultimately, the ideal in clinical practice is to combine knowledge about the medicine and the disease, experience of both, and information about the patient and the individual's circumstance in order to make wise treatment choices (Table 7.6, p 92). This requires the application of current knowledge, as well as good observational skills, open communication and clinical experience to reduce the risk of adverse reactions and maximise successful outcomes.

TABLE 7.6 Factors to Consider in the Rational Use of Complementary Medicines

Factors to consider	Rationale
Products that are not produced under a code of GMP **should not be used.**	The quality of the product cannot be guaranteed.
Know the benefits, risks, potential adverse reactions and interactions and seek out reliable information. Additional training and/or access to accurate and updated information is important.	More than half the population use CMs and there is no sign of their popularity abating. Some CMs have proven benefits and offer cost-effective treatment options; however, safety issues also exist. Marketing/sales and company information is not sufficient, and education in the area of CM efficacy and safety may be limited.
Do not rely on label claims alone.	Although manufacturers must hold the evidence to support the claims made on a product label, often the label claims do not provide enough information to make an informed judgment.
Do not rely on label dose recommendations alone.	Some manufacturers state the lowest effective dose on the label to ensure that a patient's general requirements will be met; however, in practice, practitioners should prescribe a dose to meet the individual's needs, which may be higher than label doses, yet still be within safe limits.
Take care when high-risk medicines are involved.	In combination with drugs that have a narrow therapeutic index and many anticancer and HIV medicines, screen for interactions. In the case of herbal medicines, any product containing St John's wort (*Hypericum perforatum*) should be considered higher risk. Screen for interactions.
Take care with people considered to be at higher risk of adverse reactions or in 'at risk' circumstances.	Older age; reduced renal or liver function; acute or severe disease; polypharmacy; history of atopy and/or confusion; when drugs with a narrow therapeutic index are involved; during pregnancy or lactation; in children; before major surgery
Ensure that all health professionals involved in a patient's care are aware of CM use.	Effective communication will foster appropriate and safe use.
Do not assume all healthcare professionals have the knowledge to monitor safe use.	Few medical practitioners have had formal training in the safety issues of CM, and not all health practitioners have ready access to evidence-based safety data.
Know the manufacturer and supplier details.	If in doubt about a product, call the manufacturer or supplier for more information.
Know the prescriber's details (if relevant).	The original prescriber may have valuable information about the patient and the medicine, which may assist informed decision making.
Medicines should be stored appropriately.	Appropriate storage will depend on the patient's circumstance (e.g. at home, in hospital or in a hospice), level of vigilance and the type of medicine used.

CHAPTER 8
INTERACTIONS WITH HERBAL AND NATURAL MEDICINES

A pharmacological interaction is said to occur when the response to one medicine varies from what is usually predicted because another substance has altered the response. Usually the term 'interaction' has a negative connotation when referring to medicines, because it can lead to drug toxicity or a loss of drug effect, and it may be difficult to predict. However, interactions can also benefit the patient by improving outcomes, reducing side effects or reducing costs. In order for healthcare professionals to interpret interaction data and avoid or beneficially manipulate an interaction, or deal with an adverse effect due to an interaction, it is essential to have an understanding of the mechanisms involved.

Although thousands of drug interactions are studied each year, there has been relatively little scientific investigation into interactions with herbal and natural medicines. Research conducted with pharmaceutical medicines can provide some theoretical insights into the mechanisms of drug–herb interactions, but predicting clinical significance is difficult. Unlike conventional medicines, herbs and food-based supplements contain a complex mixture of bioactive chemicals, some of which may contribute to the overall therapeutic effect of the substances. The chemical composition is also variable and depends on factors such as the plant part used, seasonality, growing and harvesting conditions, and extraction and manufacturing processes. Furthermore, some plant constituents have poor oral bioavailability, so in vitro screening for interactions will produce misleading results.

Evidence from controlled human studies has been increasing steadily in recent years; however, most information is still derived from in vitro and animal experiments. This approach is not without its limitations, as using evidence to predict what will happen in humans from studies not conducted in humans is bound to have inaccuracies and therefore must be interpreted cautiously.

It must be mentioned that even when evidence from a controlled human study is available, predicting the likelihood and severity of a real-life interaction in a specific patient is still difficult and prone to error. Ultimately, the clinical importance of a herb–drug interaction depends on factors that relate to the medicines involved and the patients themselves. The chief medicinal factors will be dose, duration and frequency of use, and administration route. Individual patient factors include age, gender, food intake, gastric and urinary pH, current state of health, preexisting disease and genetic polymorphism.

INTERACTION MECHANISMS

When one considers the great variation in physical properties and pharmacological effects of the numerous substances used as medicines, together with the variable nature of herbal medicines, it is apparent that a virtually endless number of interactions are possible. It is generally accepted, however, that there are two major interaction mechanisms, namely pharmacokinetic and pharmacodynamic interactions. A third minor category of physicochemical or pharmaceutical interactions also exists. Regardless of the mechanism involved, there can be three possible outcomes from an interaction:

- increased therapeutic or adverse effects (additive or synergistic)
- decreased therapeutic or adverse effects (additive or synergistic)
- a unique response that does not occur when either agent is used alone.

PHARMACOKINETIC INTERACTIONS

Pharmacokinetics refers to the quantitative analysis of the absorption, distribution, metabolism and excretion of a medicine. Pharmacokinetic interactions occur when there is an alteration to any of these four processes, causing a change in the amount and persistence of available drug at receptor sites or target tissues. As a result, a change in the magnitude of effect or the duration of effect can occur without a change in the type of effect. Interactions of this type may have multiple mechanisms, making clinical predictions difficult. Additionally, there are many patient factors that influence the pharmacokinetics of a drug, such as age, liver and renal function, degree of physiological stress, and the presence of other diseases such as hyperthyroidism.

Factors affecting absorption

Drug absorption is determined by the physicochemical properties of a drug, as well as by its formulation and route of administration. Because most herbal and nutritional medicines are administered orally, as tablets, capsules, teas and tinctures, this discussion will focus on interactions associated with these dose forms.

Most absorption of orally administered medicines occurs in the small intestine, which has a larger surface area than the stomach and greater membrane permeability. If a slow-release dosage form is taken and it continues to release drug for more than 6 hours, then absorption will also occur in the large intestine. The absorption of oral dose forms is influenced by differences in pH along the gastrointestinal tract, surface area per luminal volume, blood perfusion, the presence of bile and mucus, and the nature of epithelial membranes. Changes to gastrointestinal flora, transport systems, chelation and ion exchange also influence absorption.

Interactions at this level can alter the rate of absorption and/or extent of absorption of a medicine.

Changes in relative rate of absorption

Although a medicine may eventually be fully absorbed, a significantly slowed absorption rate may mean that it never reaches effective serum levels, or that an unwanted 'sustained release' effect causes prolonged activity or a delay in prompt relief. In some clinical situations, decreased rates of absorption are of no concern; however, in others it may be important. Generally, a decreased rate of absorption is less important for medicines that are given in multiple-dose regimens to achieve a steady state serum level than for those that are given as single doses or are required to produce a rapid effect (e.g. analgesics).

Changes in extent of absorption

Altering the extent of absorption may also have significant consequences. Increasing the amount of medicine absorbed may produce higher plasma levels and a higher risk of adverse reactions or toxicity. Alternatively, reducing the amount of medicine absorbed may result in reduced efficacy or therapeutic failure. This is particularly of concern for medicines with a narrow therapeutic index, such as warfarin and digoxin.

Mucilaginous herbs

Although little research has been conducted to determine the effects of herbal medicines on the absorption of other medicines, one double-blind study found that guar gum slowed the absorption rate of digoxin, but did not alter the extent of absorption, whereas penicillin absorption was both slowed and reduced (Huupponen et al 1984). This brings into question the effects of other gums and highly mucilaginous herbal medicines, such as *Ulmus fulvus* (slippery elm), *Althea officinalis* (marshmallow) and *Plantago ovata* (psyllium). Poorly lipid soluble, the mucilaginous content forms an additional physical barrier to absorption, but whether this will have a clinically significant effect on rate and/or extent of absorption of other medicines is uncertain and remains to be tested.

Nutrients

More research has been conducted on the way nutrients interact and alter the absorption of pharmaceutical medicines than with herbal medicines. The interactions between iron and many minerals provide a useful example. Aluminium, calcium bicarbonate or magnesium trisilicate taken in antacid preparations are known to reduce the extent of iron absorption owing to an alteration in gastric pH. This type of interaction is easily avoided by separating the intake of iron by at least 2 hours from the last dose of antacid.

Intrinsic drug transporters

Until recently, when an orally administered medicine exhibited poor absorption, it was generally assumed that this was because of either

physicochemical problems or significant first-pass hepatic metabolism. Recently, it has been recognised that for many medicines poor oral bioavailability could be related to the influence of transporter proteins (Benet & Cummins 2001). Transporter proteins are associated with the transfer of some medicines from the intestinal lumen, through the biological barrier of the intestinal mucosa, into the systemic circulation and back again. Transporters fall into two main categories: carriers and pumps. Carriers are involved in three types of transport processes: facilitated diffusion, co-transport and counter-transport. Pumps are distinguished from carriers by the linkage of transport to an external source of energy. Examples of transporters in the intestine are P-glycoprotein (P-gp), members of the multi-drug-resistance-associated protein family (breast-cancer resistance protein, organic cation and anion transporters), and members of the organic anion polypeptide family (Wagner et al 2001). Of these, P-gp is the most studied (see *Clinical note*).

Herbal and natural medicines affecting P-gp

The influence of herbal and natural medicines on P-gp expression has only recently been considered, so much is still unknown and speculative. To date, most research has centred on St John's wort, although clinical testing with other herbs has now gained momentum: every few months more studies investigating the likelihood and clinical significance of proposed interactions are published.

In 1999, clinical testing found that St John's wort significantly reduces serum levels of digoxin after 10 days' co-administration (Johne et al 1999). The suspected mechanism of interaction was chiefly liver enzyme induction; however, the magnitude of effect seen in this study, and in others, suggested that P-gp induction was involved (Hennessy et al 2002). More recently, several clinical tests have confirmed that St John's wort has significant P-gp induction effects. One study found up to a 4.2-fold increase in P-gp expression compared with a placebo after 16 days' administration.

Clinical note — P-glycoprotein: an important drug transporter

P-glycoprotein was first studied in the context of cancer research, where its overexpression in tumour cells is associated with multi-drug resistance (Jodoin et al 2002). In cancer cells, P-gp is one of the transporters responsible for actively expelling chemotherapeutic drugs from cells, thereby decreasing intracellular concentrations and thus drug efficacy. As a result, identification of those substances that reduce P-gp expression and can be administered safely with chemotherapeutic agents is being investigated.

P-gp is found on the surface of hepatocytes, and epithelial cells of the renal tubules, the intestine, placenta and capillaries in the brain (Lin 2003). It plays an important role in the processes of absorption, distribution, metabolism and excretion of medicines. P-gp has a counter-transport activity, meaning it can transport medicines from the blood back into the gastrointestinal tract, thereby reducing bioavailability.

In humans, P-gp demonstrates genetic polymorphism, which may partly account for the inter-individual variability seen in drug absorption. One study conducted in 25 volunteers supports this idea and found that a greater than eightfold difference in expression of intestinal P-gp is possible (Lown et al 1997).

The expression of P-gp can be altered by a number of factors, such as everyday foods, herbs and pharmaceutical medicines. In the case of P-gp inhibition, there will be an increase in absorption, systemic exposure and tissue distribution of medicines that are P-gp substrates, whereas P-gp induction produces the opposite effect.

Interactions with substances that inhibit P-gp are of great interest, as they can potentially enhance the absorption of important medicines that are generally poorly absorbed, such as chemotherapeutic medicines. Alternatively, P-gp inhibition may theoretically increase the incidence of side effects or the toxicity of some medicines, producing unwanted effects.

Some important P-gp substrates are:

Berberine	Methotrexate
Colchicine	Morphine
Cortisol	Nifedipine
Cyclosporin	Progesterone
Digoxin	Protease-inhibitors
Erythromycin	Taxol
Indinavir	Tamoxifen
Loperamide	*Vinca* alkaloids

Similar results were seen in another study in which 14 days' administration of St John's wort resulted in a 1.4-fold increased expression of duodenal P-gp (Durr et al 2000). Induction of P-gp is attributed to pregnane X receptor activation by the hyperforin constituent (Lin 2003). Low hyperforin products are therefore less likely to induce P-gp.

St John's wort is not the only natural substance found to influence P-gp. In vitro studies suggest that rosemary extract may have the opposite effect, inhibiting P-gp. Treating multi-drug-resistant mammary tumour cells with rosemary extract produced an increase in intracellular concentrations of doxorubicin and vinblastine (both P-gp substrates) (Plouzek et al 1999). The same effects were not seen in cells that lack P-gp expression, suggesting that rosemary extract inhibits P-gp activity. The isoflavone genistein has also been investigated, with some results suggesting inhibition of P-gp-mediated drug transport (Castro & Altenberg 1997). Other studies have found that different polyphenols, such as green tea polyphenols, resveratrol (a polyphenol from red wine), curcumin, caffeine, theanine and methoxyflavones from orange, may inhibit drug transport via P-gp (Jodoin et al 2002).

Grapefruit juice is well known to interact with a number of medicines, so it is not surprising that it has also been investigated for effects on P-gp. Currently, evidence is conflicting, as several studies have found that components in grapefruit juice inhibit P-gp (Eagling et al 1999, Ohnishi et al 2000, Soldner et al 1999, Spahn-Langguth & Langguth 2001), whereas a randomised, crossover clinical study found no significant effects (Becquemont et al 2001). A more recent in vitro study produced similar results with 5% normal concentration of grapefruit, orange and apple juices; however, inhibition of other transporter proteins was observed (Dresser et al 2002).

New research suggests that quercetin inhibits P-gp expression (Choi & Li 2005, Chung et al 2005, Kitagawa et al 2005, Wang et al 2004). Studies with experimental models have demonstrated that pretreatment with quercetin increases the bioavailability of the calcium-channel blocker, diltiazem (Choi & Li 2005), and of digoxin (Wang et al 2004). Intriguingly, one in vivo study found quercetin significantly decreased the oral bioavailability of cyclosporin, which is the opposite to what would be expected, suggesting that other mechanisms may also be involved (Hsiu et al 2002).

Although in vitro studies have also identified an inhibitory effect on P-gp for silymarin, the active constituent group in St Mary's thistle (Chung et al 2005, Zhang & Morris 2003), recent clinical testing found no significant effect in vivo (Gurley et al 2006).

Table 8.1 (p 98) lists herbal and natural medicines that have suspected or known effects on P-gp, together with the research that gives evidence for these effects.

Factors affecting metabolism

Metabolism can occur before and during absorption, thereby limiting the amount of drug reaching the systemic circulation. In the intestinal lumen, digestive enzymes and bowel flora are capable of causing a wide range of metabolic reactions. The intestinal mucosa is also capable of metabolising drugs, with new research suggesting it is a major metabolic organ for some medicines (Doherty & Charman 2002).

For many medicines, metabolism chiefly occurs in the liver in two apparent phases, known as phase I or functionalisation reactions and phase II or conjugation reactions. Phase I reactions include oxidation, hydroxylation, dealkylation and reduction. Examples of Phase I reactions include conversion of an active drug to an inactive, less active, more active or toxic metabolite, and conversion of an inactive prodrug to an active metabolite. Phase II reactions include glucuronidation, sulfation, acetylation and methylation glutathionation, glycination and other amino acid conjugations (taurine, glutamine, carnitine, arginine), and usually result in the formation of inactive compounds that are water-soluble and easily excreted (Blower et al 2005).

Although there are many enzymes responsible for phase I reactions, the most important enzyme group is the cytochrome P450 system (CYP), which comprises more than 50 enzymes and is responsible for the metabolism of many drugs, nutrients, endogenous substances and environmental toxins.

Cytochromes

Cytochrome P450 is a generic term for a super-family of enzymes (haem containing mono-oxygenases) that have existed throughout nature since the beginning of life more than 3.5 billion years ago (Pirmohamed & Park 2003). The P450s are found chiefly in the liver, but also to a lesser extent in the intestines, kidneys, skin and lungs. These enzymes are

TABLE 8.1 Herbal and Natural Medicines with Suspected or Known Effects on P-Glycoprotein

Herbal/natural medicine	Effect	Evidence
St John's wort	Induction	Clinical studies (Hennessy et al 2002, Johne et al 1999) In vivo and clinical study (Durr et al 2000) In vitro (Perloff et al 2001), also positive for hypericin Case report (Barone et al 2000)
Grapefruit juice	Inhibition	Clinical studies (Di Marco et al 2002, Edwards et al 1999) In vivo (Spahn-Langguth & Langguth 2001, Tian et al 2002) In vitro (Eagling et al 1999, Ohnishi et al 2000, Soldner et al 1999, Takanaga et al 1998)
Grapefruit juice	No effect	Clinical study (Becquemont et al 2001)
Orange and apple juice	Inhibition	Clinical study: Seville orange (Di Marco et al 2002) In vivo: orange (Tian et al 2002) In vitro (Ikegawa et al 2000, Takanaga et al 2000)
Rosemary extract	Inhibition	In vitro (Plouzek et al 1999)
Genistein and diadzein	Inhibition	In vitro (Evans 2000, Castro & Altenberg 1997)
Genistein and diadzein	Possible induction	In vitro (den Boer et al 1998)
Resveratrol	Inhibition	In vitro (Jodoin et al 2002)
Curcumin	Inhibition	In vitro (Anuchapreeda et al 2002, Romiti et al 1998)
Quercetin	Inhibition	In vitro and in vivo (Choi & Li 2005, Chung et al 2005, Kitagawa et al 2005, Scambia et al 1994, Wang et al 2004)
Green tea polyphenols, especially epigallocatechin gallate	Inhibition	In vitro (Jodoin et al 2002, Sadzuka et al 2000)
Piperine (a major component of black pepper)	Inhibition	In vivo (Bhardwaj et al 2002)
St Mary's thistle	Inhibition	In vitro tests (Chung et al 2005, Zhang & Morris 2003)
St Mary's thistle	No effect	Human study (Gurley et al 2006)

responsible for foreign compound metabolism, which evolved about 400–500 million years ago to enable animals to detoxify chemicals in plants. The cytochrome P450 (CYP) enzymes are the most powerful in vivo oxidising agents and are able to catalyse the oxidative biotransformation of a wide range of chemically and biologically unrelated exogenous and endogenous substrates. They are named by a root symbol CYP, followed by a number for family, a letter for subfamily, and another number for the specific gene. For example, CYP3A4 would refer to a specific enzyme from the cytochrome P450 system, family 3, subfamily A and gene 4. Three main CYP families (CYP1, 2, 3) are responsible for metabolism of therapeutic drugs. The different P450 isoforms vary in their abundance within the liver. Of these, the cytochromes CYP2C9, CYP2D6 and CYP3A4 are the most abundant in the human body (Pirmohamed & Park 2003).

The CYP2C sub-family accounts for 15–20% of the total P450 content of the liver, and metabolises approximately 20% of all drugs (Pirmohamed & Park 2003). The main member of this sub-family is CYP2C9, which is responsible for the metabolism of a number of compounds, including warfarin, phenytoin and various NSAIDs. Cytochrome 2D6 is responsible for the metabolism of approximately 25% of therapeutically used drugs, although it accounts for only < 5% of the total P450 content. The CYP3A sub-family accounts for 30% of the total P450 content and is responsible for metabolism of about 50% of therapeutic drugs. Table 8.2 provides examples of common drugs

TABLE 8.2 Selected Drugs that Act as Substrates for CYP Enzymes

CYP enzyme	Drugs
CYP1A2	amitriptyline, caffeine, melatonin, naproxen, paracetamol, tacrine, theophylline, verapamil, R-warfarin
CYP2B6	amitriptyline, diazepam, methadone, midazolam, tamoxifen, temazepam, testosterone
CYP2C9	amitriptyline, celecoxib, diclofenac, fluoxetine, ibuprofen, tamoxifen, S-warfarin
CYP2C19	amitriptyline, imipramine, indomethacin, omeprazole, progesterone, propranolol, R-warfarin
CYP2D6	amitriptyline, beta blockers, codeine, fluoxetine, flecainide, haloperidol, nicotine, ondansetron, paroxetine, sertraline, tamoxifen, tramadol
CYP3A4	alprazolam, caffeine, codeine, cyclosporin, erythromycin, HIV antivirals (e.g. indinavir), lovastatin, midazolam, oestradiol, ondansetron, progesterone, simvastatin, tamoxifen, taxol, testosterone

and the cytochromes chiefly responsible for their metabolism. For a more complete list that is frequently updated, see Flockhart 2007.

The expression and activity of many CYP isoenzymes vary enormously between individuals. Part of the inter-individual variability is environmentally determined by the concomitant intake of drugs and foodstuffs that cause induction and inhibition of the different P450 isoforms. P450 gene polymorphism may also influence expression and activity of CYP enzymes, as this can lead to:

- abolished activity of a CYP enzyme (e.g. CYP2C9, CYP2C19 and CYP2D6 can be genetically absent in some livers [USFDA 2006])
- reduced activity
- altered activity
- increased activity where there is gene duplication.

For example, one study identified that 30% of Ethiopians had multiple copies of the 2D6 gene (up to 13), resulting in ultra-rapid metabolism of CYP2D6 substrates (Aklillu et al 1996). As a result, standard doses of CYP2D6 substrates (e.g. beta-blockers, some opioids and tricyclic antidepressants) will not produce anticipated or adequate responses, and higher drug doses are necessary to produce therapeutic effects. It has also been estimated that 7% of Caucasians lack CYP2D6. These individuals will not experience the anticipated therapeutic effects of prodrugs that are CYP2D6 substrates, such as codeine, and will appear more sensitive to the side effects of CYP2D6 substrates (e.g. beta-blockers, some opioids and tricyclic antidepressants) (USFDA 2006).

Another example is the polymorphic distribution of CYP2C9, which is absent in 1% of Caucasians. More than 100 currently used drugs are known substrates of CYP2C9, corresponding to approximately 10–20% of commonly prescribed drugs. Of note, CYP2C9 is chiefly responsible for the metabolism of NSAIDs and COX-2 specific inhibitors (e.g. celecoxib).

Many other factors affect CYP activity, such as the ingestion of foreign compounds (e.g. environmental contaminants) or the ingestion of certain constituents found in food, beverages and medicines.

Because of overlapping substrates, many drug interactions involve both P-gp and CYP3A4.

Enzyme inhibition

Competitive CYP inhibition is dose-dependent and occurs when inhibitors compete with other substances for a particular enzyme. Non-competitive inhibition is also possible and occurs when a substance either destroys or binds irreversibly to a CYP enzyme. In both instances, serum levels of those drugs chiefly metabolised by the affected enzyme will become elevated and the inhibition process is rapid. This is of particular concern with medicines that have a narrow therapeutic index, as very small changes in dose or blood levels can produce significant changes in activity. In the case of enzyme inhibition, raised blood levels can lead to increased side effects and toxicity.

Although inhibition of a CYP enzyme is generally regarded as raising the serum levels of an active drug, this is not always the case. If the drug involved is a prodrug, then it is inactive in its administered form and must be converted to its active form, usually via metabolic processes. If metabolism is slowed, then

the production of active metabolites will also be slowed. An example is codeine, which is primarily metabolised by CYP2D6 into its active analgesic metabolite morphine; therefore, CYP2D6 inhibition has the potential to slow or reduce its analgesic activity.

Inhibitors do not all have the same strength and can be classified as strong, moderate or weak, depending on their effect on drug clearance compared to normal values. For example, Flockhart describes a strong inhibitor as one that causes more than 80% decrease in clearance, a moderate inhibitor as one that causes a 50–80% decrease in drug clearance, and a weak inhibitor as one that causes a 20–50% decrease in drug clearance (Flockhart 2007).

Enzyme inhibition is not always harmful and has been manipulated to raise serum drug levels without the need to increase the dose administered. The result has obvious cost advantages when extremely expensive drugs are involved and has been used in some hospitals for medicines such as cyclosporin.

To date, the most studied natural substance capable of significantly inhibiting CYP enzymes is grapefruit. The finding that grapefruit juice markedly increases the bioavailability of some orally administered medicines was based on an unexpected observation from an interaction study between the calcium-channel antagonist felodipine and ethanol. In the study, grapefruit juice was used to mask the taste of ethanol, but actually affected the results by reducing CYP3A4 by 62% and significantly raising felodipine levels (Bailey et al 1998). Since then, the constituents of grapefruit juice have been extensively studied and found to affect the transport and metabolism of many other medicines (Eagling et al 1999, Kane & Lipsky 2000).

Increasingly, research is being conducted to determine whether other commonly used herbal medicines have an affect on CYP activity in vivo. For example, one research group in the United States screened *Citrus aurantium*, *Echinacea purpurea*, milk thistle (*Silybum marianum*), and saw palmetto (*Serenoa repens*) extracts for effects on CYP1A2, CYP2D6, CYP2E1 and CYP3A4 activity in healthy subjects (Gurley et al 2004). Of the four herbs, only *E. purpurea* was found to have any effect on the CYP enzymes tested, with a minor influence on CYP1A2 and CYP3A4. Using the same method, extracts of the herbs goldenseal (*Hydrastis canadensis*), black cohosh (*Cimicifugaracemosa*), kava kava (*Piper methysticum*) and valerian (*Valeriana officinalis*) were tested for effects on CYP1A2, CYP2D6, CYP2E1 or CYP3A4/5 activity (Gurley et al 2005). Goldenseal strongly inhibited CYP2D6 and CYP3A4/5 activity in vivo, whereas kava kava inhibited CYP2E1, black cohosh weakly inhibited CYP2D6 and no effect was observed for valerian. In a separate study, testing *Panax ginseng* and *Ginkgo biloba*, no effect was observed on CYP activity; however, garlic oil inhibited CYP2E1 activity by 39% (Gurley et al 2002). There are many other examples to be found in the individual monographs of this book.

Enzyme induction

Alternatively, many different medicines and everyday substances have been found to induce the CYP enzymes (e.g. broccoli, Brussels sprouts, char-grilled meat, high-protein diets, tobacco and alcohol). Research is now identifying a number of herbal medicines that cause CYP induction to various degrees; however, the most studied to date is St John's wort.

Clinical tests have confirmed that long-term administration of St John's wort has significant CYP inducer activity, particularly CYP3A4 (Durr et al 2000, Roby et al 2000, Ruschitzka et al 2000, Wang et al 2001). It appears that the hyperforin component is a potent ligand for the pregnane X receptor, which regulates expression of CYP3A4 mono-oxygenase. In this way, hyperforin increases the availability of CYP3A4, resulting in enzyme induction (Moore et al 2000).

Lack of in vitro — in vivo correlation

It is interesting to observe an apparent lack of in vitro – in vivo correlation with some studies of CYP. For instance, in vitro investigations implicate milk thistle extract and/or silibinin as inhibitors of human CYP3A4, CYP2C9, CYP2D6 and CYP2E1; however, in vivo evidence for CYP-mediated interactions by milk thistle is less compelling (Gurley et al 2004). This may be owing to poor bioavailability of key constituents, large inter-individual differences in absorption of constituents, inter-product variability in the ratios of constituent, poor dissolution of dosage forms or other mechanisms.

Factors affecting excretion

The kidneys are the major organs of excretion, but it also occurs to a lesser extent via other routes such as saliva, sweat, faeces, breast milk

Clinical note — Pharmacogenetics

Pharmacogenetics largely deals with genes encoding drug transporters, drug-metabolising enzymes and drug targets (Ingleman-Sundberg 2004). It is now well established that the polymorphism of metabolising enzymes, and in particular that of cytochromes P450s, has the greatest effect on inter-individual variability of drug response, as evidenced by many studies. These polymorphisms affect the response of individuals to drugs used in the treatment of depression, psychosis, cancer, cardiovascular disorders, ulcer and gastrointestinal disorders, pain and epilepsy, among others. The costs of genotyping are reducing and our knowledge about the benefits of predictive genotyping for more effective and safe drug therapy is increasing. This means that in future predictive genotyping for CYP enzymes will become routine, allowing individualised prescribing to produce better clinical outcomes with less risk of side effects.

and the lungs. If a medicine is chiefly eliminated by one pathway, then alterations to that particular pathway can theoretically have a significant influence on its excretion.

With regard to urinary excretion, factors that alter renal function can interfere with the excretion of medicines and their metabolites. There are three main ways that renal function can be modified (Blower et al 2005):

- altered renal tubular reabsorption by substances that affect urinary pH
- changes in renal tubular secretion by agents that either compete for active secretion or that alter the activity of membrane transporter proteins
- changes in glomerular filtration induced by agents that alter cardiac output.

Alterations to urinary pH are easily achieved with regard to herbal and natural substances; for example, the half-life of an acidic medicine, such as a salicylate, can be increased with acidification of urine — for example, with high doses of ascorbic acid, because less is eliminated. Alternatively, the half-life of a weakly basic drug, such as amphetamine, may be decreased when urine is acidified. Alkalisation of urine produces the opposite effects and can occur with low-protein diets or the ingestion of substances such as potassium citrate.

PHARMACODYNAMIC INTERACTIONS

Pharmacodynamic interactions result when one substance alters the sensitivity or responsiveness of tissues to another. This type of interaction results in additive, synergistic or antagonistic drug effects and is of particular concern when medicines used simultaneously have overlapping toxicities.

In practice, clinicians frequently use additive or synergistic pharmacodynamic interactions to improve clinical outcomes. For example, medical doctors may prescribe a combination of antibiotics against difficult-to-eradicate microorganisms, or several antihypertensive drugs to one patient. Herbalists widely prescribe combinations of herbs with similar actions to strengthen clinical effects, and naturopaths may combine nutritional and herbal supplements in a similar way.

Pharmacodynamic interactions do not always produce wanted results, such as when several medicines with overlapping adverse effects or toxicities are used together, leading to more serious adverse effects. An example is the combined use of an opioid analgesic, which can induce drowsiness, and an antiemetic drug such as metoclopramide, which can also induce drowsiness. Other unwanted effects include potentiating drug activity to a clinically uncomfortable or dangerous level, or reducing activity and therefore the effectiveness of treatment.

Although pharmacodynamic interactions involving herbal and natural medicines and pharmaceutical medicines have not been thoroughly investigated, theoretical predictions are easy to produce. For example, case reports suggest that kava kava may have dopamine receptor antagonist activity and therefore theoretically can interact with dopamine agonists (e.g. L-dopa), opposing their effect (Meseguer et al 2002, Spillane et al 1997). Predicting real-life responses is difficult, because the evidence does not come from a controlled clinical study and individual factors such as dose, administration route and patient health further influence outcomes.

PHYSICOCHEMICAL INTERACTIONS

Physicochemical interactions occur when two substances come into contact and are either physically or chemically incompatible. This

type of interaction can take place during the manufacture or administration of medicines and can affect both the rate and the extent of absorption of one or both medicines. Physicochemical interactions are a well-known concern among medical herbalists and naturopaths who prescribe and dispense their own herbal combinations.

Reduced absorption

Tannins

Herbs with significant tannin content have the potential to be involved in physicochemical interactions with other medicines, both outside and within the body, because they form precipitates with proteins, nitrogenous bases, polysaccharides and some alkaloids and glycosides (Mills 1991). Additionally, tannins will form complexes with metal ions such as iron, inhibiting their absorption (Glahn et al 2002). To avoid this interaction, herbal extracts containing tannins are traditionally not mixed with extracts containing alkaloids (Bone & Mills 2000).

In practice, herbal medicines containing tannins are used both internally and externally. When used internally, it is recommended that they be taken between meals or on an empty stomach to minimise precipitation of dietary proteins and digestive enzymes in the gut (Baxter et al 1997). Additionally, tannins can reduce the absorption of some minerals, so should not be taken at the same time. For example, the absorption of iron is significantly reduced in the presence of tannins, with one study finding amounts as small as 5 mg of tannic acid are able to inhibit iron absorption by 20% and higher levels of 100 mg by 88% (Brune et al 1989).

Tannins are widely found in the plant kingdom, as shown in Table 8.3.

TABLE 8.3 Common Herbs with Significant Tannin Content

Common name	Botanical name
Agrimony	*Agrimony eupatorium*
Bearberry	*Arctostaphylus uva-ursi*
Bistort	*Polygonum bistorta*
Meadowsweet	*Filipendula ulmaria*
Raspberry	*Rubus idaeus*
Rhubarb	*Rheum* spp. root
Spinach	*Chenopodium* spp.
Tea	*Camellia sinensis*
Tormentil	*Potentilla tormentilla*

Chelation

Physicochemical interactions can also occur via a process of chelation, which is the chemical interaction of a metal ion and other substance that results in the formation of a molecular complex in which the metal is firmly bound and isolated. In other words, the metal ion irreversibly binds to a second molecule, leading to reduced activity or inactivation of that metal. A common example is the interaction between iron and various drugs, including tetracycline antibiotics.

A number of compounds found naturally in food have the potential to interact with medicines in this way. For example, oxalic acid found in spinach and rhubarb or phytic acid found in bran can form insoluble complexes with calcium, thereby reducing its absorption.

Increased absorption

Not all physicochemical interactions result in reduced absorption. It is widely accepted that interactions between plant components can enhance clinical effects by increasing the bioavailability of key pharmacologically active constituents.

The results of continuing investigation into the chemistry of St John's wort provide a good example. In vivo studies using hypericin and pseudohypericin found that the solubility of these two active constituents increases by approximately 60% in the presence of natural procyanidins (Butterweck et al 1998). Further research has isolated naturally occurring hyperoside, rutin and quercetin as some of the key components responsible for this interaction.

Although still largely speculative, the interaction between naturally occurring surfactant constituents, such as saponins, and poorly lipid soluble active constituents could feasibly result in increased absorption through a micellisation process. Besides improving oral bioavailability, the interaction could also improve dermal penetration.

Different forms of saponins are widely found in the plant kingdom and are used either internally or externally, depending on the particular herb (Table 8.4).

SYNERGY HERBAL RESEARCH

In practice, herbalists use inter-herbal interactions to produce better outcomes. This practice is much the same as that of medical practitioners employing multi-target drug therapy in the treatment of cancer, hypertension

TABLE 8.4 Common Herbs Containing Saponins	
Common name	**Botanical name**
Astragalus	*Astragalus membranaceus*
Bupleurum	*Bupleurum falcatum*
Horsechestnut	*Aesculus hippocastanum*
Japanese ginseng	*Panax japonicus*
Licorice	*Glycyrrhiza glabra*
Poke root	*Phytolacca decandra*
Soybean	*Glycine max*
Withania	*Withania somnifera*

and antibiotic resistance. Owing to the chemical complexity of herbal medicines, intra-herbal interactions are also being identified that largely explain the therapeutic superiority of many herbal drug extracts over single constituents isolated from the same herbal extracts. Synergistic effects can be produced if the constituents of an extract affect different targets or interact with one another in order to improve the solubility and thereby enhance the bioavailability of one or several substances of an extract. Synergy research in phytomedicine has established itself as a new activity in recent years and focuses on studying intra-herbal and inter-herbal interactions to better understand how therapeutic benefits can be harnessed.

INTERACTION SCREENING TOOLS

Information about interactions is derived from in vitro tests, studies with experimental animal models and, increasingly, clinical studies. Most interactions studies conducted to date have focused on herbal constituents and their effects on cytochrome (CYP) enzymes and, increasingly, P-glycoprotein (P-gp), with few studies investigating effects on drug transport or phase II metabolism.

In vitro tests

Most studies conducted to investigate herb–drug interactions have used in vitro testing of herbal constituents in microsomal systems, supersomes, cytosols, expressed enzymes or cell-culture systems such as transfected cell lines, primary cultures of human hepatocytes and tumour-derived cells. While in vitro models provide a quick screening method for potential herb–drug interactions they do not always correlate with in vivo findings. One problem frequently encountered in the existing in vitro literature is the use of inappropriately high concentrations of single, isolated constituents obtained from commercial sources, and utilisation of these in experiments when only a small fraction of the compound may actually be bioavailable. Many natural products are generally subject to first-pass metabolism and to a much larger extent than conventional pharmaceutical agents, which are in most cases specifically developed to be substantially bioavailable or otherwise formulated as prodrugs. In addition, many are less bioavailable because of their hydrophilic nature or large molecular size (Markowitz et al 2008).

Animal studies

These studies may give important information on herb interactions. Probe substrates/inhibitors can be used to explore the effects of herbs on the activity of specific CYP enzyme in vivo, e.g. caffeine for CYP1A2, tolbutamide for CYP2C9, mephenytoin for CYP2C19, dextromethorphan or debrisoquin for CYP2D6, chlorzoxazone for CYP2E1 and midazolam or erythromycin for CYP3A4. In addition, a cocktail of probe drugs have been used to explore the activities of multiple CYPs in the same experiment. Ultimately, in vivo clinical studies are more reliable than in vitro tests as a means of determining the clinical importance of herb–drug interactions, although these studies can quickly be confounded by the documented variability found in specific constituents between individual botanical products as well as by the choice of probe substrates administered (Markowitz et al 2008).

Relying solely on in vitro or animal model experiments to predict clinically relevant herb–drug interactions is problematic and can provide inaccurate information. The herbs *Ginkgo biloba* and saw palmetto will be used here as examples to illustrate this point.

In vitro and/or tests with animal models have shown both cytochrome induction and inhibition for *Ginkgo biloba* (Shinozuka et al 2002, Ryu & Chung 2003, Ohnishi et al 2003, Kubota et al 2004, Kuo et al 2004, He & Edeki 2004, Gaudineau et al 2004, von Moltke et al 2004, Sugiyama et al 2004a, Sugiyama et al 2004b, Chatterjee et al 2005, Chang et al 2006a, Mohutsky et al 2006a, Zhao et al 2006, Chang et al 2006b). In contrast, four clinical studies have failed to identify a clinically significant effect on a variety of cytochromes. In one clinical study, Gurley et al (2002) demonstrated that *Ginkgo biloba* had no significant effect on CYP1A2, CYP2D6 or CYP3A4 activity. Markowitz et al (2003b) also conducted a

human study and found no significant effects on CYP2D6 or CYP3A4 activity. Two further clinical studies found no significant effect for *Ginkgo biloba* on CYP2C9 activity (Greenblatt et al 2006, Mohutsky et al 2006b).

Saw palmetto showed potent inhibition of CYP3A4, CYP2D6, and CYP2C9 in vitro (Yale & Glurich 2005); however, no significant effect was observed on CYP2D6 or CYP3A4 activity according to a clinical study by Markowitz et al (2003a). Gurley et al (2004) also found no significant effect for saw palmetto on CYP1A2, CYP2D6, CYP2E1 or CYP3A4 activity in healthy subjects.

To add to the complexity of the problem, in some instances researchers have conducted testing with individual herbal components or different forms of a herb and found different effects on CYPs. For example, using animal models Fukao et al (2004) demonstrated that diallyl sulphide (100 micromol/kg) increased cytochrome CYP2E1 activity slightly but significantly (1.6-fold versus control), whereas diallyl disulfide and diallyl trisulfide did not affect CYP2E1 activity or the hepatic total CYP level or CYP1A1/2 activity. The significance of these results in clinical practice is difficult to determine, as the overall effect on CYP activity will depend on the concentrations of these various constituents present in a garlic product. The example also highlights the general difficulty in extrapolating results for one herbal extract to another, as there may be a significant chemical variation between batches of the same herbal product and between different products of the same herb grown and produced by various manufacturers.

Clinical studies

These studies provide the most relevant information; however, they are costly to produce and are mostly conducted with young, healthy males, which may or may not accurately reflect the responses of other populations (e.g. women, the elderly).

Table 8.5 presents a summary of the strengths and limitations relevant to different types of interactions research.

PUTTING THEORY INTO PRACTICE

It is clear that many patients will be taking herbal and natural medicines and pharmaceutical medicines at some stage of their lives. In some instances, use will overlap, so a patient will be taking several medicines at the same time. In order to promote the safe use of all medicines, the following section provides ideas for consideration and discussion, practical tools to aid in reducing the risk of interactions and in detection of adverse reactions, and general recommendations.

INTERACTION MECHANISMS

Predicting the clinical importance of a herb–drug interaction is difficult and largely depends on factors that relate to the medicines administered and the individual patient. Having an understanding of the interaction mechanisms involved is also essential.

Medicine factors

Consider the types of medicines involved, administration route, dosage and duration of use. Drugs with a narrow therapeutic index are of most concern, as minor changes to serum levels can have clinically significant outcomes. Drugs that are administered intravenously will not always be subject to the same concerns as orally ingested drugs. In the case of herbal medicines, some preparations contain multiple CYP or transporter-modulating constituents, with some constituents causing induction and others inhibition. This means the overall outcome will depend on the amount of inducer/inhibitor constituents present, the CYPs or transporters affected and the relative strengths of inducers/inhibitors. Since herbal medicines naturally vary in constituent ratios owing to environmental and process factors, their effects on CYPs and transporters are more difficult to predict than for single-entity drugs.

Individual patient factors

The severity of the interaction is also influenced by factors such as age, gender, preexisting medical conditions and comorbidities, environmental influences and diet. Genetic polymorphism is increasingly becoming recognised as another significant factor altering a patient's risk of experiencing adverse drug reactions. The importance an interaction is given is also related to some extent to the setting in which it occurs. Risk can be minimised or managed when patients openly discuss their use of herbal and pharmaceutical medicines with all their healthcare providers and they are carefully supervised.

Problems and pitfalls interpreting the evidence

Firstly, understanding the basic mechanisms involved is essential, as is keeping in mind the type of evidence that might suggest the possibility

of an interaction. It is important to note the general lack of correlation between in vitro and in vivo tests, and the inaccuracies of extrapolating data from animal models to predict clinical significance in humans. In many cases, interaction studies are absent, so clinicians must use their professional judgment to evaluate what is known about the medicines and the patient, and then the likelihood of a clinically relevant interaction.

A PREDICTIVE ALGORITHM

The METOPIA algorithm provides a framework for healthcare professionals when making rational decisions about the introduction of a second, potentially interacting medicine. In this chapter, it is assumed that a herbal medicine is involved. METOPIA stands for:

Medication and mechanisms

- What types of medicines are involved? High-risk medicines such as those with a narrow therapeutic index require closer monitoring.
- Is an interaction theoretically possible? This needs to be based on a fundamental understanding of the pharmacokinetic parameters and pharmacodynamic effects of the medicines involved.

Evidence available?

- Is there supportive evidence for an anticipated interaction?
- If so, what is the weight of that evidence (theoretical, in vitro, in vivo, case reports or clinical trials)?

If the information gathered so far suggests an interaction is possible, continue with the following steps.

Timing and dose — introducing which, when and for how long?

- When are the medicines being taken — at the same time or are doses separated by several hours? It is particularly important to determine the timing if a physicochemical interaction is anticipated.

TABLE 8.5 Advantages and Limitations of Herb–Drug Interaction Studies

Study type	Advantages	Limitations
In vitro	Provides information about specific mechanisms under controlled conditions. Relatively simple to conduct compared with clinical studies. Inexpensive tests to conduct compared with clinical studies. Relatively quick to conduct.	Does not account for poor bioavailability of the test compound. May use one isolated constituent, whereas herbal extracts contain multiple constituents. Does not account for human genetic polymorphism. May use clinically irrelevant concentration. Metabolites of botanical extracts are poorly characterised for most extracts and may contribute to the net inhibitory or inductive effects observed, which will not be detected with in vitro testing.
In vivo using animal models	Can address some of the issues relating to bioavailability. Can produce quicker results than clinical studies. Can provide information when clinical studies are not able to be conducted.	Species variations make results difficult to interpret. Selection of appropriate dosage can be difficult and very large doses are often used. Does not account for human genetic polymorphism.
Clinical studies	Provide the most relevant information and are the most definitive.	Most studies conducted in healthy male subjects; however, most relevant results are obtained when conducted with the population that will be using the product. Inter-product variability in constituent ratios means tested product may not accurately represent effects of other products. Cannot differentiate between gut and liver effects (e.g. cytochromes). Does not provide information about mechanisms. Are costly and time consuming. May never be done for ethical reasons (e.g. safety studies in pregnancy).

- What is the duration of use? Interaction mechanisms may develop only over several days or weeks (such as CYP induction), or may occur more rapidly.

Outcomes possible

- What is the potential clinical outcome of an interaction — major, minor or neutral? In regard to herbal medicine, this is often speculative.

Practitioner considerations

- Is the practitioner in a position to monitor and manage an interaction should it become significant? In a hospital setting, an interaction is generally considered important if something must be done to relieve patient symptoms or if it will have a significant impact on critical therapy. Practitioners and nursing staff are in an ideal position to monitor for interactions and respond quickly should this be necessary. In a community setting, general practitioners, pharmacists, naturopaths and herbalists are better placed, and adequate patient self-monitoring becomes more important.

Individual considerations

- What are the patient's individual preferences and ability to self-monitor a potential interaction should it arise?

Action required

Having established the criteria so far, five actions are possible:

- *Avoid* — consider an alternative treatment that is unlikely to produce undesirable interaction effects.
- *Avoid unless adequate medical monitoring is possible* — changing the dose and regimen may be required for safe combined use.
- *Caution* — tell patients to be aware that a particular event is possible and to seek advice if they are concerned.
- *Observe* — the practitioner is alert to the possibility of an interaction, even though it is unlikely to have clinical consequences and is likely to be a neutral interaction.
- *Prescribe* — the outcome of the interaction is beneficial and can be used to improve clinical outcomes.

ASSESSING THE LIKELIHOOD OF AN ADVERSE DRUG–HERB INTERACTION

The likelihood that an adverse reaction is responsible for a patient's presenting signs and symptoms should always be considered. If suspicious, then it is essential to take appropriate steps to clarify the likelihood of an adverse reaction.

Patient evaluation

Factors to consider are:

- detailed description of the event — severity of symptoms, signs, onset, duration, frequency
- differential diagnoses (e.g. non-medicinal causes, such as exacerbation of condition, laboratory error or an interaction).

Causality and probability

Determining a cause-and-effect relationship between a medicine and an adverse reaction can be difficult. The degree of certainty that links a medicine to a specific reaction can be classified as definite, probable, possible, conditional or doubtful, and must be assessed in each individual case. Several algorithms exist to help clinicians determine the likelihood of an adverse reaction. Table 8.6 shows the Naranjo algorithm adapted for use as an interaction detection tool (Naranjo et al 1981). The adverse drug reaction possibility classification is based on the total score:

>8	highly probable
4–7	probable
1–3	possible
0	doubtful

NEXT STEPS IF INTERACTION IS LIKELY

Analysis of the medicine

If an interaction involving a herbal or natural medicine is highly likely, then it must be authenticated, botanically verified and analysed for the presence of contaminants. These essential steps will establish whether the interaction is due to an intrinsic property of the medicine itself, and therefore reproducible, or to extrinsic factors such as poor manufacturing processes.

Case reporting

All suspected adverse reactions should be reported to several authorities:

- The local government agency responsible for post-marketing surveillance and collecting adverse drug reaction case reports. In Australia this is the Adverse Drug Reactions Advisory Committee (ADRAC) (Reporting

TABLE 8.6 Assessing the likelihood that an adverse reaction is caused by an Interaction

Question	Yes	No	Don't know	Score
Do previous conclusive reports of this interaction exist?* It is suggested that several resources are examined to determine whether the report is a possible, probable or confirmed interaction.	+1	0	0	
Did the adverse event appear after the suspected medicine/herb/nutrient was co-administered?	+2	–1	0	
Did the adverse reaction improve after the suspected medicine/herb/nutrient was discontinued?	+1	0	0	
Did the adverse reaction reappear when the medicine/herb/nutrient was readministered?	+2	–1	0	
Are there alternative causes (other than the suspected medicine/s) that could produce this reaction?	–1	+2	0	
Was the medicine detected in the blood (or other fluids) at levels known to be toxic or subtherapeutic, when previous levels were within the normal range?	+1	0	0	
Was the reaction more severe when the dose of medicine/herb/nutrient was increased, or less severe when decreased?	+1	0	0	
Has the patient had a similar reaction to the same or similar medicine in any previous exposure, when concomitant complementary medicines were not used?	–2	+1	0	
Was the event confirmed by objective evidence?	+1	0	0

- Relevant local herbal and natural medicine associations such as the National Herbalists Association of Australia (www.nhaa.org.au)
- Relevant product manufacturer (Manufacturers keep their own records and are obligated to inform the TGA.)
- Prescriber, if applicable.

Chapter 7 provides further practical information about the safe use of CAM and risk factors for adverse events and interactions.

TWO MEDICINES REQUIRING SPECIAL ATTENTION

DIGOXIN

Digoxin is a drug indicated for the treatment of numerous cardiac ailments, such as atrial fibrillation and severe heart failure. It has a positive inotropic effect on both normal and failing hearts, although its primary benefit is mediated by neurohormonal modulation. It has a narrow therapeutic index and therefore minor changes in dose or serum levels can have clinically significant consequences. Digoxin is subject to pharmacokinetic and pharmacodynamic interactions with pharmaceutical, herbal and natural medicines, resulting in possible therapeutic failure or toxicity.

Potassium changes

Potassium states are of special concern with digoxin because hypokalaemia lowers the threshold for drug toxicity. It is well known that pharmaceutical medicines such as thiazide diuretics and corticosteroids have the potential to induce a state of hypokalaemia. There are several herbal medicines that require attention such as *Glycyrrhiza glabra* (licorice), *Paullinia cupana* (guarana) and anthraquinone laxatives (e.g. aloes, buckthorn, cascara and senna). As with potassium-depleting drugs, adequate potassium intake should be recommended and potassium levels monitored together with clinical signs and symptoms.

Alternatively, there are a number of herbal medicines and foods that contain significant amounts of potassium that could increase the threshold for drug efficacy. Some of the common herbs and foods containing greater than 50,000 ppm of potassium include asparagus, beetroot, bok choy, cucumber, lettuce, rhubarb, *Avena sativa* (oats), *Taraxacum officinale* (dandelion) and *Apium graveolens* (celery).

P-gp and changes to metabolism

Digoxin is a substrate for P-gp, therefore serum digoxin levels are altered when P-gp induction or inhibition occurs. It is known that drugs such as verapamil and quinidine, which affect P-gp, can significantly interact with digoxin and in recent years several herbal and natural medicines have also been identified with the potential to alter P-gp activity. Of these, the herb St John's wort has been investigated under controlled clinical conditions and found to decrease the digoxin area-under-the-curve by 25% after 10 days' treatment (Johne et al 1999). Monitoring of plasma digoxin concentration and clinical effects is required when patients commence or cease St John's wort while taking digoxin. As discussed earlier, several other herbs affect P-gp expression and concurrent use should be supervised.

Pharmacodynamic interactions

Pharmacodynamic interactions are theoretically possible when herbs containing naturally occurring cardiac glycoside constituents, such as oleander (*Nerium oleander*), false hellebore (*Adonis autumnalis*) and lily of the valley (*Convallaria majalis*), are ingested at the same time. Although not commonly prescribed for internal use, theoretically these plants may reinforce drug activity and induce symptoms of toxicity. Signs and symptoms of digoxin toxicity include anorexia, nausea, vomiting, diarrhoea, weakness, visual disturbances and ventricular tachycardia.

It has been speculated that the herb hawthorn (*Crataegus oxyacantha*) could potentiate the effects of cardiac glycosides, as both in vitro and in vivo studies indicate that it has positive inotropic activity. Furthermore, the flavonoid components of hawthorn also affect P-gp function and cause interactions with drugs that are P-gp substrates, such as digoxin. In practice, however, results from a randomised crossover trial that evaluated co-administration of digoxin 0.25 mg with *Crataegus* special extract WS 1442 (hawthorn leaves with flowers) 450 mg twice daily for 21 days found no significant difference to any measured pharmacokinetic parameters (Tankanow et al 2003). Although this is reassuring, combined use should be supervised by a healthcare professional and drug requirements monitored.

In practice, the likelihood and significance of these interactions varies considerably, and the response required to ensure safe use of medicines can be multifaceted. For example, if Mr A has been taking St John's wort for several months and then digoxin is introduced, routine monitoring of digoxin levels enables appropriate doses to be determined and ensures the safe use of both medicines. However, it is essential to advise Mr A to inform his healthcare professional when use of St John's wort is going to be ceased or the dosage changed, as digoxin levels will require closer monitoring during the change. On the other hand, if Mrs B has been taking digoxin for some time and then St John's wort is to be introduced, additional monitoring is required for at least 3 weeks to determine whether a new effective digoxin dose is required. Once again, if there is to be an alteration to St John's wort use, Mrs B should be advised to see a healthcare professional for monitoring during the transition.

Interference with therapeutic drug monitoring for digoxin

In 1996, a case was reported of a possible interaction between Siberian ginseng and digoxin (McRae 1996). More specifically, it involved an elderly man whose serum digoxin levels rose (but did not produce toxic symptoms) when he concurrently took a Siberian ginseng product, fell when the product was stopped, and then rose again when use was resumed. Unfortunately, the report was inaccurate, as the product was later analysed and found to contain digitalis. Additionally, no case reports suggesting drug toxicity were published over the following years. Research published earlier this year suggests that eleutherosides found in the herb are chemically related to cardiac glycosides and may interfere with digoxin assays. Furthermore, several other herbal medicines have been identified with the ability to interfere with drug monitoring for digoxin, such as Dan Shen, Chan Su, *Uzara* root and Asian ginseng (Dasgupta 2003). According to Dasgupta, monitoring free digoxin eliminates the interference from Dan Shen and Chan Su, but is not useful in overcoming interference by Siberian or Asian ginseng. For these herbs, using the EMIT urine test or the Bayer, Randox, Roche or Beckman assays is appropriate.

WARFARIN

Warfarin is an important anticoagulant drug with a narrow therapeutic index. If blood levels become elevated, potentially serious

TABLE 8.7 Suspected or known interactions between Digoxin and Herbal Medicines

Increased digoxin effects possible	Decreased digoxin effects possible
Herbs that induce potassium loss with long-term use: • *Glycyrrhiza glabra* (licorice) • *Paullinia cupana* (guarana) • Anthraquinone-containing herbal laxatives (senna, cascara, aloes and buckthorn) Some herbal diuretics may also induce some degree of potassium loss; however, clinical significance is unknown.	Herbs currently known to induce P-gp and/or CYPs in a clinically significant manner: • *Hypericum perforatum* (St John's wort)
Herbs containing cardiac glycosides: • *Nerium oleander* (oleander) • *Adonis autumnalis* (false hellebore) • *Convallaria majalis* (lily of the valley)	Herbs containing > 50,000 ppm potassium: • *Avena sativa* (oats) • *Taraxacum officinale* (dandelion) • *Apium graveolens* (celery)
Pharmacodynamic interaction theoretically possible, although not seen in one clinical study: • *Craetagus oxyacantha* (hawthorn)	Foods containing >50,000 ppm potassium: • asparagus • beetroot • bok choy • cucumber • lettuce • rhubarb • spinach
Herbs and natural constituents known or suspected to inhibit P-gp or CYPs: • apple juice • curcumin • daidzein • genistein • grapefruit • green tea polyphenols • orange juice (seville oranges) • piperine • quercetin • resveratrol • rosemary extract	

consequences can arise if bleeding complications develop, whereas reduced blood levels can result in failure to protect the patient from thromboembolic events. Pharmacologically, the anticoagulant effect is dependent on its ability to interfere with hepatic synthesis of vitamin K-dependent clotting factors. As such, any significant changes to vitamin K ingestion can alter the drug's activity. Common foods with high vitamin K levels (> 100 micrograms/100 g) are: beef (liver), broccoli, cabbage, cauliflower, egg yolk, kale, lettuce, spinach, canola oil (rapeseed) and soybean oil.

Pharmacodynamic interactions

Pharmacodynamic interactions can theoretically occur when other medicines with coagulant or anticoagulant activity are used concurrently. Medicines with antiplatelet activity, such as ginger and garlic, can theoretically increase the risk of bruising or bleeding when taken concurrently with warfarin. Other herbal medicines suspected to potentiate the pharmacological effects of warfarin include guarana and bilberry in very high doses. Alternatively, herbs containing naturally occurring coumarins exhibit weak anticoagulant activity, if any at all (unless converted to dicoumarol as a result of improper storage), so do not necessarily pose an additional bleeding risk (see also Chapter 9).

The case of *Ginkgo biloba* is a curious one, as there is evidence that one of its components, ginkgolide B, is a potent platelet-activating factor antagonist (Smith et al 1996). However, three placebo-controlled studies have failed to detect a significant effect on platelet function or coagulation (Bal Dit et al 2003, Jiang et al 2005, Kohler 2004). One was an escalating dose study, which found that 120 mg, 240 mg or 480 mg given daily for 14 days did not alter platelet function or coagulation (Bal Dit

et al 2003). Interaction studies have further found that the INR does not increase when patients are concurrently taking *Ginkgo biloba* with warfarin (Engelsen et al 2002, Jiang et al 2005). Owing to the serious nature of such potential interactions, a cautious approach is advised.

Pharmacokinetic interactions

Warfarin consists of a pair of enantiomers and is extensively metabolised by CYP1A2, 3A4 and 2C9. Metabolism of the more biologically active isomer, the S form, occurs chiefly by CYP2C9, whereas a minor metabolic pathway is CYP3A4. The less potent R isomer is chiefly metabolised by CYP1A2. Therefore, any alteration to the expression or activity of these specific enzymes can affect the drug's pharmacokinetics.

As is the case with nearly all herbal medicines, predicting the clinical significance of these theoretical interactions is difficult because most evidence currently comes from in vitro and in vivo tests and case reports.

THE RATIONAL USE OF HERBAL AND NATURAL MEDICINES

Overall, when manufactured and prescribed appropriately, the safety of herbal and natural medicines is high. Serious adverse effects and dangerous interactions are rare, particularly in comparison with the thousands of reports attributed to pharmaceutical medicines. Even so, the assessment of adverse reaction and interaction likelihood should remain integral to patient management.

Currently, there are few large-scale clinical studies confirming and clarifying the clinical significance of most suspected interactions, so the two algorithms presented in this chapter should be used only as general guides. As always, it is important to recognise that using this information in practice requires individual interpretation, because the clinical effects of any interaction, no matter how well documented, will not occur consistently in each patient, each time or to the same degree of intensity. Ultimately, it is the application of current knowledge together with good observational skills, open communication and clinical experience that will reduce the risk of unwanted interactions and maximise successful outcomes. Table 8.8 lists key steps towards the rational use of herbal and natural medicines.

TABLE 8.8 Rational Use of Herbal and Natural Medicines

- Be informed and seek out unbiased information — do not rely on label claims alone.
- Know the benefits, risks, potential adverse reactions and interactions — additional training and/or access to accurate and updated information is important.
- Do not assume all healthcare professionals have the knowledge to monitor safe use.
- Be aware that medical practitioners' and pharmacists' knowledge of herbal and natural medicines may be limited.
- Ensure that all healthcare professionals involved in a patient's care stay informed of herbal and natural medicine use.
- Take care with children, the elderly, and pregnant or lactating women.
- Take care when high-risk medicines are being taken.
- Take care with HIV, cancer or other serious illnesses.
- Know the manufacturer or supplier details.
- Store medicines appropriately.

CHAPTER 9
PREOPERATIVE CARE: CONSIDERATIONS

Reducing the risk of surgery and maximising successful outcomes is the common effort of surgeons, anaesthetists, physicians, nurses and other healthcare professionals. However, few consider the influence of herbal and natural medicines and whether this has the potential to alter outcomes. Even fewer consider the effects of these medicines after surgery. This chapter explores the potential of herbal and natural medicines to hinder surgical outcomes and also introduces the concept of using these medicines beneficially.

EXTENT OF CM USE

According to a number of hospital surveys conducted in the United States and in Australia, use of complementary medicines (CMs) is well established among surgical patients (Braun et al 2006a, Grauer 2004, Kaye et al 2000, Leung et al 2001, Norred 2002, Norred et al 2000, Silverstein & Spiegel 2001, Tsen et al 2000).

One survey of 3106 patients attending preoperative clinics in the USA found that 51% were using CMs, and that women were more likely users than men (Tsen et al 2000). Age was also a factor, with patients aged between 40 and 60 years greater consumers of CMs. Overall, only 21% of patients sought advice from a healthcare provider about supplement use, whereas the majority cited friends and family or their own decision as reasons for taking these medicines.

Another survey of 1017 patients presenting for pre-anaesthetic evaluation found that approximately one in three were taking one or more herb-related compounds (Kaye et al 2000). Disturbingly, nearly 70% of these patients did not report use when they were asked during routine anaesthetic assessment. Lack of communication was also detected in a review of 2560 patients, which identified that 39% were taking natural supplements, with herbal medicines being the most popular (Leung et al 2001). Of these, 44% did not consult with their primary-care physician and 56% did not inform their anaesthetist before surgery.

Similar trends have also been identified among Australian surgical patients (Braun et al 2006a, Grauer 2004). A survey of 508 presurgical inpatients at two tertiary hospitals found that in the 2 weeks before admission, 46% had used CMs, of which 38% were self-prescribed (Braun et al 2006a). Just over half these patients planned to continue using them while in hospital. During the 2 weeks before admission, 64% had not discussed use with any community-based or hospital-based healthcare professional. Similar to findings of other studies, patients using CMs were most likely to be female, and to have pursued higher education and earn above-average income. Interestingly, this study found that age was not predictive of use, and that older patients were just as likely as young patients to be using CM. Importantly, 58% of surgical patients did not discuss their use with a hospital doctor, nurse or pharmacist. When patients were asked why they did not tell hospital staff, it was not because they feared being judged negatively, but overwhelmingly because they were not asked. This was also the first Australian study to ask patients about their interest in hospital-based CM therapies; 85% expressed an interest.

Previously, a study that evaluated preoperative use of CM products at two other hospitals had found that 20.4% had used vitamin

supplements and 14.3% herbal medicines in the previous 6 weeks, but only 28% had informed hospital staff about use (Grauer 2004). Once again, the majority of patients had self-selected their treatment.

These findings pose several important questions, such as whether surgeons, anaesthetists, physicians or pharmacists are aware of the potential safety issues associated with CMs, routinely ask patients about herbal and natural medicines in a way that encourages open dialogue, and have the knowledge and resources to interpret the answers. Survey results published in 2001 found that, although physicians did ask about herbal and natural medicine use, most did not check with reference texts for more information (Silverstein & Spiegel 2001). Disturbingly, the survey also detected an obvious lack of knowledge about common herbal medicines among physicians. A more extensive study was conducted recently with hospital doctors and pharmacists at an Australian tertiary hospital (Braun et al 2006b). The study of 127 surgeons, anaesthetists, physicians and pharmacists found that 68% thought CMs could be dangerous and that patients' use needs to be monitored; however, only 28% routinely asked patients about CM use. All groups lacked knowledge and confidence in dealing with CAM, and 81% felt they had insufficient knowledge to be able to identify whether a CM product could adversely affect patient care. Despite this, few checked for side effects or interactions when patients using CMs were identified.

When patients do report using herbal and natural medicines, hospital doctors and pharmacists do not routinely document this information in patients' charts, making effective communication even more difficult (Braun et al 2006b, Cohen et al 2002). Cohen et al (2002) found the prevalence of supplement use was 64% in a group of 212 patients, but only 35% of all supplements were recorded in patients' charts.

ASSESSING POTENTIAL FOR ADVERSE EFFECTS

The use of CAM by surgical patients should not pose any serious concern, unless they have the potential to cause adverse reactions that would negatively affect the outcome of surgery and impede recovery. Potential unwanted effects such as increased bleeding risk, sympathomimetic effects or detrimental interactions with medicines commonly used in the perioperative period are some examples.

Two studies conducted in the United States have investigated this further and suggest that some CM products used by surgical patients have the potential to alter bleeding risk, cardiovascular stability and interact with anaesthetics. A survey of 500 elective surgical patients found that 51% used CAM products during the 2 weeks before surgery, and that 27% of CMs taken had the potential to inhibit coagulation, 12% to affect blood pressure, 9% to cause sedation, 5% to have cardiac effects and 4% to alter electrolytes (Norred et al 2000). A larger survey of elective outpatients from 16 hospitals in the United States found that 67% used herbal and natural supplements or homoeopathic medicines and, of these, 34% used medicines that had the potential to interact with anaesthetics or to inhibit coagulation (Norred 2002). A review of the medicines used identified garlic (9.5%), cranberry (5.2%), ginkgo (4.6%), ginseng (4.2%), echinacea (4.1%) and products containing ephedra (3.2%) as the most commonly consumed herbal medicines, whereas multivitamins (37.5%), vitamin E (23.3%), calcium (21.5%) and vitamin C (21.4%) were the most commonly taken nutritional supplements.

Although useful, the results obtained by these two papers should be interpreted carefully because much of the safety information presented is speculative and based on studies conducted in other populations or test models. Close inspection of the lists of herbal and natural supplements claimed to inhibit coagulation reveals that no distinction is made between those medicines with clinically observed effects and those with predicted effects based on in vitro or in vivo evidence. Furthermore, the majority of claims made about adverse reaction potential are based on case reports and in vitro and in vivo tests, and not on controlled clinical trials. Without documenting where evidence comes from for each claim, readers can easily give equal weight to all claims, making the lists of limited clinical value and likely to overstate the risk. Additionally, both papers fail to state full botanical names when referring to herbal medicines and are open to misinterpretation.

Developing a list of herbal and natural supplements with a realistic potential to cause adverse effects in surgery is difficult at the current time, as the pharmacology of many of these medicines, including pharmacodynamic and pharmacokinetic properties, has yet to be fully elucidated. Until evidence from controlled

clinical studies is available, other evidence will be used but should be interpreted cautiously.

SAFETY, SIDE EFFECTS AND INTERACTIONS WITH OTHER MEDICINES

The risk of harm associated with the use of CMs is largely unknown; however, it is likely to be greatest in high-risk surgery; that is, when the surgical procedure to be undertaken and the patient's health status put the patient at real risk of serious complications. Factors such as preexisting fluid and electrolyte status, cardiorespiratory performance, comorbidities and medical pretreatments need to be considered when assessing safety in patients (Girbes 2000). Additionally, the type of surgical procedure should be considered, in particular those procedures in which increased bleeding would be a serious complication (e.g. orthopaedics or neurosurgery) or put significant physical strain on the patient (e.g. coronary bypass) would be considered high risk.

BLEEDING RISK

Surgery is often associated with some degree of blood loss, but this is usually limited by the body's haemostatic mechanisms, which finely regulate interactions between components on the blood vessel walls, circulating platelets and plasma proteins. A retrospective survey of adverse surgical outcomes in several US hospitals found that postoperative bleeding accounted for 10.8% of all surgical adverse events, making it the third most frequent adverse surgical event (Gawande et al 1999). In practice, whether bleeding risk is a serious concern is usually dictated by the type of surgery to be undertaken. For instance, minor dental procedures would not be as seriously affected by increased bleeding as neurosurgery.

A number of explanations may account for increased bleeding, such as undiagnosed clotting disorders, liver disease or the preoperative use of certain medicines such as antiplatelet agents. Over time, it has become recognised that some CMs also have the potential to influence the body's haemostatic response. Initially evidence was derived from case reports suggesting CM use was associated with bleeding or from in vitro tests indicating antiplatelet activity; however an increasing number of clinical studies are now being published to more rigorously determine which CAM products cause clinically significant bleeding.

Herbal medicines and food supplements

Whether preoperative use of herbal medicine alters bleeding risk is difficult to determine because few controlled trials are available for this specific population. Evidence is usually extrapolated from other sources to identify those medicines with suspected antiplatelet or anticoagulant activity and, while still largely speculative, this provides a guide until more robust evidence is available.

Difficulties arise when evidence is contradictory, making clinical recommendations even more difficult. The herb *Tanacetum parthenium*, also known as feverfew, provides a good example. Several test-tube studies and animal models have observed inhibition of platelet aggregation (Heptinstall et al 1988, Jain & Kulkarni 1999, Makheja & Bailey 1982); however, no significant effects were seen in a small study of 10 patients receiving feverfew (Biggs et al 1982). The problem of inconsistent information can add to practitioners' confusion, as some databases are infrequently updated or give undue weight to case reports and seemingly less consideration of safety information derived from clinical studies. The case of ginkgo biloba illustrates this point.

Ginkgo biloba

Ginkgo biloba is a popular herbal medicine used mainly for cognitive decline and peripheral vascular diseases, supported by good evidence. Concern over whether *G. biloba* significantly increases bleeding first arose in response to several case reports describing haemorrhage during or after surgery (Hauser et al 2002, Schneider et al 2002) and evidence that one of its components, ginkgolide B, is a platelet-activating factor antagonist (Smith et al 1996). In the following years, at least 10 clinical studies have been conducted that have found no evidence of significant bleeding or platelet effects due to *G. biloba* ingestion (Bal Dit et al 2003, Engelsen et al 2003, Kohler et al 2004, Jiang et al 2005, Wolf 2006, Beckert et al 2007, Gardner et al 2007, Aruna & Naidu 2007, Lovera et al 2007, Carlson et al 2007). Studies have included young healthy volunteers, older adults, people with multiple sclerosis and people using warfarin or aspirin at the same time as *G. biloba*. An escalating-dose study found that 120 mg, 240 mg or 480 mg given daily for 14 days did not alter platelet function or coagulation (Bal Dit et al 2003). Only one clinical study demonstrated that EGb761 (80 mg/day) produced a significant

reduction in blood viscosity after 30 days' treatment (Galduroz et al 2007). When the available body of evidence is considered, it appears unlikely that *G. biloba* causes a significant bleeding risk to most patients. Unfortunately, a number of popular electronic databases and reference texts still cite bleeding risk as a major concern with its use, particularly when used in combination with warfarin (Braun 2008).

Food supplements contain concentrated forms of dietary foods, such as fish oils or fibre. Herbal and food supplements overlap in many cases because various herbs are also eaten as foods (e.g. ginger). Keeping this in mind, it is not unusual to find evidence suggesting that normal dietary intake of a food does not appreciably alter bleeding risk, whereas ingesting concentrated products will. For example, 4 g ginger daily does not alter platelet aggregation or fibrinogen levels according to one clinical study, whereas a dose of 10 g/day significantly reduces platelet aggregation according to another (Bordia et al 1997).

Commonly used herbal medicines and food supplements available OTC that have been found to inhibit platelet aggregation under clinical test conditions include garlic, ginger root, onion, policosanol and pine bark extract (Araghi-Niknam et al 2000, Arruzazabala et al 2002, Bordia et al 1975, 1997, Harris et al 1990, Jung et al 1991). Often, very high doses above normal dietary intakes are required to produce these results.

Fish oils

Fish oils supplements are extremely popular and are considered by some healthcare professionals to increase the risk of bleeding in surgery. A search through the Medline database reveals several case reports where bleeding episodes are attributed to fish oil ingestion (Buckley et al 2004, Jalili & Dehpour 2007, McClaskey & Michalets 2007). In each case, the person affected was elderly and also taking warfarin. One was a report of an elderly man taking high-dose omega-3 fatty acids (6 g/day) with both aspirin and warfarin who developing a subdural haematoma after a minor fall (McClaskey & Michalets 2007). Another case is reported of a 67-year-old woman taking warfarin for 1.5 years who doubled her fish oil dose from 1000 to 2000 mg/day, causing an associated elevation in INR from 2.8 to 4.3 within 1 month (Buckley et al 2004). A third case was of a 65-year-old male who had been taking warfarin for 6 months and then was recommended trazodone and fish oils, causing his INR to rise to 8.06 (Jalili & Dehpour 2007).

Although these case reports suggest omega-3 fatty acids interact with warfarin and increase the risk of bleeding, several intervention studies have come to a different conclusion. One randomised study of 511 patients taking either aspirin (300 mg/day) or warfarin (INR 2.5–4.2) found that a dose of 4 g/day of fish oils did not increase the number of bleeding episodes, bleeding time or any parameters of coagulation and fibrinolysis (Eritsland et al 1995). A smaller placebo-controlled study by Bender et al (1998) of patients receiving chronic warfarin therapy found that fish oil doses of 3–6 g/day produced no statistically significant difference in INR between the placebo lead-in and treatment period within each group. There was also no difference in INR between groups.

Most recently, Harris (2007) examined 19 clinical studies that used doses of fish oil varying from 1 g/day to 21 g/day in patients undergoing major vascular surgery (coronary artery bypass grafting, endarterectomy) or femoral artery puncture for either diagnostic cardiac catheterisation or percutaneous transluminal coronary angioplasty. Of note, in 16 studies patients were taking aspirin and in 3 studies patients were taking heparin. The review concluded that the risk of bleeding was virtually non-existent. Frequent comments accompanying the studies were 'no difference in clinically significant bleeding noted' or 'no patient suffered from bleeding complications'. The same conclusion was reached in a 2008 review that stated no published studies have reported clinically significant bleeding episodes amongst patients treated with antiplatelet drugs and fish oils (3–7 g/day) (Harris et al 2008). In light of this body of evidence, it is apparent that fish oil supplementation does not significantly increase bleeding risk.

Emerging evidence further suggests that administration of fish oil to presurgical patients before cardiothoracic surgery has significant benefits, such as reduced rate of postoperative atrial fibrillation (Calo et al 2005). Such benefits have major implications for patients, hospital administrators and hospital waiting lists.

Salicylate-containing herbs

Many salicylate-containing herbs, such as willowbark and meadowsweet, are suspected of having blood-thinning activity based on their chemical relationship to aspirin. When these

herbs are ingested, salicylic acid is formed, which accounts for some of their anti-inflammatory and antipyretic activity. The synthesis of aspirin involves adding an acetyl group to salicylic acid, which not only reduces the irritant effect of the salicylic acid but also confers an antiplatelet effect. The conversion of salicylic acid to acetylsalicylic acid does not occur in the body, so it is unlikely that these herbs will have an appreciable effect on bleeding (Forrelli 2003). This has been borne out in a clinical study, which found that a therapeutic dose of *Salicis cortex* extract (willowbark containing 240 mg salicin per daily dose) produced a total serum salicylate concentration bioequivalent to 50 mg acetylsalicylate, which had a minimal effect on platelet aggregation (Krivoy et al 2001).

Coumarin-containing herbs

A similar confusion has arisen surrounding the presence of naturally occurring coumarin compounds in herbs. Coumarin compounds are benzo-alpha-pyrones and are found in popular herbal medicines such as dong quai, alfalfa, celery, fenugreek and red clover. Nearly all natural coumarin compounds contain a hydroxyl or methoxy group in position 7, whereas dicoumarol and related anticoagulants are hydroxlated in the 4 position (Bone & Mills 2000). This difference in chemical structure is important because it influences the entity's potential to induce significant anticoagulant activity. It has been estimated that natural coumarins, which naturally are not substituted at the 4 position, have one-thousandth the anticoagulant activity of dicoumarol, so are unlikely to cause significant bleeding episodes (Bone & Mills 2000). As an example, a placebo-controlled study failed to identify significant changes to platelet aggregation, fibrinolytic activity or fibrinogen for the herbal medicine fenugreek, even though it contains naturally occurring coumarins (Bordia et al 1997).

Nutritional supplements

The safety of using preoperative nutritional supplements is also largely based on suspected antiplatelet or anticoagulant activity and is poorly researched. As such, identifying key supplements that increase bleeding risk is not straightforward and contradictory evidence also exists. Vitamin E provides a good example.

Although widely cited as affecting bleeding times, clinical studies with vitamin E supplements have produced conflicting results in recent years. According to one clinical study, a daily dose of 1200 IU of vitamin E (800 mg of D-alpha-tocopherol) taken for 28 days had no effect on platelet aggregation or coagulation compared with controls (Morinobu et al 2002). A dose of 600 mg (900 IU) of RRR-alpha-tocopherol taken for 12 weeks did not alter coagulation activity compared with placebo in another clinical study (Kitagawa & Mino 1989). However, doses of 75 IU and 450 IU have been shown to decrease platelet aggregation in human subjects in other studies (Calzada et al 1997, Mabile et al 1999).

ELECTROLYTE STATUS AND BLOOD-PRESSURE EFFECTS

Whether preoperative use of CAM products significantly alters electrolyte status or blood pressure and thus increases the surgical risk is unknown and still largely speculative. Controlled trials are unavailable, so evidence is extrapolated from other sources to identify those medicines with suspected activity.

Glycyrrhiza glabra

There are a small number of OTC herbal medicines with the potential to induce hypokalaemia, sodium retention or significant cardiovascular effects. The best documented of these is probably *Glycyrrhiza glabra* (licorice), which has significant pharmacological activity and the potential to cause adverse effects when used long-term in high doses. Determining a dose that is safe for all is difficult, as there is a great deal of individual variation in susceptibility to the herb's effects. One dose-response study that tested licorice in a variety of individuals has identified that doses as low as 50 g (75 mg glycyrrhetinic acid) taken daily for 2 weeks are capable of raising blood pressure in sensitive individuals (Sigurjonsdottir et al 2001). A return to baseline levels may take several weeks according to Commission E (Blumenthal et al 2000) and is also likely to vary between individuals.

G. glabra raises blood pressure and produces oedema by significantly decreasing serum concentrations of cortisol, ACTH and aldosterone, and increasing renin and sodium levels in a dose-dependent manner (Al Qarawi et al 2002). Glycyrrhetinic acid is the main constituent responsible, causing an 11-beta-hydroxylase deficiency secondary to an inability to convert 11-deoxycortisol or deoxycorticosterone into active glucocorticoids, cortisol and corticosterone (Heilmann et al 1999).

Paullinia cupana

Based on the herb's caffeine content and diuretic activity, *Paullinia cupana* (guarana) may potentially induce hypokalaemia and unwanted cardiovascular effects when used in excessive doses. Although these effects have not been tested in controlled clinical settings, results obtained for caffeine and the following case report provide some evidence of cardiovascular activity. A 25-year-old woman with preexisting mitral valve prolapse was reported as developing intractable ventricular fibrillation after consuming a 'natural energy' guarana health drink containing a high concentration of caffeine (Cannon et al 2001).

Panax ginseng

Despite *Panax ginseng*'s reputation for altering blood pressure, current evidence is contradictory and difficult to assess. Both hypotensive and hypertensive effects have been observed in animal studies with this herb, which is also known as Korean ginseng. However, interpreting the significance of these results is difficult, because injectable forms are sometimes used. Clinical observations are also contradictory, with both elevations and reductions in blood pressure having been reported (Valli et al 2002).

TISSUE PERFUSION AND REPERFUSION INJURY

Unfortunately, many critically ill surgical patients survive surgery only to die of infection or organ dysfunction over the ensuing days or weeks (Nathens et al 2002). The precise mechanism by which organ dysfunction occurs is unclear; however, there is increasing evidence that tissue injury is mediated at least in part by reactive oxygen species derived from inflammatory cells and the vascular damage caused by ischaemia–reperfusion injury. Based on this theory, research has begun to investigate the effects of pre- and postsurgical treatment with several medicines, such as antioxidant supplements. Probably the most research conducted to date has involved coenzyme Q10.

Coenzyme Q10 pretreatment

Clinical studies investigating the effects of oral coenzyme Q10 (CoQ10) supplementation before cardiac surgery suggest it may improve postoperative cardiac function, efficiency of mitochondrial energy production, reduce intraoperative myocardial structural damage and significantly reduce hospital stays (Chello et al 1996, Chen et al 1994, Judy et al 1993, Rosenfeldt et al 2002, Taggart et al 1996, Tanaka et al 1982, Zhou et al 1999).

One placebo-controlled study involving 100 patients investigated the effects of oral CoQ10 (30–60 mg) taken 6 days before surgery and found that treatment significantly lowered the incidence of low cardiac output during recovery (Tanaka et al 1982). These results suggest that presurgical treatment with CoQ10 increased myocardial tolerance to ischaemia during surgery. A smaller, randomised double-blind study also found reduced incidence of low cardiac output during recovery with CoQ10 pretreatment and a lowered incidence of elevated left atrial pressure (Chen et al 1994). Additionally, ventricular myocardial structure was better preserved in patients receiving CoQ10 before surgery, as measured by electron microscopy.

Besides having beneficial effects on cardiac output, pretreatment with CoQ10 has a number of other effects. A randomised, placebo-controlled study of 40 patients undergoing elective coronary artery bypass found that CoQ10 (150 mg/day) taken for 7 days before surgery produced a significantly lower incidence of ventricular arrhythmias during the recovery period compared with placebo (Chello et al 1994). Additionally, mean dopamine dosage required to maintain stable haemodynamics was significantly lower with CoQ10 pretreatment. One placebo-controlled study involving high-risk surgical patients used 100 mg/day CoQ10 for 14 days before surgery and for 30 days afterward (Judy et al 1993). This treatment regimen dramatically hastened the recovery to 3–5 days, compared with 15–30 with a placebo, and significantly reduced the incidence of complications.

A recent randomised, double-blind trial investigated the effects of preoperative high-dose CoQ10 therapy (300 mg/day) in patients undergoing elective cardiac surgery (mainly coronary artery bypass graft surgery or valve replacement) (Rosenfeldt et al 2005). The study of 121 patients found that approximately 2 weeks of active treatment resulted in significantly increased CoQ10 levels in the serum, atrial myocardium and mitochondria compared to a placebo; however, no effects on duration of hospital stay were seen. Active treatment improved subjective assessment of physical QOL (+13%) in the CoQ10 group compared with the placebo; however, the authors point out that physical quality of life

does not necessarily indicate improved cardiac pump function and further studies are required with larger sample sizes to clarify the role of CoQ10 in cardiac surgery.

Most recently, a 3-year prospective randomised clinical trial was completed at the Alfred Hospital in Melbourne. This involved 117 patients of mean age 65 years who were undergoing elective coronary artery bypass graft and/or valve surgery with or without coronary bypass (Leong et al 2007). Coenzyme Q10 (300 mg/day) was administered together with other natural metabolic agents (magnesium orotate 1200 mg/day, alpha lipoic acid 100 mg/day, omega-3 fatty acids 3000 mg/day and selenium 200 μg/day) or identical placebos for a minimum of 2 weeks before and 1 month after surgery. Active treatment produced a highly significant reduction in the release of plasma troponin I at 24 hours ($P = 0.003$) postoperatively, indicating reduced cardiac muscle damage. Additionally, patients undergoing coronary artery bypass surgery experienced a significant 50% reduction in postoperative atrial fibrillation. It was also found that patients in the placebo group stayed 17% (6%–30%) longer in hospital than those in the metabolic group ($P = 0.002$). This result equates to an extra 1.3 days. These findings have major implications for patients' long-term mortality, quality of life and hospital costs.

The encouraging results obtained from CoQ10 in cardiac surgery may have special significance for the elderly, because recovery of cardiac function in this group is inferior to younger patients. It has been suggested that the aged myocardium is more sensitive to stress, and may therefore not be as well equipped to deal with the physical stress sustained during surgery. Rosenfeldt et al (1999) confirmed this theory, demonstrating an age-related deficit in myocardial performance after aerobic and ischaemic stress and the capacity of CoQ10 treatment to correct age-specific diminished recovery of function.

Although most clinical research has been conducted in patients undergoing cardiac surgery, one study suggests that pretreatment may have benefits in other situations. The effects of randomly assigned supplemental oral CoQ10 (150 mg/day) in 30 patients undergoing elective vascular surgery for abdominal aortic aneurysm or obstructive aorto-iliac disease abdominal clamping also produced positive results (Chello et al 1996). Pretreatment for 7 days before surgery reduced the degree of peroxidative damage during abdominal aortic cross-clamping compared with that seen in the placebo group.

Although CoQ10 is the most studied antioxidant vitamin supplement for cardiac surgery support, investigation into others has begun.

INTERACTIONS WITH MEDICINES COMMONLY USED DURING SURGERY

An interaction is said to have occurred if there is an alteration to the predicted effect of one substance when it has been given together with

Clinical note — Alfred Hospital's Integrative Cardiac Wellness Program

In recent years the increasing incidence of high-risk and elderly patients presenting for major surgery has presented a challenge for surgeons, due to the associated increased mortality and complication rate and costs. Over the last few years at the Alfred Hospital and the Baker Heart Research Institute, Melbourne, Australia, researchers in the Cardiothoracic Surgical Research Unit, led by Professor Frank Rosenfeldt, have developed regimens of metabolic therapy with the pyrimidine precursor orotic acid, and the antioxidant and mitochondrial respiratory chain component coenzyme Q10. These regimens improve the response of the ageing and failing heart to hypoxia, ischaemia/reperfusion injury and aerobic stress such as occur during cardiac surgery. Omega-3 fatty acids and the antioxidant alpha-lipoic acid have been added to the metabolic cocktail, in light of emerging research showing benefits for this population. The metabolic regimen is now being combined with holistic therapy comprising inpatient and outpatient wellness education to create a novel integrative program of 'perioperative rehabilitation'. This approach is known as the Integrative Cardiac Wellness Program and officially commenced at the Alfred Hospital in 2008.

For more information, see www.thealfred.org.au/icwg/.

another. Owing to this lack of predictability, the term 'interaction' is often given a negative connotation, but interactions can also be manipulated to advantage and offer potential benefits to patients.

As discussed in Chapter 8, herb–drug interactions have not been extensively researched in clinical studies. As such, recommendations are based on the best available evidence at the time of writing, chiefly sourced from primary biomedical literature. Furthermore, clinicians using this information in practice are advised that it requires individual interpretation, as the clinical effects of any interaction, no matter how well documented, will not occur consistently in each patient, each time or to the same degree of intensity.

Although there are myriad different surgical procedures currently being performed in hospitals and day-surgery centres, the same general drug classes tend to be used. These are analgesics and anaesthetics. In both cases, concurrent use of herbal and natural medicines theoretically has the potential to produce unwanted interactions or, alternatively, beneficial interactions.

ANALGESICS

Pain is a complex phenomenon involving both an alteration to normal neuronal activity and an individual's perception of that alteration. As such, the sensation of pain is largely subjective and greatly influenced by psychological factors. A number of different medicines are used to relieve pain in the hospital setting.

Opioid analgesics, such as pethidine and morphine, are effective for most kinds of pain, inducing a sense of calm. Unfortunately, their use is associated with a number of unwanted effects such as nausea and vomiting, reduced gastrointestinal motility, constipation, drowsiness and the development of physical and psychological dependence.

Currently, controlled clinical trials to identify significant interactions are lacking; however, it is possible to make some theoretical predictions. Concurrent use of another medicine that can further induce constipation, nausea or sedation has the potential to make these symptoms more troublesome (e.g. supplements containing calcium, iron, phytostanols or sterols). Medicines that have mild laxative effects, such as dandelion root and herb, psyllium husks, probiotics and yellow dock root, may be beneficial. Besides using CAM products to reduce adverse effects, techniques that can reduce the perception of pain have the potential to augment analgesic effectiveness (e.g. acupuncture, massage, biofeedback, meditation and possibly aromatherapy).

ANAESTHETICS

Local anaesthesia is often used to eliminate pain during minor surgery. Local anaesthetics tend to have an intense and short-lived effect, although this depends largely on the technique of administration and whether a vasoconstrictor agent has been co-administered. General anaesthesia can involve the use of several medicines, in addition to the anaesthetic agent, in order to dry secretions (e.g. antimuscarinic agents), reduce anxiety (e.g. benzodiazepines), produce amnesia and provide postoperative pain relief.

Whether CAM products significantly interact with anaesthetics is largely unknown and still speculative because controlled clinical studies are lacking. Evidence extrapolated from other sources can identify those medicines with pharmacological actions that suggest an interaction is theoretically possible, but clinical significance remains uncertain. For instance, medicines with sedative activity can theoretically prolong or potentiate the sedation induced by the anaesthetic drug combination.

Valeriana officinalis

Both in vivo and numerous clinical studies confirm sedative or hypnotic activity for the herb valerian (see Valerian monograph). Furthermore, valerian has been compared with benzodiazepine drugs in at least three human trials and has been found to be an effective treatment for insomnia (Dorn 2000, Gerhard et al 1996). One double-blind randomised trial involving 202 patients found that valerian extract 600 mg/day (Sedonium) was as effective as 10 mg oxazepam in improving sleep quality over 6 weeks (Ziegler et al 2002). Two clinical studies have found that valerian use is not associated with next morning somnolence, suggesting that the herb is short-acting (Gerhard et al 1996, Kuhlmann et al 1999). While a pharmacodynamic interaction is possible, leading to increased sedation, its short duration of action makes a clinically significant interaction between valerian and general anaesthetics unlikely.

Kava kava

Kava kava produces a significant reduction in anxiety compared with a placebo according to a 2003 Cochrane review, which analysed

results from 12 clinical studies involving 700 subjects (Pittler & Ernst 2003). Preliminary evidence suggests it may be equivalent to benzodiazepines in non-psychotic anxiety. It is also used in insomnia, with some clinical evidence supporting its use. With regard to surgery, kava kava may produce beneficial effects for the anxious patient; however, it could theoretically increase CNS sedation when used with benzodiazepines. Additionally, clinical testing has found that kava kava significantly inhibits (≈ 40%) CYP2E1, which may have implications when used together with CYP2E1 substrates such as halothane, isoflurane and methoxyflurane, causing a rise in drug serum levels (Gurley et al 2005). Kava kava should be used under professional supervision to avoid adverse outcomes.

St John's wort

Based on theoretical considerations, response to agents such as midazolam, diazepam and fentanyl may be reduced with *Hypericum perforatum* (St John's wort) because of pharmacokinetic interactions, whereas a pharmacodynamic interaction may occur with tramadol (Alfaro & Piscitelli 2001). These interactions are based on evidence that St John's wort (products containing the hyperforin constituent) induces cytochrome 3A4 and P-glycoprotein, as well as upregulating both 5-HT_{1A} and 5-HT_{2A} receptors and exerting a SSRI-like effect (see St John's wort monograph for more detail).

RECOMMENDATIONS BEFORE HIGH-RISK SURGERY

Appendix 5 is included in this book to provide clinicians with guidance when advising patients due for surgery about the safe use of CMs. It is limited to the 130 CMs reviewed in this book and focuses on those that are known or suspected to increase bleeding or interact with drugs commonly used in the perioperative period. The recommendations are conservative and not likely to be relevant to many low-risk patients or those undergoing minor surgical procedures; however, it is imperative that each patient be individually assessed before surgery.

CMs are listed alphabetically by common name. The comments section includes a brief description of the type of evidence available to support the recommendation; more detailed information is given in individual monographs. Several different recommendations are possible. Sometimes there is a recommendation to suspend use 1–2 weeks before surgery, which should provide ample time for bleeding rates to return to normal or potential interactions to be avoided. This is most likely an overestimation of the actual time required. Please note that coumarin-containing and salicylate-containing herbs have not been included in Appendix 5 unless they have demonstrated antiplatelet or anticoagulant effects in animal or human studies. In some cases, the recommendations are dose-dependent; in others, CM use appears safe but there is a theoretical concern.

It is acknowledged that, in practice, not all surgical patients will be able to follow these recommendations. In situations where bleeding would be a serious complication and a 1-week minimum deferment is not possible, tests of haemostasis before surgery should be considered.

It must be reiterated that the clinical relevance of some interactions and adverse effects is unknown and controlled studies in surgical patients are not available. However, it would seem prudent for healthcare providers to become familiar with these medicines, in order to advise patients appropriately and anticipate, manage or avoid adverse events during the perioperative period.

PATIENT-CENTRED ASSESSMENT AND MANAGEMENT DURING PERIOPERATIVE CARE

The term 'evidence-based patient choice' (EBPC) is the merging together of two important modern movements in Western healthcare, namely evidence-based medicine and patient-centred care. Evidence-based medicine requires the use of the best available evidence to make decisions about medical management. However, the individual qualities, needs and preferences of patients have sometimes been neglected as relevant factors in the decision-making process. Models of EBPC advocate shared decision making, in which patients have received the appropriate evidence for their situation and are able to communicate their personal preferences (Ford et al 2003).

QUALITY USE OF MEDICINES

Inspired by the World Health Organization, countries around the world are developing and instigating policies to ensure medicines are of acceptable safety, quality and efficacy and are accessible. At the end of 1999, Australia launched its National Medicines Policy. In

order to achieve one of the key goals of this policy, the National Strategy for the Quality Use of Medicines was developed (for more information see www.health.gov.au).

The goal of the Quality Use of Medicines (QUM) strategy is to optimise the use of medicines to improve health outcomes. It attempts to adopt EBPC into its framework, recognising that QUM requires the collaborative effort of a 'medication team' made up of doctors, pharmacists, nurses and patients. It advises also that CAM products be included in assessing a patient's medication situation. In practice, this step appears to be problematic and handled very differently by hospitals.

AUSTRALIAN HOSPITALS: POLICIES AND PROBLEMS

Although the task of getting the right medicine to the right patient should be straightforward, it is rarely the case, according to an editorial in the *Journal of Pharmacy Practice and Research* (Ryan 2003). It has been suggested that many participants are involved in the process; some of these are obvious, such as surgeons, physicians and pharmacists, and some less obvious, such as the manufacturer, pharmacy wholesaler, hospital nurse and medical educators. In the case of CMs, it is very complicated. Although hospitals should ideally respect the autonomy of patients who make informed decisions about the interventions they feel are in their best interests, they also have a duty of care. They are generally reluctant to administer herbal medicines or other substances that are not part of the standard hospital formulary, are of unknown quality and may have potential adverse effects with variable evidence of efficacy or require specific knowledge in their preparation or administration.

As a result, a number of hospitals have developed local policies that range from disallowing use of CMs (which includes herbal and natural medicines by definition) to treating these medicines as the 'patient's own'. Both approaches are problematic. Advising patients to discontinue taking all herbal and natural medicines before surgery may not free patients from risk relating to their use because withdrawal may be detrimental, in much the same way that withdrawal of some pharmaceutical medicines is associated with increased morbidity after surgery. Treating these medicines as 'the patient's own' may also provide false security, because their use may not be adequately monitored or considered in treatment and discharge plans.

The development of hospital policy and guidelines that take into account the principles of EBPC and QUM in regard to the use of CMs is no doubt very challenging, and finding consensus among all members of the 'medication team', administration bodies and patients is a difficult task. The New South Wales Therapeutic Assessment Group has developed a useful discussion paper about the use of CAM in public hospitals (see http://www.ciap.health.nsw.gov.au/nswtag/publications/otherdocs/complementary_medicines_public_hospitals_200010.pdf).

RECOMMENDATIONS

At various stages of the preoperative course, different healthcare professionals can intervene to ensure the patient is optimally prepared for surgery.

If anaesthesia is to be performed, a preoperative consultation is conducted by the attending anaesthetist. According to the Australian and New Zealand College of Anaesthetists (ANZCA), the consultation consists of a concise medical history, physical examination, a review of results of relevant investigations and current medications (see http://www.anzca.edu.au). Although not officially stated, this includes CMs. Currently in the United States, the American Society of Anesthesiologists recommends the discontinuation of all herbal medicines 2 weeks before elective surgery. In Australia and New Zealand, the situation is different because the ANZCA does not make the same general recommendation, instead relying on each anaesthetist to make an individual assessment.

Increasingly, hospital pharmacists are taking on the role of conducting presurgical medication reviews to improve patient safety. Although the focus is on the use of pharmaceutical medicines, the use of CMs is increasingly recognised and included in the medication discussion. Eight practice tips to promote patient safety and welfare are provided as a guide for all health care providers managing patients taking herbs and natural supplements during the preoperative period.

UNMANAGED INTEGRATED HEALTHCARE

Currently it appears that a number of patients are already receiving what could be described as unmanaged integrated healthcare, because they are taking herbal and natural medicines and sometimes consulting with a non-medical

EIGHT PRACTICE TIPS TO PROMOTE PATIENTS' WELFARE AND SAFETY

1. Ask all patients about the use of CMs.
According to the literature, many patients fail to disclose use of CMs to hospital staff; however, disclosure is more likely to occur if they are asked directly. Some patients may not understand what is meant by the term 'complementary medicine' so consider using phrases such as 'vitamins, minerals or herbal medicines' or 'natural medicines'. It will also be useful to determine whether the product was professionally prescribed or self-selected.

2. Suspend use of complementary medicines known or suspected to pose a safety risk 5–7 days before surgery, where appropriate.
According to the literature, a washout period of 5–7 days should be sufficient to ensure most CMs no longer present a safety concern (Ang-Lee et al 2001). If this is not possible or advisable, be aware of the potential problems and manage accordingly.

3. If in doubt, refer to drug information centres, peer-reviewed literature or reputable resources for further information.
Evidence is accumulating about CAM at a rapid rate, and it would be unreasonable to expect all healthcare professionals to keep up to date with these changes. However, referring to reputable information sources when unsure about patient safety is essential for best practice. This may involve referring to CAM practitioners with the appropriate training and expertise.

4. Document information and recommendations in patient's chart.
Patient's CM use should be documented in the medication history and/or discharge summary as appropriate. The name, strength, brand and dose used should be recorded.

5. To continue use of CMs or not?
If a patient is experiencing benefits from the use of a CM, and the available evidence indicates efficacy and safety, use should be continued, but monitored. If a patient is using a CM with known or suspected potential to cause adverse outcomes, an honest discussion about what is known and not known about the risks should ensue. If the patient still wishes to continue using the CM against professional advice, they should be asked to sign an acknowledgment form that informs them of the potential adverse effects and that their attending doctor or pharmacist has recommended against continued use. This should also be documented in the patient's medication history and/or discharge summary.

6. Consider if and when a patient can resume taking the CM.
If use of an effective CM has been withdrawn, recommencement will be required to restore the patient's response. This should be discussed when taking the medication history.

7. Recommend CMs with known safety and benefit.
If research indicates a CM has significant benefits during the perioperative period, then evidence-based practice dictates it should be considered in the patient's management.

8. If an adverse event does occur, report this through the relevant channels.
Little research is available to determine the clinical significance of CMs in the perioperative period. As such, case reports provide useful clues that can guide future research to better determine factors affecting patients' safety.

practitioner while being prescribed pharmaceutical medicines and consulting medical practitioners.

The ultimate aim of surgery is to improve a patient's quality of life by increasing their perception of health and their happiness in life, and reducing limitations so that they will ideally be able to participate in life in a more spirited way (Yun et al 1999). Surveys have identified that up to 50% of surgical patients are using CMs, no doubt as a means of achieving the same outcomes. While judicious self-care can offer numerous benefits to the individual, society and the healthcare system, there is clearly the potential for serious adverse outcomes, such as bleeding or drug interactions. The withholding of CMs because of lack of knowledge, fear or misinformation can also be problematic and result in patients being deprived of a therapeutic benefit or in the induction of withdrawal effects. It is not unreasonable to expect that, at some time in the future, unnecessarily

withdrawing CMs or failing to properly advise patients against the use of a potentially harmful product will give rise to serious adverse events resulting in litigation.

Until further clinical testing has been conducted to determine whether the herbal and natural medicines discussed here will adversely affect or beneficially influence the outcome of surgery, a collaborative yet cautious approach is recommended.

CHAPTER 10
CANCER AND THE SAFETY OF COMPLEMENTARY MEDICINES

Complementary medicine (CM) is commonly used by oncology patients and therefore it is important for healthcare providers to become familiar with this use (Bernstein & Grasso 2001, Ernst & Cassileth 1998, Richardson et al 2000). Typically, cancer patients use vitamins and herbal medicines, spiritual practices and psychosocial and physical therapies. Unfortunately, only 25% of cancer patients using CAM receive information from their conventional healthcare providers and communication between patients and doctors about CM is virtually non-existent (Ernst 2003).

Patients with cancer want access to reliable and authoritative information about CM so that they can discuss benefits and limitations with their healthcare providers and make an informed decision about use. A study of children with cancer has revealed that parents also want information about CM, especially at the beginning of treatment and also in the hospital wards (Molassiotis & Cubbin 2004). Medical and CM practitioners, pharmacists and nurses can play an important role in this regard and do much to guide and support patients using or considering CM. However, in order to provide an informed and rational opinion, healthcare providers require a working knowledge of CM and an awareness of its benefits and potential to cause harm. They also need to keep an open mind, have access to reliable resources and develop collaborative partnerships across several disciplines.

WHY DO PEOPLE WITH CANCER USE COMPLEMENTARY THERAPIES?

People with cancer choose CM as a means of addressing physical and psychosocial issues.

For physical issues, CM is used to provide symptomatic relief from the disease and/or its treatments. This includes addressing symptoms such as pain, nausea and vomiting, fatigue, constipation, weight loss and cachexia, and dyspnoea. It is sometimes used to minimise long-term adverse consequences of treatment such as organ toxicity.

For psychosocial issues, CM offers an avenue for dealing with anxiety, depression, stress and fear. It also provides an opportunity for patient empowerment and can give a sense of control and improve wellbeing.

Patients with cancer who use CM report various positive effects, such as reduced anxiety, stress, nausea, pain and dyspnoea, and improved physical energy, mood, concentration and optimism (Molassiotis & Cubbin 2004, Ponholzer et al 2003). According to a study of children with cancer, CM use was associated with increased confidence, improved pain relief and relaxation (Molassiotis & Cubbin 2004). Importantly, most people with cancer do not expect CM to cure or slow their disease and generally use it as a supportive measure during conventional treatment, chiefly to relieve symptoms and emotional anguish (Ponholzer et al 2003, Rees et al 2000, Richardson et al 2000).

The use of CM is widespread and increasing, partly because of increased access to health information and the growth in research-based evidence supporting the effectiveness of complementary therapies. In addition, CM practitioners tend to have longer consultations than medical practitioners with patients and adopt a holistic approach that focuses on presenting symptoms, the patient's lifestyle and issues that encompass mind, body and spirit. The

Clinical note — Integrative oncology

Integrative medicine may be described as 'practicing medicine in a way that selectively incorporates elements of CM into comprehensive treatment plans alongside solidly orthodox methods of diagnosis and treatment' (Rees & Weil 2001). Integrative oncology (IO) is a subset of integrative medicine. It is a term being increasingly adopted to include complementary medicine (CM), but integrated with conventional cancer treatment, as opposed to being considered a rival or true 'alternative' (Smyth 2006). IO is an evolving evidence-based specialty that focuses on the roles of complementary therapies to increase the effectiveness of conventional cancer treatment programs by improving defined outcomes such as symptom control, quality of life, reduction of patients' distress, rehabilitation and prevention of recurrence (Sagar 2008). The core principles of IO include individualisation, holism, dynamism, synergism and collaboration (Leis et al 2008). CM therapies used in IO include natural medicines (botanicals, vitamins and minerals), nutrition, acupuncture, meditation and other mind-body approaches, music therapy, touch therapies, fitness therapies and others (Sagar 2006).

Integrative medicine in general has grown quickly in the United States and now virtually all major medical centres have departments devoted to integrative patient care, either as true stand-alone centres or departments with a research interest in this area (Boyd 2007). This is particularly true of the major cancer centres, many of which — including Memorial Sloan Kettering Cancer Center, New York; M.D. Anderson Cancer Center, Houston, Texas; Johns Hopkins University, Baltimore, Maryland; Duke University, Durham, North Carolina; and the Dana Farber Cancer Institute, Boston, Massachusetts — have developed integrative cancer programs. In addition, programs such as the Cancer Treatment Centres of America have inpatient and outpatient programs with teams of practitioners, including medical oncologists, surgeons and radiation therapists, as well as credentialled naturopathic doctors, nutritionists, mind–body specialists and other integrative practitioners. Institutions are providing services to patients, exploring the effectiveness gap in their clinical services and are determining efficacy of complementary therapies through randomised controlled trials and, increasingly, mixed method whole systems research (Sagar 2006).

For readers interested in keeping up to date with this evolving area, the journal *Integrative Cancer Therapies* is recommended, as it provides useful research and editorial information about complementary medicine in cancer care.

increased interest in health prevention strategies, such as diet and stress management, are also well catered for by complementary therapists, who see these approaches as essential to good clinical practice.

POOR DISCLOSURE

Although the use of complementary medicines (CMs) is popular among people with cancer, many do not inform their medical doctors that they are using it. This may be because they anticipate disinterest or a negative response or think doctors are unable or unwilling to contribute meaningful information, or because it is perceived as irrelevant to the biomedical treatment course (Adler & Fosket 1999). It is therefore not unusual for patients to be receiving treatment and advice from a variety of practitioners without a central healthcare provider coordinating and supervising care.

Lack of disclosure can give rise to serious problems such as drug interactions and failure to recognise CM-induced adverse effects and withdrawal effects. In oncology, this can have far-reaching consequences. Open and honest communication about CM should be the standard for both patients and clinicians in order to avoid or minimise adverse events and provide an opportunity for patients to express their personal preferences for treatment.

CM IN THE ONCOLOGY SETTING

Despite the increased interest in developing integrative approaches to cancer, many medical oncologists remain sceptical about the value of these modalities. There are several good reasons for oncologists and other staff to take such developments seriously and learn more

about CM instead of dismissing it as eccentric and unproven (Smyth 2006):

- **To enhance mutual respect between patient and doctor.** Oncology patients are using CM and yet all too often they are reluctant to discuss this or even to inform doctors that they are doing so. Mutual respect will help build communication pathways and provide the clinician with an opportunity to ensure that no harm is introduced unwittingly by patients themselves.
- **To encourage research into CM.** One of the major reasons for the medical profession's scepticism of CM is the poor evidence base for many of these treatments. Enquiry, instead of dismissal, will encourage further investigation and research into this area.
- **To increase doctors', pharmacists' and nurses' knowledge of CM.** With ever-increasing access to information and knowledge, patients will continue to challenge their professional advisors on every aspect of cancer management. Complementary medicine approaches will continue to feature strongly in many patients' minds, placing demands on healthcare professionals in the years ahead. One way to help patients is to provide an informed, evidence-based opinion, while acknowledging that, in some cases, randomised studies may not be conducted for years but that other forms of evidence may exist and provide guidance.

BENEFITS OF CM IN ONCOLOGY

A growing number of CM therapies are being subjected to clinical trials to determine their effectiveness and role in cancer treatment. In most instances, CM therapies are being investigated for symptom relief and improvements in quality of life.

A review in the *European Journal of Cancer* illustrates that the weight of evidence to support the use of some complementary approaches in cancer is clearly positive or showing a positive trend (Ernst 2003). According to the review, positive evidence exists for *Allium* spp vegetables (e.g. onions), detoxification, Sho-saiko-to, St John's wort, acupuncture and relaxation, while there is positive trend for green tea, phyto-oestrogens, Gerson diet, *Aloe vera*, melatonin, support group therapy, hypnotherapy, therapeutic touch and enzyme supplements.

Evidence is well established for psychosocial therapies in cancer management, such as hypnosis, music therapy, meditation and stress management, and for acupuncture (Cassileth 1999). For example, there is evidence from randomised trials supporting the value of hypnosis for cancer pain and nausea; relaxation therapy, music therapy and massage for anxiety; and acupuncture for nausea (Vickers & Cassileth 2001). Studies involving people with cancer or cancer survivors report benefits of yoga for stress, anxiety, insomnia and cancer-related symptoms and show it increases quality of life (Bower et al 2005, Cohen et al 2004).

Results from clinical studies and/or experimental models indicate that several other therapies have the potential to reduce drug-induced side effects and toxicities. For example, a Cochrane systematic review that analysed the results of four trials using a Chinese decoction containing the herb astragalus (huang-qi) as an adjunct to chemotherapy concluded that co-administration of the herbal treatment with chemotherapy produced a significant reduction in nausea and vomiting and a decrease in the rate of leucopenia (Taixiang et al 2005). The review also stated that no evidence of harm was identified with use. The herbs ginger and baical skullcap have been found to reduce symptoms of cisplatin-induced nausea in experimental models (Aung et al 2003, Sharma & Gupta 1998, Sharma et al 1997), and animal and human studies suggest long-term carnitine administration may reduce cardiotoxic side effects of adriamycin (Mijares & Lopez 2001, Waldner et al 2006). Additionally, preclinical and clinical studies suggest that anthracycline-induced cardiotoxicity can be prevented by administering coenzyme Q10 during cancer chemotherapy that includes drugs such as doxorubicin and daunorubicin. Studies further suggest that coenzyme Q10 does not interfere with the antineoplastic action of anthracyclines and might even enhance their anticancer effects (Conklin 2005). Many other natural substances such as St Mary's thistle, grapeseed extract, St John's wort, parthenolide (from feverfew) and curcumin show promise in preliminary studies in reducing chemotherapy-induced organ toxicity or other associated adverse effects and are discussed in individual monographs in this book. Research has also been conducted with individual antioxidant vitamins and minerals.

A comprehensive model of cancer care requires that patients take an active role in their healthcare and find partners to work with them during the process. Medical practitioners play a key role; however, many other healthcare providers can augment their

work and help provide patients with holistic care. A number of complementary therapies have proven benefits and are considered safe. These should be made available to patients to increase their sense of wellbeing and improve their quality of life and experience of cancer, its treatments and recovery.

SUPPORTIVE MEASURES

Supportive care is care that helps patients and their families cope with cancer and its treatment, starting from pre-diagnosis, through the process of diagnosis and treatment, to cure, continuing illness or death, and into bereavement. It helps the patient to maximise the benefits of treatment and to live as well as possible with the effects of the disease.

A number of CM therapies and treatments can provide substantial support to people with cancer by providing symptomatic relief, enhanced quality of life and improved sense of wellbeing, without causing harm. They also have important benefits in addition to those derived from their inherent therapeutic effect:

- They actively involve patients and provide a rare opportunity for them to exert control and tend to themselves or to have friends or family members assist them.
- Many CM therapies are time-honoured types of 'supportive care' that have been offered to patients for decades.
- Many are accessible.
- Some work by known mechanisms of action, whereas others may invoke a placebo response, an underutilised mechanism by which distress can be relieved and quality of life enhanced.

The information in Table 10.1 (pp 130–31) is a guide to some of the better known and researched therapies and treatments that may provide supportive benefits for patients. *To promote appropriate and safe use, each individual's characteristics, medication use, general health and overall situation needs to be assessed. Where herbal and nutritional medicines are mentioned, healthcare providers should check for potential interactions with drug therapy.*

CM TO IMPROVE SURVIVAL

Although CM is most often used to treat symptoms and enhance wellbeing, to a lesser extent it is being used as a potential cure for cancer. Examples of some CM treatments that have been used by patients to cure cancer are listed in Tables 10.2 (p 131) and 10.3 (p 132). Some of the listed treatments are currently under investigation and have been subject to in vitro and in vivo studies, whereas other treatments, such as Hoxsey therapy, the Di Bella regimen, shark cartilage and laetrile, are generally considered ineffective. A full review of the available evidence is beyond the scope of this chapter, but further information can be found in the relevant monographs. (Updated information is available at some of the websites listed in Table 10.5, pp 144–5.)

It is interesting to note that approximately two-thirds of commercially available anticancer drugs are derived from or related to natural products, including enzymes, hormones, plants and fungal extracts (Bryant et al 2003). For example, an extract of wild chervil was mentioned in an ancient medical text as a useful salve against tumours, and it is now known that podophyllotoxin, a cytotoxic agent, is present in the *Podophyllum* species of plants. The most recent anticancer products are the taxanes (paclitaxel and docetaxel), which are derived from the yew tree *Taxus baccata*, and the camptothecins (topotecan and irinotecan) from *Camptotheca accuminata*.

RESEARCH APPROACHES AND CONSTRAINTS

The resurgence of medical pluralism has resulted in people with cancer developing their own combinations of biomedical, complementary and self-care strategies. Consequently, the need for a solid knowledge base for the non-surgical, non-radiotherapeutical and non-chemotherapeutical aspects of the treatment experience and their combinations is substantial and will only increase.

Until recently, research efforts in CM and cancer have concentrated mainly on testing a limited number of available treatments using the well-established pharmaceutical randomised controlled trial research model, with tumour size and/or survival as primary outcomes. This has already led to the publication of hundreds of randomised trials in the peer-reviewed literature. While this work is important and will continue, it does not reflect a patient's reasons for seeking CM treatments, which are not primarily tumour reduction, but improved wellbeing and symptom relief.

WHOLE SYSTEMS RESEARCH (WSR)

Cancer care is currently developing into a complicated network of interventions that are delivered at different times and places

TABLE 10.1 CM Therapies Used to Support Cancer Patients

Condition	CM therapy
Anxiety and stress	Acupressure: pressure with fingertips to key locations Aromatherapy: lavender, rosemary, chamomile and marjoram oils are popular; a few drops of oil in the bath, on a pillow, in an oil diffuser or in massage vehicle Meditation and other relaxation techniques: seated or lying down; class or DVD; visualisation and imagery Therapeutic massage: with a trained massage therapist Herbal medicines: brahmi, lemon balm, rhodiola, valerian, passionflower, kava kava, withania, Siberian ginseng; under professional supervision Nutritional supplements: vitamin B complex, SAMe Yoga: class or DVD; breathing exercises can be done by bedridden patients
Backache and muscle aches	Hydrotherapy: e.g. warm bath or spa Nutritional medicine: magnesium and/or calcium supplements, particularly if muscle cramping or muscle tension is a problem Therapeutic massage: with a trained massage therapist Herbal medicines: willowbark, devil's claw tea; or stronger forms under supervision
Depression	Herbal medicine: lemon balm, St John's wort, ginkgo, rhodiola Nutritional medicine: SAMe, fish oils, vitamin B complex Meditation and other relaxation techniques: seated or lying down; class or DVD Yoga: class or DVD; breathing exercises can be done by bedridden patients
Diarrhoea	Probiotics: recolonise bowel with beneficial bacteria Glutamine: symptom relief Herbal medicine: bilberry, chamomile, goldenseal, raspberry leaf tea; or stronger forms under supervision
Dyspepsia	Herbal medicine: dandelion, chamomile, peppermint, cinnamon, ginger, meadowsweet, fenugreek, raspberry leaf teas; or stronger forms under supervision Food supplements: probiotics, colostrum, glutamine
Headaches	Acupressure: pressure with fingertips to key locations Acupuncture Herbal medicine: willow bark, devil's claw Nutritional medicine: magnesium and calcium supplements: particularly if muscle tension is a problem
Nausea and vomiting	Acupuncture Possibly hypnosis Music therapy in combination with antiemetics for stronger effects Herbal medicine: ginger, cinnamon, peppermint tea; or stronger forms under supervision Lime juice taken in water
Pain	Acupuncture: may also increase mobility Biofeedback Herbal medicine: willowbark, ginger, devil's claw tea; or stronger forms under supervision Hypnosis Nutritional supplements: SAMe, fish oil supplements Therapeutic massage: with a trained massage therapist TENS daily for 6+ sessions; may improve fatigue and quality of life, provide acute pain relief and reduce analgesic requirements

TABLE 10.1 CM Therapies Used to Support Cancer Patients *continued*	
Condition	**CM therapy**
Insomnia	Aromatherapy: lavender, rosemary, chamomile and marjoram oils are popular; a few drops of oil in the bath, on a pillow, in an oil diffuser or in massage vehicle Herbal medicine Lemon balm, passionflower, Siberian ginseng, valerian, chamomile tea; or stronger forms under supervision Therapeutic massage: with a trained massage therapist Meditation

TABLE 10.2 Complementary Medicines That have been Used to Improve Cancer Cure Rates	
Complementary medicine	**Comments**
Cat's claw *(Uncaria tormentosa)*	See monograph.
Chapparral	
Coenzyme Q10	There have been several positive case reports.
Curcumin	Attracting a lot of interest from researchers. See monograph.
Essiac tea	Herbal mixture originally formulated by an Ojibwa healer and popularised in the 1920s by a nurse, Rene Caisse. (Essiac is Caisse spelt backwards.) The four main herbs in Essiac tea are burdock root (*Arctium lappa*), Indian rhubarb (*Rheum palmatum*), sheep sorrel (*Rumex acetosella*) and the inner bark of slippery elm (*Ulmus fulva* or *U. rubra*).
Green tea	Attracting a lot of interest from researchers. See monograph.
Laetrile	A single compound isolated from a natural substance (apricot pits and almonds); promoted as 'vitamin B17'.
MGN-3	This is a mushroom and rice bran extract.
Maitake mushroom extract (*Grifola frondosa*)	Maitake D-fraction is used.
Mistletoe extract	Has been subjected to clinical trials in Europe.
Pau d'arco	Used as a tea. Thought to be an old Inca remedy for many illnesses, including cancer. It is made from the bark of an indigenous South American evergreen tree, and its active ingredient, lapachol, has been isolated. See monograph for further information.
PC-SPES	Chinese formulation of eight herbs consisting of isatis (*Isatis indigotica*), either liquorice (*Glycyrrhiza glabra*) or Gan coa (*G. uralensis*), Chinese skullcap (*Scutellaria baicalensis*), reishi (*Ganoderma lucidum*), saw palmetto (*Serenoa repens* or *Sabal serrulata*), Asian ginseng (*Panax ginseng*), denodrantherm (*Denodrantherma morifolium*) and rabdosia (*Rabdosia rubescens*). It is no longer available, as it was also found to contain diethylstilboesterol and warfarin, which increase the risk of adverse effects.
714X	A liquid medicine made from camphor, nitrogen, ammonium salts, sodium chloride, and ethanol, generally given by injection.
Shark cartilage	Thought to have potential owing to antiangiogenic properties. See monograph for further information.

with different intentions. Some interventions are offered by healthcare professionals at an oncology centre; others are offered by CM practitioners; still others, such as special diets, meditation and OTC natural supplements, form part of a patient's individualised package of self-care. These treatment interventions are influenced by psychosocial factors such as the nature of the patient–provider relationship, varying levels of social support, and an individual patient's personality. Ultimately, a patient's outcomes are a result of all components of care, and it is likely that the effect of the whole is greater than the sum of its parts (Verhoef et al 2005).

TABLE 10.3 CM Therapies That have been Used to Improve Cancer Cure Rates

CM therapy	Comments
Chelation therapy	The use of agents to chelate heavy metals.
The Di Bella regimen	Consists of melatonin, bromocriptine, retinoids, and either somatostatin or octreotide.
Electromagnetic therapy	
Fasting and juice therapies	
Hoxsey therapy	Consists of a caustic herbal paste for external cancers or a herbal mixture for 'internal' cancers, combined with laxatives, douches, vitamin supplements and dietary changes; one of oldest alternative cancer treatments in the United States, dating back to the 1920s.
Ozone therapy	

As a result, there is a need to consider whether the current research approaches in clinical cancer care adequately cover the ongoing treatment choices and combinations. One approach developed by CM researchers is whole systems research (WSR), which is proposed as an additional research method for modern systems of care, whether they include complementary medicine or not.

WSR focuses on the multidisciplinary approach taken by patients, rather than adopting a reductionist perspective where all variables remain constant except one that is altered. WSR also focuses more on the individual patient and less on group-averaged results, under the assumption that there will be patient heterogeneity in response and that important information about the healing approach in that heterogeneity may otherwise be missed (Verhoef et al 2005). Integral to WSR is the belief that clinical research should reflect real-world practice and then be used to inform future clinical practice. A mixed-methods approach that holds qualitative and quantitative research methods in equal esteem and captures information about different domains is advocated, because whole systems are complex and no single method can adequately capture the meaning, process and outcomes of these interventions (Verhoef et al 2005).

In summary, WSR is research that:

- encompasses the investigation of both the processes and the outcomes of complex interventions
- includes *all* aspects of any internally consistent approach to treatment (philosophical basis, patients, practitioners, setting of practice and methods/materials)
- acknowledges unique patient, family, community and environmental characteristics and perspectives.

OUTCOMES RESEARCH

Researchers in Canada have determined nine outcome domains relevant to WSR (Fonnebo et al 2007), as follows: physical, psychological, social, spiritual, quality-of-life, holistic, individualised, process and context outcomes. At the same time, validated outcome instruments have been identified to measure these domains as well as gaps where no adequate measures currently exist. Researchers in the UK and at the University of Arizona, USA, have led the way by conceptualising and developing these instruments, some examples of which are Measure Yourself Medical Outcome Profile, Measure Yourself Concerns and Wellbeing, the Patient Enablement Questionnaire, and the Consultation and Relational Empathy Measure (Fonnebo et al 2007).

EXPLORING EXCEPTIONAL PATIENTS

Becoming familiar with patients' individual experiences and collating information to find common themes is one method of identifying therapeutic approaches that show promising results and warrant further clinical research. In a way, this method of data collection is much like the practice of traditional healers of old, who were required to develop excellent observational and history-taking skills to learn more about the benefits and risks of treatments being applied.

This realisation has led to several international initiatives to collect and systematically categorise and review histories of patients who experience an unexpected benefit or spontaneous remission after CM treatments. Several research groups in different countries have initiated studies in this area, either collecting histories from the treatment providers or recruiting case histories mainly from patients themselves (Launso et al 2006). The US National Cancer Institute concentrates on a series of what they designate as 'best cases', whereas in Norway the National Research Centre in Complementary and Alternative Medicine (NAFKAM) includes both 'best' and 'worst' cases in its reviews.

Clinical note — NAFKAM: 'The Exceptional Case History Registry'

This registry is held at the National Research Centre in Complementary and Alternative Medicine (NAFKAM), University of Tromsø, Norway. Its purpose is to establish a database that can contribute to the generation of knowledge about the factors influencing the development of exceptional disease courses after the use of complementary treatment. Researchers carry out a thorough medical evaluation of the case histories that patients send to NAFKAM. At the same time, NAFKAM is interested in collecting information about the experiences and the knowledge of people who themselves define their courses of illness as exceptional. The registry is seen as an important window to patient-based knowledge about disease and treatment courses.

From Galilei 2007

Clinical note — Senate enquiry into services and treatments options for persons with cancer: key recommendations

In June 2005 a report entitled 'The cancer journey: Informing choice' was released as a result of a Senate inquiry conducted earlier in the year (Commonwealth of Australia 2005). The inquiry aimed to investigate the delivery of services and options for treatment for people diagnosed with cancer and to determine how less conventional and complementary cancer treatments can be assessed and judged. With regard to complementary medicine, several important recommendations were made, including a recommendation that the National Health and Medical Research Council provide a dedicated funding stream for research into complementary therapies and medicines and convene an expert working group to identify the research needs relating to complementary therapies, including issues around safety, efficacy and capacity building. The development of collaborative partnerships across disciplines was also advised. The Senate committee also recommended improved provision of authoritative information to patients and health professionals. Importantly, it recommended that where quality of life may be improved by complementary approaches, the means to make such therapies more accessible needs to be reviewed.

LIMITED FUNDING

Despite the enormous popularity of CM, relatively little research has been conducted into the efficacy and safety of its use by people with cancer compared to similar research into conventional medicine. Currently, the majority of research into CM has been conducted in the USA, where a significant effort has been made, with government funding. In 1998 the Office of Cancer Complementary and Alternative Medicine (OCCAM) was established within the National Cancer Institute (NCI) in the United States to coordinate and enhance activities of the NCI in CAM research as it relates to the prevention, diagnosis and treatment of cancer, cancer-related symptoms and side effects of conventional cancer treatments (see http://www.cancer.gov/). Since the establishment of OCCAM, the NCI's research expenditure for CAM has more than quadrupled, from approximately US$28 million for the financial year (FY) 1998 to approximately US$129 million in FY 2004.

In the UK, the National Cancer Research Institute has a complementary therapies clinical studies development group, which is looking at prioritising areas for study and methodological issues. In Australia and New Zealand there is still relatively little government funding for research in this area; however, the establishment of the National Institute of Complementary Medicine (NICM) in 2007 is an important step towards increasing awareness of this need and lobbying government and philanthropic organisations.

ADVERSE REACTIONS AND INTERACTIONS

One area of great concern is the potential for CMs to reduce the efficacy of oncology treatments or increase their adverse effects and toxicity beyond acceptable limits. In conventional drug therapy, interactions are an ongoing concern, although the clinical relevance of these interactions has not always been investigated. In the area of CM, the issue is even more complicated because much remains unknown about the mechanisms of action of many herbal and natural medicines, and relatively little drug interaction research has been conducted.

ADVERSE REACTIONS

Type A and type B adverse reactions are possible with all therapeutic agents, including complementary medicines (see Chapters 7 and 8). Type A effects are the most common and predictable because they are dose-related, generally of mild to moderate intensity, and reversible. Regarding vitamins, minerals and the cancer patient, toxicity concerns mainly relate to vitamin A and the minerals selenium and zinc.

Vitamin A

Cumulative toxicity is possible with daily doses exceeding 100,000 IU, although some adults can experience toxicity signs and symptoms at lower doses. Symptoms tend to resolve within days to weeks. Supplementation should be avoided in chronic renal failure and liver disease, and high-dose vitamin A should be avoided during radiochemotherapy.

Selenium

Cumulative toxicity is possible with daily doses exceeding 1000 micrograms/day. The organic form of selenium found in high-selenium yeast is less toxic and safer than other forms.

Zinc

Single doses of 225–450 mg can induce vomiting. Long-term daily use of 100–150 mg interferes with copper metabolism and can cause hypocuprinaemia, red blood cell microcytosis and neutropenia.

For further information about individual herbs, vitamins and minerals, refer to the relevant monographs.

INTERACTIONS

Cytotoxic anticancer drugs are among the strongest drugs available and tend to have a complex pharmacological profile, narrow therapeutic index, steep dose–toxicity curve and many pharmacokinetic and pharmacodynamic differences both within and between patients (Beijnen & Schellens 2004). Often combinations of medicines are used to address the cancer itself, reduce the associated drug toxicities and provide palliation and symptom relief. As such, polypharmacy is standard practice. Additionally, many cancer patients are elderly and may be taking medicines for comorbid conditions such as cardiovascular disease, and as the number of concomitant medicines increases, so too does the risk of interactions (Blower et al 2005). Age-related changes to renal and hepatic functions and reduced homeostatic reserve are other complicating factors that make the prediction and avoidance of interactions difficult in this population.

As discussed in Chapter 8, there are two main categories of interaction, pharmacodynamic and pharmacokinetic, and a minor category known as physicochemical:

- **Pharmacodynamic** interactions occur when one substance alters the sensitivity or responsiveness of tissues to another. This type of interaction results in additive, synergistic or antagonistic drug effects and is frequently employed in clinical practice to improve patient outcomes. It is of particular concern when medicines used simultaneously have overlapping toxicities.
- **Pharmacokinetic** interactions occur when there is an alteration to the absorption, distribution, metabolism or excretion of a medicine. This interaction results in a change to the amount and persistence of available drug at receptor sites or target tissues. As a result, a change in magnitude of effect or duration of effect can occur, but no change to the type of effect is seen. This interaction is sometimes harnessed to increase serum levels of an expensive medicine without increasing the actual dose.
- **Physicochemical** interactions occur when two substances come into contact and are either physically or chemically incompatible. This type of interaction can take place during the manufacture or administration of medicines and result in the inactivation of one or both medicines.

Regardless of the mechanism involved, three possible outcomes can arise from an interaction: increased therapeutic or adverse effects; decreased therapeutic or adverse effects; a unique response that does not occur when either agent is used alone.

Pharmacodynamic interactions

Antioxidants and chemotherapy

Chemotherapy-related toxicity is a major concern in oncology. The toxicity experienced with the use of chemotherapy agents can be sufficiently severe as to require dosage reduction, delays in treatment and even cessation of potentially effective treatments. Chemotherapy-induced toxicity is also a concern in those patients who are cured or achieve prolonged survival, but experience long-term side effects that reduce their quality of life (Weijl et al 2004).

Much debate has arisen about whether antioxidant supplementation alters the efficacy of cancer chemotherapy. From a theoretical perspective, there is concern that antioxidant supplements have the potential to reduce treatment effectiveness, especially if oxidative mechanisms play a role in producing cytotoxic effects. Drugs with mechanisms of action which include free radical generation include, but are not limited to, alkylating agents (e.g. melphalan, cyclophosphamide), anthracyclines (e.g. doxorubicin, epirubicin), podophyllin derivatives (e.g. etoposide), platinum coordination complexes (e.g. cisplatin, carboplatin) and camptothecins (e.g. topotecan, irinotecan) (Labriola & Livingston 1999). Unfortunately, free radicals produced during the course of treatment are also a major source of serious side effects. For example, cisplatin and other platinum-induced toxicities include nephrotoxicity, ototoxicity and peripheral neuropathy, while doxorubicin and other anthracyclines often cause cardiotoxicity (Block et al 2007). There are other chemotherapy drugs that are thought to be less reliant on free radical production as a mechanism of action, such as plant-derived agents (e.g. vinca alkaloids and taxanes), antimetabolites (e.g. methotrexate, fluorouracil, cytarabine) and hormonal agents (Labriola & Livingston 1999).

Attempting to characterise chemotherapeutic compounds solely in this manner oversimplifies the issue, as most effective chemotherapeutic agents are multi-mechanistic and their relative ability to generate free radicals is not only dose-dependent but also dependent on the localisation and metabolism of the drug within specific tissues (Block et al 2007). Importantly, these cytotoxic drugs tend to have additional mechanisms of action that are not reliant on free radical generation, enabling them to target cells in a number of different ways.

Similarly, antioxidants have multiple mechanisms of action and, depending on their use and dosage, have the potential to serve as free radical molecules themselves.

Currently, clinical evidence is generally lacking to support concerns that antioxidant supplementation given concurrently with reactive-oxygen-species-(ROS)-generating chemotherapy will diminish the efficacy of treatment; however, the area remains underresearched and definitive evidence is still not available.

A historical perspective The concept of administering antioxidant vitamins in cancer probably arose in the 1970s as a result of publications by Linus Pauling and Ewan Cameron. In one of their early papers entitled 'Orthomolecular treatment of cancer — the role of vitamin C in host defence', it is proposed that cancer treatment must be multidisciplinary and include all that medicine and surgery has to offer and also treatments that maximise the individual patient's resistance to cancer (Cameron & Pauling 1974). The phrase 'orthomolecular treatment' was described as a means of enhancing patients' responses, achieved by manipulating certain biochemical reactions. High-dose vitamin C supplementation was chosen as a good candidate to enhance host resistance, based on theoretical considerations, preliminary studies and the observation that many cancer patients had depleted vitamin C levels.

Cameron and Pauling went on to publish two controlled retrospective studies in 1976 and 1978 that showed that the mean survival times were, respectively, more than four and three times as great for the ascorbate subjects as for the controls with the use of intravenously and orally administered high-dose vitamin C (Verrax & Buc Calderon 2008). Pauling and collaborators were convinced that high doses of ascorbate would increase the formation of collagen, leading to tumour encapsulation. Rapidly, several criticisms were raised about the design of the Pauling/Cameron studies since they were not randomised or placebo-controlled and had other methodological weaknesses. In an attempt to either duplicate or refute the amazing results obtained by Cameron and Pauling, the Mayo Clinic initiated different controlled double-blind studies, but these did not find that treatment was effective against advanced malignant disease.

In the last 30 years, our knowledge of the pharmacokinetics and pharmacodynamics of ascorbic acid has increased and provides the rationale to support its re-evaluation as adjuvant treatment for cancer patients. Indeed, ascorbic acid is cytotoxic against a wide variety of cancer cells but presents a low toxicity towards normal cells, which could lead to the consideration of ascorbate as an interesting anticancer agent (Verrax & Buc Calderon 2008).

The evidence today A number of comprehensive reviews in the peer-reviewed literature have assessed the effects of combined

antioxidant and chemotherapy usage on different outcomes such as side-effect reduction, reduced toxicity and, to a lesser extent, survival. While there are some promising findings, particularly indicating that antioxidants reduce chemotherapy-induced toxicity, definitive conclusions about safety and efficacy cannot yet be drawn because of the variations in study design, intervention protocols, eligibility criteria, statistical power, timing of the observation or intervention, malignancy type and anticancer regimens.

Block et al (2007) evaluated data from 19 randomised controlled trials (n = 1554 patients) in which studies measured survival and/or treatment-response levels of patients who were given antioxidants concurrently with chemotherapy in order to determine if the antioxidants enhanced or interfered with the efficacy of the chemotherapy. Reviewers found no evidence to support concerns that antioxidant supplementation diminished the efficacy of chemotherapy in study populations comprising mostly advanced or relapsed patients; overall, studies showed a positive trend in the survival and response rates for the groups receiving the antioxidants. Although these results are certainly encouraging, only four studies provided adequate statistical data to support the positive conclusion made by Block et al.

Statistics were more robust to support the conclusion that antioxidant therapy reduced chemotherapy-induced toxicity. Seventeen studies reported on toxicity; 15 of these showed similar or reduced toxicities in the antioxidant group compared to controls; only one study reported significantly greater general toxicity, although the result was somewhat expected owing to the well-documented toxicities of high-dose vitamin A. One other study reported that 2 out of 8 measured toxicities were non-significantly higher; however, the authors reported difficulty in interpretation because of poor patient compliance in the antioxidant group. More specifically, with regard to neurotoxicity, all 11 studies found antioxidant supplementation led to similar or less neurotoxicity compared to controls.

The comprehensive review looked at antioxidants with different mechanisms, such as free-radical scavengers that act as reducers or that break lipid chains (melatonin, *N*-acetylcysteine [NAC], Vitamin E, glutathione [GSH], beta-carotene and vitamin C), metal chelators (Vitamin C, epigallocatechin gallate from green tea [EGCG]), cellular protectors (vitamins A, C, E and melatonin), those that target and repair DNA aberrations (EGCG) and antioxidant enzymes created by combining with a protein to form selenoproteins (selenium, GSH). Only studies in which cancer patients were undergoing chemotherapy at the same time were included, as were all types of cancer and various chemotherapies that utilised the reactive oxygen species mechanism.

Some recently published reviews have come to a similar conclusion (Simone & Simone 2008, Simone et al 2007). The authors evaluated 280 peer-reviewed in vitro and in vivo studies, including 50 human studies involving 8,521 patients (5,081 of whom were given nutrients) and concluded that studies have consistently shown that antioxidants do not interfere with therapeutic modalities for cancer. Furthermore, they contend that non-prescription antioxidants and other nutrients enhance the killing of therapeutic modalities for cancer, decrease their side effects and protect normal tissue. In 15 human studies, 3,738 patients who took non-prescription antioxidants and other nutrients actually had increased survival.

In contrast, a 2008 review (Lawenda et al 2008) advises against the concurrent use of antioxidants during chemotherapy because of the possibility of tumor protection and reduced survival. The authors identified 16 randomised clinical trials that studied the concurrent use of antioxidant supplements and chemotherapy; six of those trials included a placebo control. Although no decrements in tumor response rates or survival rates were observed in the studies that reported response data, it was reported that none of the studies were sufficiently powered to evaluate these endpoints.

Theories explaining the observed improvement in survival and/or treatment response reported in some clinical studies with antioxidant supplementation have been offered (Conklin 2004, Block et al 2007). It is suggested that oxidative stress can slow the cell-cycle progression of cancer cells, which can interfere with the ability of anticancer agents to kill cells, and that the formation of reactive oxygen species (ROS), such as aldehydes, can inhibit drug-induced apoptosis and further diminish treatment effects. It is further proposed that the use of antioxidant agents during chemotherapy could enhance treatment effectiveness by decreasing this unwanted effect of ROS generation. In the 2007 review by Block et al, it was suggested that antioxidant therapy

reduced free-radical-induced damage to normal tissues, leaving non-oxidative cytotoxic mechanisms unaffected. In this way, patients experienced fewer dose-limiting toxicities, so that more of them could successfully complete prescribed regimens.

Cisplatin and antioxidants

One of the most important drugs used for the treatment of a wide range of solid tumours is cisplatin, but it induces numerous toxicities that are mainly caused by the formation of free radicals, leading to oxidative organ damage. Long-term side effects of treatment include nephrotoxicity, loss of high-tone hearing and peripheral neuropathy. As a strategy to reduce oxidative damage and drug-induced toxicities, antioxidants (nutritional and herbal) have been investigated in both animals and humans, with some studies showing amelioration or prevention of some side effects and possibly increased treatment effectiveness (Ali & Al Moundhri 2006, Lamson & Brignall 1999, Ohkawa et al 1988, Seifried et al 2003).

Neurotoxic protection The neurotoxicity of chemotherapy depends not only on the anticancer agent used, the cumulative dose and the delivery method, but also on the capacity of the nerve to cope with the nerve-damaging process. The sensory and motor symptoms and signs of neurotoxicity are disabling, and have a significant impact on the quality of life of cancer patients. Moreover, the risk of cumulative toxicity may limit the use of highly effective chemotherapeutic agents. Therefore, prophylaxis and treatment of peripheral neurotoxicity secondary to chemotherapy are major clinical issues (De 2007).

Experimental and clinical studies have been conducted to investigate whether naturally derived antioxidants prevent cisplatin-induced neurotoxicity, overall producing promising results. In a recent review of four trials, for example, the combination of vitamin E with cisplatin was shown in all trials to reduce the incidence of chemotherapy-induced peripheral neuropathy (Wolf et al 2008). While no data was included on the long-term survival of the patients involved, numerous studies have been undertaken that failed to show a detrimental effect from combining vitamin E with chemotherapy. For instance, Argyriou et al conducted a randomised, open label trial with blind assessment to investigate whether vitamin E supplementation (600 mg/day) has a neuroprotective effect in chemotherapy-induced peripheral nerve damage (Argyriou et al 2005). Thirty-one patients with cancer treated with six courses of cumulative cisplatin, paclitaxel or their combination regimens were randomly assigned to be controls receiving standard care, or to receive oral vitamin E at a daily dose of 600 mg/day during chemotherapy and for 3 months after its cessation. The incidence of neurotoxicity differed between the two groups, occurring in 25% patients taking vitamin E and 73% of controls ($P = 0.019$).

In several experimental settings, the prophylactic administration of acetyl-L-carnitine (ALC), the acetyl ester of L-carnitine, prevented the occurrence of peripheral neurotoxicity commonly induced by chemotherapeutic agents and further promoted recovery of nerve function (De 2007). Recent in vitro research suggests alpha-lipoic acid exerts neuroprotective effects against cisplatin-induced neurotoxicity in sensory neurons by protecting against mitochondrial toxicity, which is an early common event in cisplatin-induced neurotoxicity (Melli et al 2008).

Nephrotoxic protection Many different agents have been shown to ameliorate experimental cisplatin-induced nephrotoxicity including antioxidants (e.g. melatonin, vitamin E, selenium, St John's wort, capsaicin, garlic powder, spirulina, tetramethylpyrazine, a major constituent of the Chinese herb *Ligusticum wallichi*, and many others) and modulators of nitric oxide (e.g. zinc histidine complex, L-arginine) (Ali & Al Moundhri 2006, Khan et al 2006, Mohan et al 2006, Razo-Rodriguez et al 2008, Saleh & El-Demerash 2005, Shimeda et al 2005). Only few of these agents have been tested in humans.

A randomised study using 4000 micrograms/day of selenium (as seleno-kappacarrageenan), given 4 days before to 4 days after treatment with cisplatin, found that it effectively reduced drug-induced nephrotoxicity and bone-marrow suppression (Hu et al 1997). Another randomised study that tested oral vitamin E (300 mg/day), given before treatment and continued for 3 months post-treatment, showed it significantly reduced the incidence and severity of neurotoxicity associated with cisplatin (Pace et al 2003).

Alternatively, combination therapy with vitamins C and E and selenium in 48 subjects failed to exert protective effects against cisplatin-induced nephrotoxicity and ototoxicity, according to a double-blind study (Weijl et al 2004). The doses used in that study were 1000 mg vitamin C (as L-ascorbic acid), 400 mg

vitamin E (as DL-alpha-tocopherol-acetate) and 100 micrograms selenium (as sodium selenite), which was taken as a milky beverage 7 days before the onset of chemotherapy and continued until 3 weeks after cessation of therapy. Unfortunately, the interpretation of the results is difficult, as the study was hampered by very poor patient compliance, with only 36% of the intervention patients drinking the antioxidant-enhanced beverage for the duration of the test period. Additionally, the study has been criticised for using insufficient doses of antioxidants and, although supplementation led to a marked increase in plasma antioxidant levels before cisplatin treatment, enhanced levels were not maintained during chemotherapy. Clearly, further investigation is required.

Antioxidants and radiation therapy

Until recently, research attention has focused primarily on the interaction of antioxidants with chemotherapy, and relatively little attention has been paid to the interaction of antioxidants with radiotherapy. In general, oncologists take the view that antioxidants diminish the effectiveness of radiation therapy; however, there is great variation in the degree of concern over this issue.

Reviews by Moss (2007) and Lawenda et al (2008) provide summaries of the available evidence to determine whether antioxidants interfere with radiation therapy. The different conclusions drawn by the two reviews clearly indicate that the issue of safety in this population is far from decided.

In the literature, published studies have reported on the use of alpha-tocopherol for the amelioration of radiation-induced mucositis; pentoxifylline and vitamin E to correct the adverse effects of radiotherapy; melatonin alongside radiotherapy in the treatment of brain cancer; retinol palmitate as a treatment for radiation-induced proctopathy; a combination of antioxidants (and other naturopathic treatments) and external beam radiation therapy as definitive treatment for prostate cancer; and the use of synthetic antioxidants, amifostine, dexrazoxane, and mesna as radioprotectants. Moss (2007) concluded that, with few exceptions, most of the studies draw positive conclusions about the interaction of antioxidants and radiotherapy.

In contrast, Lawenda et al (2008) came to a different conclusion and advised against the concurrent use of antioxidant supplements. Five randomised clinical studies are reported that investigated the use of high-dose vitamin E (400–600 mg/day or 400 IU/day), high-dose beta-carotene (30 mg/day) or melatonin (20 mg/night) in patients with head and neck cancers, non-small-cell lung cancer, brain metastases or glioblastoma multiforme who were receiving radiotherapy. Two of these studies produced negative findings. The most concerning was that generated by Bairati et al (2005) who conducted a randomised, double-blind, placebo-controlled study involving 540 head and neck cancer patients treated with radiation therapy. Patients receiving supplementation with alpha-tocopherol (400 IU/day) and beta-carotene (30 mg/day) administered during radiation therapy and for 3 years thereafter tended to have less severe acute adverse effects during radiation therapy; however, the rate of local recurrence of the head and neck tumour tended to be higher in the supplement arm of the trial. Subgroup analysis published later found that interactions between antioxidant supplementation and cigarette smoking during radiation therapy were associated with an increase in both disease recurrence and cancer-specific mortality, whereas no increase in either of these outcome measures was observed for the non-smokers (Meyer et al 2008).

Lawenda et al (2008) point out that it is important to distinguish between high-dose and relatively low-dose antioxidant supplementation and the variations in antioxidant classes, because these differences may substantially define the efficacy and safety profiles of specific antioxidant supplements as therapy for cancer patients receiving selected chemotherapy agents or radiation therapy. Conklin, from the University of California, Los Angeles (UCLA) puts forward the theory that while radiation kills cells by generating high levels of free radicals, the effect is most successful in well-oxygenated tissues (Moss 2007). Tumours, particularly large ones, are often hypoxic at their core, thereby diminishing the effectiveness of radiation. He further suggests that the degree of free radical generation is proportional to the oxygen tension in the tissue, and with improved blood flow, resulting from relatively low-to-moderate doses of antioxidants, improved neoplastic activity may be seen. Conklin also makes the point that the dose of antioxidant supplementation must be sufficiently low to avoid the risk of diminishing treatment efficacy.

Increased risk of bruising and bleeding

A number of commonly used herbs and natural supplements demonstrate antiplatelet activity and have the potential to increase the incidence of bruising and/or bleeding when taken in sufficient dosage. This is of particular concern for patients undergoing major surgery who are taking anticoagulants or conventional antiplatelet agents. A list of these substances is given in Chapter 9.

Hormonally responsive tumours

Hormonal agents are used when a neoplasm is sensitive to hormonal growth controls in the body; for example, prostate cancer is stimulated by male androgens and breast cancer by oestrogen. Chemical treatment may consist of anti-androgens, anti-oestrogens and/or cytotoxic agents. Many constituents in herbs and everyday foodstuffs can theoretically stimulate or inhibit tumour growth or interact with hormonal treatments. The flavonoid group of naturally occurring chemicals provides a good example.

Flavonoids are polyphenolic compounds that are widely found in vegetables, nuts, fruits, beverages (e.g. coffee, tea and red wine) and medicinal herbs such as St Mary's thistle and St John's wort. They exert a wide range of biochemical and pharmacological actions and have been the focus of much interest, especially with regard to their cancer-protective activities, which are attributed to free radical scavenging, modification of the enzymes that activate or detoxify carcinogens, and inhibiting the induction of the transcription factor activator protein-1 activity by tumour promoters (Moon et al 2006).

Some of these compounds have been found to decrease oestrogen biosynthesis; for example, the flavones chrysin and baicalin, the flavonones (naringenin) and isoflavones (genistein, biochanin A) (Moon et al 2006). This is achieved by inhibiting the activity of aromatase (cytochrome P19) and could theoretically have a use in breast and prostate cancer (Kao et al 1998). Additionally, some flavonoids, such as soy isoflavones, can bind to oestrogen receptors and might slow down cell proliferation as a consequence (Wood et al 2006). Unfortunately, the bioavailability of many dietary flavonoids tends to be low, so effects seen in vitro do not necessarily reflect in vivo responses; however, this may not be true for herbal preparations or functional foods with concentrated flavonoid levels that may achieve much higher plasma concentrations.

Soy and isoflavones Dietary soy isoflavones have attracted a lot of attention as potential cancer-protective agents, chiefly because of observations that high consumption in Asian diets has been correlated with lower incidence of prostate and breast cancers. Currently the data available is contradictory and it is still unclear under what conditions soy isoflavones have cancer protective effects, if at all.

The potential for soy isoflavones to either enhance or antagonise the effects of anticancer medicines such as tamoxifen has also been investigated in several experimental models. Most studies have focused on genistein, because of its relatively strong binding (in comparison to daidzein) to the alpha- and beta-oestrogen receptors and its oestrogenic/anti-oestrogenic activities, which are stronger than those of other isoflavones (Constantinou et al 2005). Some studies have raised the possibility that genistein could compete with tamoxifen for oestrogen receptors and thereby decrease the drug's efficacy, an observation seen in two experimental models (Constantinou et al 2005, Ju et al 2002). Alternatively, research conducted with daidzein has produced positive results and showed that it enhanced the effect of tamoxifen against mammary carcinogenesis in the rat model (Constantinou et al 2005). In fact, the combination of tamoxifen/daidzein was more effective than tamoxifen alone for reducing tumour burden, incidence and multiplicity, as well as increasing tumour latency. When these results are taken together, it appears that although the isoflavone genistein may have a deleterious effect when combined with tamoxifen, the use of soybeans in combination with tamoxifen is not necessarily dangerous and beneficial effects may even be possible.

Drug inactivation — chemical incompatibility

Predicting interactions between natural products and chemotherapeutic drugs is difficult and occasionally unexpected findings come up. The following case highlights the challenges in making interaction predictions in the area of IO and provides a good example of drug inactivation caused by a natural compound.

In recent years, chemopreventative and chemotherapeutic effects of green tea have been reported in different malignancies and have become well known. Epigallocatechin-3-gallate (EGCG), the most abundant and biologically active polyphenol in green tea, selectively inhibits cell growth and induces

apoptosis in cancer cells without adversely affecting normal cells. The antitumour effects of EGCG include inhibition of angiogenesis, modulation of growth-factor-mediated proliferation, suppression of oxidative damage, induction of apoptosis and cell-cycle arrest. As a result, it has become a popular beverage amongst people with cancer or at risk of cancer.

In 2006, Shammas et al (2006) reported that EGCG demonstrated potent and specific antimyeloma activity in experimental models, thereby suggesting it could have a role in chemoprevention and possibly treatment of multiple myeloma. As a result, a few years later EGCG was tested in vitro and in vivo to investigate whether combining it with the proteasome inhibitor bortezomib (BZM), commonly used in the treatment of multiple myeloma, would result in an increase in the drug's antitumour activity (Golden et al 2009). The results were surprising, as green tea extract almost completely blocked the effects of BZM both in vitro and in vivo.

Upon further investigation, it was found the interaction was due to a 1,2-benzene diol moiety contained in some of the green tea constituents, particularly the epigallocatechin-gallate (EGCG) which formed stable covalent bonds with the boronic acid moiety of BZM. The formation of the new boronate product resulted in little to none of the proteasome-blocking effect usually observed for BZM, thereby neutralising the cytotoxic activity of BZM. The pronounced antagonistic function of EGCG was evident only with boronic acid-based proteasome inhibitors (bortezomib, MG-262, PS-IX), but not with several non-boronic acid proteasome inhibitors (MG-132, PS-I, nelfinavir).

Although the in vivo component of this study was carried out in mice, the evidence is compelling and strongly suggests that in current practice the combination of BZM and green tea should be avoided until proven safe in clinical studies. It is important to note that this interaction was not based on an antioxidant/free radical mechanism and hence cannot be extrapolated to other antioxidants based solely on their free radical scavenging activity. Whether other agents containing the 1,2-benzene diol moiety also interact with boronic acid-based proteasome inhibitors in the same way is unknown, but it would be prudent to avoid concurrent use until safety is established. Some components containing the 1,2-benzene diol moiety found in the diet and as constituents in several herbal medicines include quercetin and myricetin, which have previously been shown to inhibit BZM in vitro (Liu et al 2008).

Pharmacokinetic interactions

Pharmacokinetic interactions often involve metabolising enzymes or drug transporters that have great significance in chemotherapy. Cytochrome enzymes (CYP) and drug transporters in the intestinal epithelium affect the bioavailability of many oral chemotherapy agents and can induce multidrug resistance.

P-glycoprotein

One mechanism responsible for multidrug resistance is overexpression of the adenosine-triphosphate(ATP)-binding cassette-containing family of proteins such as P-glycoprotein (P-gp), which has a counter-transport role and actively forces substrates out of cells. These proteins are expressed in both healthy cells, such as the blood–brain barrier, and resistant tumour cells, and act as a barrier. Of significance, they are highly expressed in the lumen of the gut and can substantially impede the oral uptake of several anticancer medicines (Beijnen & Schellens 2004). Examples of anticancer medicines that are P-gp substrates are:

- daunorubicin
- docetaxel
- doxorubicin
- paclitaxel
- taxol
- tacrolimus
- vinblastine
- vincristine.

An interaction will occur when a substrate is co-administered with another substance that alters the expression of the relevant counter-transport protein. In regards to P-gp, expression can be altered by a number of factors such as common foods, herbs and pharmaceutical medicines. A promising strategy is to use P-gp inhibitors to increase drug bioavailability and reverse multidrug resistance in tumours; for example, the use of oral cyclosporine and paclitaxel has proved successful in a phase II study of people with advanced non-small-cell lung cancer (Kruijtzer et al 2002). Alternatively, P-gp inducers can have the opposite effect and reduce the bioavailability of P-gp substrates and increase drug resistance: they should be avoided when medicines that are P-gp substrates are administered.

Herbal and natural medicines affecting P-gp The influence of herbal and natural medicines on P-gp expression has only recently been investigated, so much is still unknown and speculative. To date, most research has centred on St John's wort (*Hypericum perforatum*), which has significant P-gp induction effects, as demonstrated in clinical testing (Durr et al 2000). Studies have found that, after 16 days of continual use, P-gp expression can increase 4.2-fold. The hyperforin constituent is responsible for the induction effect, which is achieved by activation of the pregnane X receptor (Moore 2000). In Europe, some manufacturers have produced low-hyperforin-containing herbal products, which may not have the same effect. Besides St John's wort, the isoflavone genistein is reported in other studies to inhibit P-gp-mediated drug transport (Castro & Altenberg 1997).

Alternatively, rosemary extract acts as a P-gp inhibitor. According to an in vitro study, multidrug-resistant mammary tumour cells treated with rosemary extract produced an increase in intracellular concentrations of doxorubicin and vinblastine, both of which are P-gp substrates (Plouzek et al 1999), and the same effects were not seen in cells that lack P-gp expression. More recently, an in vitro study identified that bitter melon (*Momordica charantia*) leaf extract exhibited dose-dependent P-gp inhibition, which resulted in intracellular vinblastine accumulation (Limtrakul et al 2004). The effect was not seen for the fruit. Many other natural substances affect P-gp and have potential as useful adjuncts in the chemotherapeutic treatment of cancer.

Cytochromes and metabolism

Many drugs undergo two phases of metabolism: phase I, or functionalisation reactions, and phase II, or conjugation reactions. Many medicines, nutrients, environmental toxins and endogenous substances undergo metabolism by the CYP P450 system during phase I metabolism. As a result, an active substance can be converted into an inactive, less active, more active or toxic metabolite, or an inactive prodrug can be converted into an active one. Although there are over 50 enzymes in the CYP system, the most important for drug metabolism are CYP1A2, 2D6 and 3A4. In particular, CYP3A4 is involved in the metabolism of many anticancer medicines, some examples of which are the oxazaphosphorines (cyclophosphamide, ifosfamide) and the taxanes (paclitaxel, docetaxel) (Beijnen & Schellens 2004) (see also Table 10.4).

Interactions occur when CYP substrates and inducers or inhibitors are taken at the same time.

Herbal and natural supplements affecting CYP enzymes Many factors can interfere with CYP activity, such as the ingestion of foreign compounds (e.g. environmental contaminants) or of certain constituents found in food, beverages, herbs or medicines. Of the herbal medicines commonly available, most research has been conducted with St John's wort, which significantly induces CYP enzymes, particularly CYP3A4 with long-term administration (Durr et al 2000, Roby et al 2000, Ruschitzka et al 2000). Once again, these effects are attributed to the interaction between hyperforin and the pregnane X receptor, which regulates expression of CYP3A4 mono-oxygenase. In this way, hyperforin increases the availability of CYP3A4, resulting in enzyme induction (Moore et al 2000). Clinically, this means that serum levels of those medicines that are CYP3A4 substrates will be reduced, which can reduce drug effectiveness and possibly induce therapeutic failure.

In recent years a growing number of other herbal medicines have been subjected to interaction studies and investigated for effects on CYP isoenzymes and transporter proteins, using new in vitro and in vivo techniques. The evidence from these tests suggests that several other herbal medicines have the potential to

TABLE 10.4 Cytochrome Enzymes Involved in the Metabolism of Chemotherapeutic Drugs

Cytochrome enzyme	Chemotherapeutic drug
CYP 1A1, 1A2	dacarbazine
CYP 2A6	cyclophosphamide, ifosfamide, tegafur
CYP 2B6	cyclophosphamide, ifosfamide
CYP 2C8	cyclophosphamide, ifosfamide, paclitaxel
CYP 2C9	cyclophosphamide, ifosfamide
CYP 2C19	teniposide
CYP 2D6	tamoxifen, doxorubicin, vinblastine
CYP 2E1	dacarbazine
CYP 3A4	teniposide, etoposide, epipodophyllotoxin, cyclophosphamide, ifosfamide, vindesine, vinblastine, vincristine, vinorelbine, paclitaxel, docetaxel, irinotecan, tamoxifen
CYP 3A5	etoposide, tipifarnib

affect drug absorption and/or metabolism. However, readers are advised that translation of in vitro data to clinical practice is problematic and imperfect, and in vivo testing is required before an interaction prediction can be made.

For example, silymarin, the active constituent group from St Mary's thistle, significantly decreases CYP3A4 activity in primary cultures of human hepatocytes; however, four clinical studies have found no clinically significant effects in vivo (Gurley et al 2004, DiCenzo et al 2003, Leber & Knauff 1976, Piscitelli et al 2002). The daily doses of silymarin used in the clinical studies ranged from 210 mg to 480 mg.

ELIMINATION

Although most anticancer medicines are eliminated though metabolism, some, such as the platinum compounds and methotrexate, are eliminated mainly by the kidneys through glomerular filtration and active tubular secretion (Beijnen & Schellens 2004). Urinary excretion can be altered by substances that affect urinary pH, which will affect renal tubular reabsorption. One substance sometimes used by cancer patients is ascorbic acid. Although low-dose ascorbic acid is unlikely to cause detrimental effects, high doses that acidify the urine can affect the excretion of drug metabolites, which precipitate in the renal tubules at low pH. As a result, there has been a theoretical concern that high-dose vitamin C could precipitate methotrexate. A study by Sketris et al (1984) investigated the proposed interaction and found that it does not appear to be clinically significant; however, caution is still advised.

CLINICAL IMPLICATIONS OF INTEGRATIVE MEDICINE

People with cancer expect their healthcare providers to work with them to achieve adequate symptom relief, improved quality of life and a cure. In order for this to be achieved, a holistic approach that combines several different disciplines is best.

Although the role of some forms of CM in cancer is still unclear, there is evidence to support the use of several therapies and treatments. When therapies are considered safe and provide a supportive role in cancer, either for symptom relief or improvements in wellbeing and quality of life, they should be made available and become a part of standard protocol. This requires access to reliable information and a collaborative partnership with a variety of healthcare providers based on mutual respect and open communication.

SHARED DECISION MAKING

A wide range of patient- and physician-related factors affect clinical decision making and subsequent use or disuse of CM.

1. General safety issues

Patient safety is paramount. Medicinal CM treatments (CMs) can pose a risk to patients via several mechanisms:

- Interference with blood clotting. Cancer patients often have low platelets at various points throughout their treatment, either as a direct result of the cancer itself, or as a temporary side effect from the chemotherapy or radiotherapy. CMs that significantly inhibit blood clotting will increase the risk of haemorrhage.
- Interactions with conventional chemotherapy drugs or radiation therapy resulting in diminished therapeutic effect.
- Interactions with conventional chemotherapy drugs or radiation therapy resulting in increased toxicity and/or other side effects.

Product quality is particularly important to assess in this population. For example, products contaminated with microorganisms can have serious consequences for immunosuppressed patients who have limited ability to mount an immune response.

Such concerns obviously do not relate to non-medicinal CM therapies such as massage and meditation, which may provide significant improvement to patients' wellbeing and quality of life during treatment. In this regard, finding an appropriately trained and credentialled practitioner with experience in treating cancer patients provides some safeguard against possible harm.

2. Availability of credible information sources

Credible, accurate and timely information is required for both patients and healthcare providers in order for evidence-based patient-centred care to occur.

Asking patients about their interest in and use of CM therapies is essential for good practice. Understanding their reasons for use and the information sources to which they have referred when making such decisions is also important. For many patients, family and friends are the main sources of information;

others use CM practitioners, the internet, books and magazines.

When discussing the reliability of the information, some points to guide the patient may include:

- Was the internet site used an officially recognised and registered site? Is it frequently updated and what are the credentials of the authors providing content for the site?
- Was the internet site supporting a profit-driven enterprise? Was information in advertorial style, rather than independently written?
- If CM practitioners were consulted, are they registered or accredited with a professional association? What is their training and experience? Credentials?

Healthcare providers should ensure that they:

- have access to current, credible and relevant information sources
- have effective information-seeking skills to locate information from databases and other resources
- are able to critically evaluate the information retrieved
- have a network of reliable CM practitioners who can provide additional information about treatments when necessary, as sometimes the peer-reviewed medical press has little useful information about some CM treatments.

3. Evidence of efficacy and safety

Evidence-based patient-centred care means amassing and evaluating the best available evidence and involving patients in a shared decision making process that takes into account their individual circumstances and wishes.

The emerging picture shows that the evidence base is greater for some CM therapies than others, and there is an urgent need for more research from a variety of perspectives and methodological approaches. Peer-reviewed journals provide a good starting point for gathering evidence, and frequently updated databases written by people expert in CM are also useful. It is important to note what evidence exists, but also what is missing and remains unknown. Importantly, keep in mind that *a lack of evidence is not necessarily evidence of a lack of effectiveness.* It is likely that some CM treatments being used by patients are effective, but have not yet been subjected to clinical trials. Table 10.5 gives a list of useful internet information sources.

When reviewing the evidence, look for:

- in vitro tests and studies with animal models that provide information about mechanisms, pharmacokinetic influences and the potential effects in humans, although they are not definitive
- clinical studies to provide more relevant information — consider the patient group involved, intent of treatment, interventions used (dose, form, time frames, administration method, type of extract), what other medications were also used (where relevant) and outcomes measured
- up-to-date, comprehensive reviews of the literature.

4. Intent behind using CM treatment

CM therapies are generally used as adjuncts to conventional treatments and, in the case of cancer, to improve quality of life, address symptoms and reduce toxic side effects. Far less common is their use as a potentially curative treatment. The decision to use CM therapies for symptom relief requires different consideration from using CM for curative purposes or as an alternative to conventional care.

5. Severity of disease

The use of CM by people with readily curable cancers is often viewed differently to its use by people with difficult-to-treat cancers or by palliative patients.

Highly curable cancers

When conventional treatments have a high cure rate, then concomitant use of less proven treatments should be avoided unless there is clear evidence that it will not diminish outcomes. For example, testicular cancer currently has a 99% 5-year survival rate when treated aggressively with chemotherapy (see http://www.cancervic.org.au/about-our-research/cancer-statistics). The chemotherapy used for this type of cancer commonly involves cisplatin. Although some clinical studies indicate that concurrent use of antioxidants is likely to be safe, until definitive evidence becomes available it is prudent to avoid use during curative treatment.

If the patient understands the risks associated with the use of complementary medicinal agents during curative treatment, and voluntarily decides to use CM treatment, a compromise may sometimes be reached. It is reasonable to suggest the patient takes CM treatment in between treatment cycles, but abstains for a certain time period before, during and after curative treatment to minimise the risk of drug interactions. The washout period between treatments will depend on the pharmacokinetics of the agents being used.

TABLE 10.5 Useful Web-Based Information Sources

Information source and URL	Description
National Cancer Institute (USA) http://cancer.gov	The National Cancer Institute (NCI) is a component of the National Institutes of Health (NIH), one of eight agencies that compose the Public Health Service (PHS) in the Department of Health and Human Services (DHHS). The NCI, established under the National Cancer Act of 1937, is the Federal Government's principal agency for cancer research and training. The website includes cancer topics, clinical trials, cancer statistics, research and funding, and cancer-related news.
Office of Cancer Complementary and Alternative Medicine http://www3.cancer.gov/occam	The Office of Cancer Complementary and Alternative Medicine (OCCAM) was established in October 1998 to coordinate and enhance the activities of the National Cancer Institute (NCI) in the arena of complementary and alternative medicine (CAM). The website includes CAM information, research resources, the NCI Best Case Series, clinical trials, grant application information, and funding opportunities in cancer CAM.
PDQ Cancer Information Summaries: Complementary and Alternative Medicine http://cancer.gov/cancertopics/pdq/cam	Electronic resource containing summaries of complementary therapies.
PDQ Cancer Clinical Trials http://www.cancer.gov/clinicaltrials/finding/	The Physician Data Query (PDQ) holds many clinical trials in its international registry and is maintained by the NCI. Users can perform tailored searches focusing on type of cancer, trial type (treatment, supportive care, screening, prevention, genetics, diagnostic), location, status (active or closed), phase, sponsor, and drug name.
Cancer Research Portfolio http://deais.nci.nih.gov/Query/	Electronic source for searching, organising and analysing NCI-supported research by organ/cancer site and/or by broad area of scientific interest, such as biology, cancer etiology, prevention, early detection, diagnosis, prognosis, treatment, cancer control, survivorship, and outcomes research, and scientific model systems.
National Center for Complementary and Alternative Medicine (USA) http://nccam.nih.gov/	The National Center for Complementary and Alternative Medicine (NCCAM) is one of the 27 institutes and centres that make up the National Institutes of Health (NIH). Congress established NCCAM in 1998 to explore complementary and alternative healing practices in the context of rigorous science, to train complementary and alternative medicine (CAM) researchers, and to disseminate authoritative information to the public and professionals.
Office of Dietary Supplements (USA) http://ods.od.nih.gov/	The US *Dietary Supplement Health and Education Act 1994* authorised the establishment of the Office of Dietary Supplements (ODS) at the NIH to promote scientific research in the area of dietary supplements. The website covers background information about claims and labelling for dietary supplements and botanicals, tips for supplement users, how to spot health fraud, and access to US Department of Agriculture and NIH databases.
American Cancer Society http://www.cancer.org/docroot/eto/eto_5.asp?sitearea=eto	The American Cancer Society (ACS) is a nationwide community-based voluntary health organisation. With headquarters in Atlanta, Georgia, the ACS has state divisions and more than 3400 local offices. The ACS journal, *CA A Cancer Journal for Clinicians* archives numerous articles on CAM.
Consumer Labs http://www.consumerlab.com/	ConsumerLab.com, LLC (CL) provides independent test results and information to help consumers and healthcare professionals evaluate health, wellness, and nutrition products. It publishes results of its tests on its site, including listings of brands that have passed testing. Products that pass CL's testing are eligible to bear the CL Seal of Approval.

Sources: Lee 2005, Schmidt and Ernst 2004, Vickers and Cassileth 2001

For chemotherapy, for example, St John's Wort should be discontinued at least 7 days before any chemotherapy that is metabolised by the CYP3A4 enzymatic pathway or involves the P-gp transporter (see Chapter 8). Treatment may be recommenced after five times the elimination half-life of the chemotherapy agent. Making an accurate determination of appropriate washout periods is difficult owing to interpatient variability of pharmacokinetics, and the difficulty in interpreting pharmacokinetic data. As a result, a conservative estimation of the half-life is recommended.

The Micromedex database states that the drug cyclophosphamide has an elimination half-life of 3 to 12 hours (Commonwealth of Australia 2005). This means that St John's Wort should not be started until 3 days ($12 \times 5 = 60$ hours) after cessation of the cyclophosphamide. However, this has not taken into account the fact that cyclophosphamide has active metabolites that contribute to its pharmacological effect. No specific data are available in popular drug databases concerning the half-life or the metabolic pathway of the primary active metabolite, but a case study of 12 people is reported that identified 77% of the active metabolite present in serum 8 hours after administration. Assuming linear elimination kinetics, the elimination half-life of the active metabolite is extrapolated to be 17.3 hours; thus, the patient should wait for at least 86.5 hours before recommencing St John's Wort. In such cases, if the cyclophosphamide is being given at regular intervals (often every 14 or 21 days), the most practical option is to abstain throughout treatment and recommence 4 days after the final treatment cycle has ended.

The use of CMs during active chemotherapy attracts a greater risk of drug interactions and is more problematic. It is essential to gather credible information about the known and unknown benefits and risks and to provide this to patients so they can be involved in making an informed decision. If patients with a readily curable cancer experience drug-induced toxicities that jeopardise their ability to continue treatment or necessitates dose reduction, then concurrent use of antioxidants and other organ-protective treatments may be more acceptable and provide a useful option.

Difficult-to-cure cancers

When conventional treatments do not have a high cure rate, or a patient's response to treatments has been poor, then a different situation arises. The combined use of CMs with conventional treatments is more acceptable in this setting, although thoughtful judgment still applies.

Numerous CM therapies have been shown to reduce a variety of chemotherapy-related side effects and/or pose no obvious risk to patients. In addition, CMs shown to have potential to increase the efficacy of chemotherapy can be further explored (with less ethical problems) in this patient group.

For example, ovarian cancers in the advanced stages are often treated with single-agent cisplatin or carboplatin. Treatment cessation or dose reductions are most often due to toxicities and/or renal impairment. Various antioxidants have been shown to reduce chemotherapy-induced peripheral neuropathy

PRACTICE TIPS TO PROMOTE PATIENT SAFETY

1. Ask all patients about the use of CMs.
According to the literature, many patients fail to disclose use of CMs to hospital staff; however, disclosure is more likely if they are asked directly. Some patients may not understand what is meant by the term 'complementary medicine', so consider using phrases such as 'vitamins, minerals or herbal medicines' or 'natural medicines'. If a patient is also seeing a CM practitioner who is prescribing CM treatments, it may be important to contact the practitioner and start an open dialogue to promote patient safety and continuity of care.

2. Clear communication about risks and benefits, known and unknown
If a patient is using a CM that has known or suspected potential to cause adverse outcomes, an honest discussion about what is known and unknown about the risks should ensue. If the patient still wishes to continue using the CM product against professional advice, the patient should be asked to sign a form listing the potential adverse effects to acknowledge that the attending doctor or pharmacist has recommended against continued use. This should also be documented in the patient's medication history and/or discharge summary.

3. Suspend use of complementary medicines known or suspected to pose a safety risk
Pharmacokinetic data about the drugs involved in treatment will help determine appropriate washout periods.

4. If in doubt, refer to drug information centres, peer-reviewed literature or reputable resources for further information.
Evidence is accumulating about CM at a rapid rate and it would be unreasonable to expect all healthcare professionals to keep up to date with these changes. However, referring to reputable information sources when unsure about patient safety is essential for best practice.

5. Document information and recommendations in patient's chart.
Patient's CM use should be documented in the medication history and/or discharge summary as appropriate. The name, strength, brand and dose used should be recorded.

6. Consider if and when a patient can resume taking the CM.
If use of an effective CM has been withdrawn, recommencement will be required to restore the patient's response. This should be discussed when taking the medication history.

7. Recommend CMs with known safety and benefits.
If research indicates a complementary medicine has significant patient benefits and is low risk, then evidence-based practice dictates it should be considered in the patient's management. Furthermore, if a patient is experiencing beneficial outcomes from the use of a CM product in the time prior to cancer treatment and the available evidence indicates efficacy and safety, continued use should be considered and carefully monitored.

8. If an adverse event does occur, report this through the relevant channels.
Case reports provide useful clues that can guide future research to better determine factors affecting patients' safety.

(Wolf et al 2008), renal toxicity and haematological toxicity (Block et al 2007) and may play an important role in reducing additional organ damage. Some clinical studies further suggest that co-administration may improve survival outcomes. As a result, combined use of antioxidants and other CMs with chemotherapy may present patients with a good option.

Palliative care

The goal of palliative care is the achievement of the best quality of life for patients and their families. It involves the active holistic care of patients with advanced, progressive illness so they can live as actively as possible. It also involves assisting patients to die as they have lived, when the time arrives. Respecting a patient's choice during this period is of supreme importance. Providing relief from pain and other symptoms is paramount.

CM therapies are more accepted in the palliative care setting and can provide an important means of improving patients' quality of life, as the potential benefits of treatment tend to outweigh the potential risks. There is also a greater emphasis on patients' values and lifestyle habits in the delivery of quality care at the end of life, which allows more flexibility in patient care.

Besides providing physical benefits, the use of various CM therapies and medicinal treatments may provide significant psychological benefits for patients and their families if they have a strong need to feel they have tried everything possible that is available to them. The use of CM during this stage may assist them in coming to terms with the disease and subsequently help the family in the bereavement period.

Unfortunately, indiscriminate use of CM treatments during this period may also occur as patients and families search desperately for new treatments. This may have detrimental effects and place an unwanted burden on the patient physically, psychologically and financially if they comply with family wishes while suffering added discomfort to do so. In the UK, national guidelines for the use of complementary therapies in supportive palliative care provide a comprehensive overview of the key issues involved in CM provision and make recommendations for the safe and appropriate use of CM treatments in this population (Tavares 2003).

It is important to remember the ultimate decision to use or disuse CM treatments lies with the patient.

Communicating with patients

Clearly, the need for physicians to assist patients in treatment decision making is considerable and requires more than just being informed about CM. Physicians also need to have effective (and non-judgmental) communication skills to manage the discussion. They must also be prepared to provide information and advice about the benefits and likely outcomes of treatment, potential risks and complications, side effects and complementary treatment options. This information is needed to meet the traditional ethical principles of non-maleficence (do no harm) and beneficence (offer a benefit) (Verhoelf et al 2006).

CHAPTER 11
HERBS AND NATURAL SUPPLEMENTS IN PREGNANCY

INTRODUCTION

Most women take over-the-counter medicines at some point during their pregnancy. This may occur intentionally or happen inadvertently during the early stages of pregnancy. The advice on many product labels and package inserts is to 'consult your doctor' or 'consult your healthcare provider' before using a particular medicine, yet many healthcare providers are poorly equipped to weigh up the benefits of taking, or not taking, a particular medicine during pregnancy. The risk/benefit assessment is possibly even more complex when considering the safety and efficacy of complementary medicines (CMs).

Medical and complementary medicine practitioners, pharmacists and other healthcare providers face similar challenges when advising the pregnant patient about CMs. Despite their popularity, there is very little published evidence regarding the efficacy and safety of natural medicines during pregnancy and lactation. Modern and traditional texts may warn against use, but little information is provided about the evidence upon which such a recommendation is based. Information about the potential efficacy of CMs in pregnancy is also scarce.

This chapter aims to provide readers with an introduction to the fundamental concepts and concerns surrounding the use of complementary medicines in pregnancy. Part 1 explores the use of herbs and natural supplements in pregnancy from contemporary and traditional approaches. Safety and evidence issues are discussed in Part 2. Central to this section is a discussion about the methods of establishing the safety of any medicine in pregnancy. Part 3 provides a guide to using the information in this chapter to shape clinical practice.

PART 1: USE OF HERBS AND NATURAL SUPPLEMENTS IN PREGNANCY

It is commonly known that complementary medicine (CM) is widely used throughout the world. In many countries traditional medicine continues to form the basis of primary healthcare (WHO 2002). There is a trend in developed countries, including Australia, towards an increase in the use of traditional medicine and CM (Thomas et al 2001, MacLennan et al 2002, Tindle et al 2005, Xue et al 2007). Recent literature indicates that women frequently use CM during pregnancy; however, usage estimates vary considerably owing to variations in the definition of CM used, geographical location, socioeconomic and cultural influences. For example, surveys conducted in Europe, USA and Canada indicate that the prevalence of CM usage in pregnancy ranges from 7.1% to 96% (Forster et al 2006). In Australia it is estimated that between 10% (Henry & Crowther 2000) and 91% (Forster et al 2006) of all pregnant women will use CM at some stage during their pregnancy. With regard to herbal medicines specifically, although the majority of women discontinue taking them once they know they are pregnant, some others may commence taking them on the advice of their maternity care providers (Ranzini et al 2001).

Surveys of Australian women have revealed that nutritional supplements are frequently taken before and throughout pregnancy.

During the pre-conception period, the most common supplements taken are folate (29–33%), multivitamins (11–12%) and other supplements including vitamin C, and calcium and iron (12–15%). During pregnancy, use of folate increases to 70–79% of women (particularly in the first trimester), multivitamins to 27–35%, iron to 38–52%; use of other supplements also increases, including calcium (6–24%), vitamin B_6 (1–13% predominantly in the first trimester) and zinc (1–7%). The herbal medicine most often used in pregnancy is raspberry leaf (particularly in the last trimester) (Maats & Crowther 2002, Forster et al 2006).

Despite the widespread use of CMs, pregnant women do not always disclose their use to healthcare providers. In one study only 1% of participants' medical records listed their CM use (Maats & Crowther 2002), while another study reported that 75% of women had informed their primary care provider (Tsui et al 2001). Lack of disclosure is problematic because women miss the opportunity to receive informed advice about the effectiveness and safety of the medicines they have chosen to use and prevent unsafe outcomes, while unsupervised use potentially increases the risk of drug interactions with prescribed medicines and contributes to the under-reporting of side effects and adverse outcomes.

Some pregnant women are motivated to take CMs in lieu of conventional medicines because they believe CMs to be safer (Hollyer et al 2002). Sometimes self-prescribed use is justified, such as using nutritional supplements to meet increased nutritional requirements; to treat a pregnancy-related health issue (e.g. nausea or general pregnancy preparation); or to treat non-pregnancy-specific problems (e.g. the common cold) (Henry & Crowther 2000, Maats & Crowther 2002, Nordeng & Havnen 2004).

Pregnant women appear to use a variety of information sources to aid their selection of CMs, including healthcare practitioners (Tsui et al 2001, Forster et al 2006), friends, family members (Tsui et al 2001, Hollyer et al 2002, Maats & Crowther 2002, Nordeng & Havnen 2004) and media sources (e.g. magazines and the internet) (Tsui et al 2001).

NUTRITIONAL MEDICINE

Pregnant women may choose to use nutritional medicines as symptomatic treatment to improve their own general health and to optimise the healthy development of the growing child and its safe delivery.

Most clinicians will be aware of the changes in nutritional requirements that occur in pregnancy and the need for women to increase their dietary intake of certain nutrients such as iron, calcium, folate and others. Nutritional supplements are sometimes used to help women achieve these higher intake levels and to correct preexisting deficiencies. The National Health and Medical Research Council's nutritional guidelines for the adequate intake of vitamins and minerals (NHMRC 2006) are a guide for nutritional requirements during pregnancy. However, these guidelines are only estimates based on extrapolated data from other populations and models and do not take into account the individual's specific needs. In practice, a detailed diet and lifestyle history and sometimes additional pathology testing are necessary so that clinicians can make more appropriate individual recommendations.

Besides enabling women to meet their basic nutritional needs, nutritional supplements are also used in larger doses to act as pharmacological agents to ameliorate symptoms and address specific health complaints. For example, calcium and magnesium supplements have been used to reduce the severity of leg cramps, pyridoxine to alleviate nausea, and folate to reduce the incidence of neural tube defects. Table 11.1 (pp 151–6) lists common nutritional supplements and their use in pregnancy.

Long-term impact of maternal nutrition

The 'developmental origins of disease' hypothesis suggests that the benefits of a nutritional intervention may extend much further than the more immediate outcomes. Environmental factors during development, such as maternal nutrition, have been shown to influence the expression of our phenotype. The most sensitive time for this influence has been shown to be in utero. Fetal nutrition can alter the body's structure, function and metabolism, subsequently affecting the risk of developing diseases later in life (Barker 2004). Longitudinal studies from around the world have found that low birth weight (in relation to gestational age) is associated with an increased risk of coronary heart disease, stroke, hypertension and type 2 diabetes in adulthood (Barker 2007). Furthermore, maternal vitamin D status during pregnancy appears to influence the bone-mineral density of offspring even in late childhood (Javaid et al 2006). Similarly, there is some evidence to suggest that calcium supplementation during pregnancy can reduce

TABLE 11.1 Nutrients During Pregnancy

Nutrient	Therapeutic function/justification	Dosage recommendations and issues
Vitamin A	• Required for gene expression and cellular differentiation in organogenesis and embryonic development of the spinal cord and vertebrae, limbs, eyes and ears, and heart (Morriss-Kay & Sokolova 1996). • Poor maternal status will result in risk of infant deficiency (Ortega et al 1997) associated with poor immune function and increased risk of infection morbidity and mortality in infants and children (Grubesic 2004, Huiming et al 2005). • Maternal deficiency increases the risk of mortality (West et al 1999), premature rupture of membranes (Westney et al 1994), preterm delivery (Radhika et al 2002), reduced haemoglobin levels and anaemia (Suharno et al 1993, Bondevik et al 2000), night blindness (Livingstone et al 2003) and immune suppression (Cox et al 2006).	• Excessive supplementation shown to be associated with adverse pregnancy outcomes, particularly in the first trimester. • No association between moderate intake (< 10,000 IU) and fetal malformations (Martinez-Frias & Salvador 1990, Werler et al 1990, Botto et al 1996, Mills et al 1997, Shaw et al 1997, Mastroiacovo et al 1999, Johansen et al 2008). • Supplement labels must carry the warning, 'When taken in excess of 3000 μg retinol equivalents (10,000 IU), vitamin A may cause birth defects'.
Vitamin B_6 (pyridoxine)	• Beneficial in the treatment of nausea in pregnancy (Jewell & Young 2003, Sripramote & Lekhyananda 2003, Jamigorn & Phupong 2007). • Poor vitamin B_6 status may decrease the possibility of conception (Ronnenberg et al 2007) and increase the risk of early pregnancy loss (Wouters et al 1993, Goddijn-Wessel et al 1996, Ronnenberg et al 2007).	• RDI during pregnancy is increased slightly to 1.9 mg, and upper recommended level is 50 mg with no evidence of teratogenicity. • High-dose supplementation (mean 132 mg/day) for 9 weeks during the first trimester appears to be safe, with no associated increase in risk for major malformations (Shrim et al 2006). Doses used in studies for nausea are 30–75 mg/day.
Vitamin B_9 (folic acid)	• Deficiency can lead to homocysteine accumulation, which may be associated with abnormalities of the placental vasculature and increased risk of miscarriage and preeclampsia (Dodds et al 2008, Napolitano et al 2008, Makedos et al 2007) and is associated with a two-fold increased risk of adult schizophrenia (Brown et al 2007). • Intake of folic acid pre-conceptually and during the first 4–6 weeks of pregnancy reduces the risk of neural tube defects (NTDs) by more than 50% (Czeizel & Dudas 1992, Berry et al 1999) and may also decrease the risk of other congenital malformations, including urinary tract and cardiovascular defects, limb deficiencies and hypertrophic pyloric stenosis (Czeizel 1998). Individuals with polymorphisms in folate metabolism (methylenetetrahydrofolate reductase [MTHFR] gene) may be at greater risk of deficiency and subsequent adverse effects (Coppede et al 2007, Biselli et al 2008, Boyles et al 2008, Candito et al 2008, Steer et al 2008). In this instance, 5-methyl-tetrahydrofolate preparations are more advisable.	• Supplementation with folate has been linked to increased risk of multiple pregnancies (Czeizel 1998, Czeizel & Vargha 2004) but this has been disputed by others (Li et al 2003). • RDI in pregnancy is 600 mcg/day (200 mcg above RDI in non-pregnancy state). Upper limit recommended in pregnancy 1000 mcg — due to the possibility of masking a vitamin B_{12} deficiency.
Vitamin B_{12} (cyanocobalamin)	• Inadequate cobalamin status in pregnancy has been associated with several adverse outcomes such as preterm birth (Ronnenberg et al 2002), intrauterine growth-retardation (Muthayya et al 2006), increased risk of NTDs (Kirke et al 1993, Wright 1995, Steen et al 1998, Suarez et al 2003, Groenen et al 2004, Gaber et al 2007) and increased risk of miscarriage (Hubner et al 2008). • Vitamin B_{12} is also required for homocysteine metabolism; increased levels have been associated with numerous conditions including preeclampsia (Napolitano et al 2008) and recurrent pregnancy loss (Hubner et al 2008). Inadequate maternal status may result in an infant with poor stores, and this may be further exacerbated by low stores in breast milk (Allen 1994).	• The RDI is slightly increased to 2.6 mcg/day in pregnancy. There is no upper level of intake as there is no evidence of adverse effects. • Deficiency (indicated by macrocytic changes) may be masked by high-dose folic acid supplementation.

Nutrient	Therapeutic function/justification	Dosage recommendations and issues
Vitamin C	• It has been suggested that vitamin C deficiency plays a role in several adverse pregnancy outcomes, such as preeclampsia, intrauterine growth restriction and pre-labour rupture of fetal membranes (PROM). A recent Cochrane Review, however, reported no difference for the risk of stillbirth, miscarriage, birth weight, placental abruption or intrauterine growth restriction between women supplemented with vitamin C (alone or combined with other supplements) and those given a placebo (Rumbold & Crowther 2005a, Rumbold et al 2005). • Required for healthy immune function and significantly reduces the risk of urinary tract infections during pregnancy (Ochoa-Brust et al 2007).	• The recommended intake of vitamin is slightly increased in pregnancy to 60 mg/day. • Early reports of high-dose maternal supplementation causing 'conditioned or rebound scurvy' in infants (Cochrane 1965, Rhead & Schrauzer 1971) have not been replicated in subsequent studies (Diplock et al 1998).
Vitamin D	• High prevalence of vitamin D deficiency in pregnancy and lactation has been reported (Hollis & Wagner 2004, Sachan et al 2005, Ainy et al 2006, Judkins & Eagleton 2006, van der Meer et al 2006). • Maternal vitamin D status affects the infant's vitamin D status (Hollis & Wagner 2004), intrauterine growth of long bones (Morley et al 2006), poor infant skeletal growth and mineralisation (Zeghoud et al 1997) and, in severe maternal deficiency, an increased risk of rickets in the infant (Specker 1994). Glucose intolerance (Maghbooli et al 2008), bone health and risk of osteoporotic fracture later in life may also be influenced (Javaid et al 2006). • Vitamin D is important for normal brain development (Eyles et al 2003, Cui et al 2007) with fetal deficiency leading to alterations in brain structure and function (Feron et al 2005, Almeras et al 2007). • Supplementation may protect against multiple sclerosis (Munger et al 2004, 2006) and reduce the risk of later preeclampsia in the infant (Hypponen et al 2007). • Conversely, maternal concentrations of > 75 nmol/L of 25(OH)-vitamin D in pregnancy may increase the risk of eczema in infants and asthma in children, but has not negatively influenced the child's intelligence, psychological health or cardiovascular system (Gale et al 2008).	• The amount of vitamin D required during pregnancy and lactation to avoid deficiency may be higher than the recommended amount (RDI 5.0 mcg) (Vieth et al 2001a, Hollis 2005, 2007). The recommended upper limit is 80 mcg (NHMRC 2006). Vieth et al (2001a), however, found no adverse effects even at doses of 100 mcg (4000 IU) per day. Toxicity is rare but may occur with excessive supplementation (Koutkia et al 2001). • Breast milk is a poor source of vitamin D with infants requiring an exogenous source within a few months (Sills et al 1994, Daaboul et al 1997, Challa et al 2005, Hatun et al 2005).
Vitamin E	• Antioxidant activity is valuable in protecting the embryo (in vitro) and fetus from damage due to oxidative stress (Wang et al 2002, Jishage et al 2001, Cederberg et al 2001). Although oxidative stress plays an important role in the pathogenesis of preeclampsia (Gupta et al 2005), there is little evidence for the role of vitamin E in its prevention (Rumbold & Crowther 2005b, Polyzos et al 2007). Some evidence suggests that in women with poor antioxidant status it was beneficial (Rumiris et al 2006). • Low maternal levels contribute to increased risk of wheezing and asthma in childhood (Devereux et al 2006), and supplementation was useful in reducing pregnancy-related leg cramps (Shahraki 2006) and in increasing birth weight for gestation (Valsecchi et al 1999, Scholl et al 2006).	• The recommended intake for vitamin E (7 mg) is not increased for pregnancy. High-dose supplementation of vitamin E (400–1200 IU) appears to be safe and does not increase risk for major malformations, preterm deliveries, miscarriages and stillbirths (Boskovic et al 2005). The recommended upper limit in pregnancy is 300 mg/day (NHMRC 2006).

TABLE 11.1 Nutrients During Pregnancy *continued*

Nutrient	Therapeutic function/justification	Dosage recommendations and issues
Vitamin K	• Poor maternal vitamin K levels can lead to relative deficiency in newborn infants (Shearer 1992). Low intake combined with the reduced gastrointestinal bacterial synthesis puts infants at risk of Vitamin K deficiency bleeding (VKDB) owing to the lack of activity of vitamin-K-dependent clotting factors (II, VII, IX and X) (von Kries et al 1993). This is compounded in breast-fed infants, as breast milk contains lower levels than formula, although this may be increased with maternal supplementation during lactation (Greer et al 1997).	• The recommended intake of vitamin K during pregnancy and lactation is the same as for a non-pregnant woman (60 mcg/day). To prevent infant health risks, prophylactic treatment of one intramuscular injection of 1 mg (0.1 mL) or three 2 mg (0.2 mL) oral doses at birth, 3–5 days of age and at 4 weeks are recommended (NHMRC 2000).
Calcium	• The newborn infant skeleton holds approximately 20–30 g calcium (Prentice 2003), 80% of which is acquired during the third trimester when the fetal skeleton is rapidly mineralising (Trotter & Hixon 1974). This increased demand for calcium during pregnancy is met by alterations to maternal calcium metabolism, particularly a two-fold increase in calcium absorption mediated by increases in 1,25-dihydroxyvitamin D and other mechanisms (Kovacs & Kronenberg 1997, Prentice 2003). • A possible inverse relationship between calcium intake during pregnancy and risk of hypertension and preeclampsia has been suggested from epidemiological and clinical studies (Villar et al 1983, Villar et al 1987, Repke & Villar 1991). Supplementation (1.0–2.0 g/day) is recommended to reduce the risk of preeclampsia and gestational hypertension (Hofmeyr et al 2006, Hofmeyr et al 2007); it may also reduce the blood pressure of the offspring (Belizan et al 1997, Hatton et al 2003). • Calcium supplementation during pregnancy has been shown to reduce maternal blood lead concentrations by an average of 11% by inhibiting the mobilisation of lead from bone and inhibiting intestinal absorption (Téllez-Rojo et al 2006). Supplementation (1200 mg) during lactation also reduces the risk of infant lead exposure by decreasing the concentration in breast milk by 5–10% (Ettinger et al 2006).	• Although pregnancy is a time of high calcium requirement, there is no increase in the RDI for pregnancy (1000 mg). If supplementation is required, it appears to be safe to use (Hofmeyr et al 2006).
Chromium	• Deficiency is believed to have an effect on glucose intolerance (Jovanovic-Peterson & Peterson 1996, Jovanovic & Peterson 1999). Chromium may protect against maternal insulin resistance and gestational diabetes (Morris et al 2000); however, studies are contradictory (Aharoni et al 1992, Gunton et al 2001, Woods et al 2008).	• Recommended daily intake during pregnancy is slightly increased to 30 mcg/day. • Supplementation in gestational diabetes is likely to be safe (Jovanovic & Peterson 1999).

TABLE 11.1 Nutrients During Pregnancy *continued*

Nutrient	Therapeutic function/justification	Dosage recommendations and issues
Iodine	• Iodine deficiency occurs in both developing and developed countries (Becker et al 2006). Deficiency during pregnancy (defined as urinary iodine concentrations < 150 mcg/L) has been found even in areas considered to have generally adequate intake. In a study conducted in Rome, where a salt iodination program has been introduced, only 4% of non-pregnant women were found to be iodine deficient (< 100–199 mcg/L) compared to 92% of pregnant women, suggesting that it may be necessary to monitor pregnant women even in regions where iodine deficiency is not common (Marchioni et al 2008). It enables the manufacture of maternal thyroid hormones, is protective against cretinism (Delange 2000), is vital for the development of the fetal brain, protects against neurological damage (Perez-Lopez 2007), and is also supplied to the breastfed infant via breast milk (Berbel et al 2007). • Maternal hypothyroidism during early pregnancy is associated with other adverse outcomes including premature birth, preeclampsia, breech delivery and increased fetal mortality (Haddow et al 1999, Pop et al 2004, Casey et al 2005). High-risk women (personal or family history of thyroid disorders or a personal history of other autoimmune diseases) have more than a six-fold increased risk of hypothyroidism during early pregnancy (Vaidya et al 2007).	• Mild iodine deficiency (median UIE < 100 mcg/L) has been found in several areas in Australia, including New South Wales and Victoria (Li et al 2006). • To prevent iodine deficiency disorders, the World Health Organization (WHO), United Nations Children's Fund and International Council for the Control of Iodine Deficiency Disorders established that for a given population median urinary iodine concentrations (UIC) must be 150–249 mcg/L in clinically healthy pregnant women (Marchioni et al 2008). • Iodine requirement increases during pregnancy and recommended intakes are 250–300 mcg/day (Delange 2007). • To monitor iodine status, WHO suggest that a median urinary iodine concentration > 250 mcg/L and < 500 mcg/L indicates adequate iodine intake in pregnancy (Zimmermann 2007).
Iron	• Iron requirements increase significantly in pregnancy to support expansion of maternal red blood cell mass and fetal growth (Bothwell 2000). • Accurate assessment of iron status during pregnancy is more challenging owing to the physiological changes occurring at this time (Milman et al 1991). Haemodilution affects iron parameters such as haemoglobin concentration, haematocrit, serum iron, ferritin and total-iron binding capacity. Serum ferritin is regarded as the most reliable indicator of iron stores (Byg et al 2000), while haemoglobin levels are used as an inexpensive marker to diagnose anaemia (Reveiz et al 2007). The evaluation of iron status and of the risk of anaemia developing during pregnancy may be more accurate when done early in pregnancy before the maternal plasma volume expands (Scholl 2005). Demands are partly met by a progressive increase in iron absorption as the pregnancy advances (Bothwell 2000); however, depending on initial iron reserves, this may not be sufficient to prevent deficiency (Casanueva et al 2003). The risk of iron deficiency increases with parity (Looker et al 1997). Maternal iron stores at conception appear to be a strong predictor of the risk of anaemia in later pregnancy (Bothwell 2000, Casanueva et al 2003). WHO estimates indicate that iron deficiency anaemia affects 22% of women during pregnancy in industrialised countries and 52% in non-industrialised countries (WHO 1992). • Supplementation raised haemoglobin levels by 7.5 g/dL and reduced the risk of iron deficiency and iron-deficiency anaemia at term (Pena-Rosas & Viteri 2006).	• The RDI of iron during pregnancy is increased to 27 mg/day. Upper limit is 45 mg based on the risk of side effects and potential systemic toxicity. A daily supplement of 40 mg ferrous iron from 18 weeks' gestation appears adequate to prevent iron deficiency in 90% of women (Milman et al 2005). However, individual assessment of iron status in early pregnancy may be useful to tailor the appropriate prophylaxis to prevent iron deficiency and iron deficiency anaemia: ferritin ≤ 30 mcg/L — 80–100 mg ferrous iron/day; ferritin 31–70 mcg/L — 40 mg ferrous iron/day; those with ferritin > 70 mcg/L do not require supplementation (Milman et al 2006). • High-dose supplementation may reduce the absorption of zinc (Hambidge et al 1987, O'Brien et al 2000) and other divalent cations (copper, chromium, molybdenum, manganese, magnesium) (Rossander-Hulten et al 1991). • Side effects of high-dose supplementation typically include gastrointestinal disturbances, most commonly constipation and nausea (Melamed et al 2007).

TABLE 11.1 Nutrients During Pregnancy *continued*

Nutrient	Therapeutic function/justification	Dosage recommendations and issues
	• Numerous studies have showed an association between adverse outcomes and iron deficiency anaemia, including increased risk of maternal mortality, infection, low birth weight and premature delivery. Fetal and infant iron deficiency may adversely impact on brain development, function and neurocognition (Grantham-McGregor & Ani 2001). Poor maternal iron status may contribute to reduced fetal stores (Preziosi et al 1997, de Pee et al 2002, Emamghorashi & Heidari 2004). However, in a recent cross-sectional study pregnant women with iron deficiency or mild anaemia were not found to produce offspring with significantly altered iron levels (Paiva Ade et al 2007). Similarly, iron supplementation during the second half of pregnancy was not found to influence the iron status of the children at 6 months or 4 years of age (Zhou et al 2007). On a cautionary note, excessive iron supplementation resulting in high haemoglobin and increased iron stores may be associated with increased adverse pregnancy outcomes (Scholl 2005), including low birth weight and premature delivery (Casanueva & Viteri 2003).	
Magnesium	• Magnesium is involved as a co-factor in more than 300 enzyme pathways (Wacker & Parisi 1968) and acts as a neuromuscular relaxant. The infant has stored approximately 750 mg at birth (Prentice 2003). • Positive trials highlight the benefits of magnesium supplementation for leg cramps (Dahle et al 1995) and possibly for preeclampsia, although evidence is inconsistent for this last indication (Dawson et al 2000, Kisters et al 2000, Adam et al 2001, Duley et al 2003, Ahmed 2004, Shamsuddin et al 2005, Omu et al 2008, Seydoux et al 1992, Handwerker et al 1995, Sanders et al 1999, Makrides & Crowther 2001).	• The RDI for magnesium during pregnancy is increased slightly to 350 mg (age 19–30 years) and 360 mg (31–50 years). The upper level of intake from non-food sources is 350 mg/day.
Zinc	• Zinc deficiency has been associated with adverse outcomes in pregnancy. Numerous animal models demonstrate an association between zinc deficiency and increased developmental abnormalities and fetal losses. Deficiency has also been associated with reduced interuterine growth, preterm delivery, labour and delivery complications, poor immunological development (Caulfield et al 1998) and congenital malformations (Hambidge et al 1977). In humans, acrodermatitis enteropathica, a genetic disease that produces severe zinc deficiency, has been found to increase fetal losses and malformations, most probably owing to the key role it plays in protein synthesis and cellular growth (King 2000). • The usefulness of zinc supplementation during pregnancy is unclear. Supplementation has been shown to reduce preterm birth (Mahomed et al 2007), assist the accumulation of lean tissue in the infant during the first year of growth (Iannotti et al 2008) and reduce the risk of delivering via caesarean section (Mahomed et al 2007). • While women with preeclampsia have significantly lower zinc and superoxide dismutase (SOD) levels compared to healthy pregnant women (Ilhan et al 2002), zinc supplementation had no significant effect in pregnancy hypertension or preeclampsia (Mahomed et al 2007); and no significant differences were seen for several other maternal or infant outcomes, including pre-labour rupture of membranes, antepartum haemorrhage, post-term birth, prolonged labour, retention of placenta, meconium in liquor, smell or taste dysfunction, maternal infections, gestational age at birth or birth weight (Mahomed et al 2007).	• During pregnancy, RDI is increased to 11 mg/day, and the recommended upper level of intake is the same as for adults, at 40 mg/day. Vegans/vegetarians may need an additional 50%. • The teratogenic effects of alcohol may be exacerbated by a concurrent zinc deficiency (Keppen et al 1985).

Continued

TABLE 11.1 Nutrients During Pregnancy *continued*

Nutrient	Therapeutic function/justification	Dosage recommendations and issues
Omega-3 DHA/EPA)	• High fetal demands for omega-3 fatty acids result in the progressive decrease of maternal stores throughout pregnancy (Al et al 1995, Bonham et al 2008). • Omega 3 is important for optimal fetal and infant neurodevelopment and may be associated with benefits for other pregnancy and infant health outcomes, including growth and development of the fetal and infant brain (Horrocks & Yeo 1999), improvements to children's eye–hand coordination (Dunstan et al 2008) and higher infant cognitive function (Oken et al 2005, Hibbeln et al 2007). • Lower maternal intake was associated with: increased risk of infants with poorer outcomes for prosocial behaviour, fine motor ability, communication, and social development scores (Hibbeln et al 2007); increased risk of infant asthma (Olsen et al 2008), increased risk of postnatal depression (Levant et al 2006, 2008) and increased depressive symptoms in postpartum women (Hibbeln 2002). However, more recent studies have found no associations (Browne et al 2006, Sontrop et al 2008, Rees et al 2008, Freeman et al 2008) or mixed outcomes (Su et al 2008). • Lower dietary intake of fish (Oken et al 2007), and biochemical markers of omega-3 fatty acid intake (Velzing-Aarts et al 1999, Qiu et al 2006, Mehendale et al 2008) have been reported in women who develop preeclampsia. Intervention studies with fish oil supplementation, however, generally have not found a protective effect. In a recent Cochrane Review there was no significant difference in risk of gestational hypertension (five trials) or preeclampsia (four trials) between those taking the fish oil (133 mg/day to 3 g/day) and control groups (Makrides et al 2006).	• Fish oil supplementation during pregnancy appears to be safe. Mild side effects such as belching and unpleasant taste are reported (Makrides et al 2006, Freeman & Sinha 2007). • Recommendations for dietary intake of EPA/DHA (adequate intake) for pregnancy is 115 mg/day. An upper level of intake of 3 g is recommended for adults (no pregnancy specifications). • Maternal dietary DHA intake of at least 200 mg/day is associated with positive infant neurodevelopmental outcomes (Cetin & Koletzko 2008).
Probiotics	• Prenatal and postnatal supplementation with probiotics may play a role in immune regulation and the prevention of allergies developing in the infant. Numerous positive studies in the prevention of allergies, including eczema, in the child have involved the following strains: *Lactobacillus reuteri* (ATCC 55730) (Abrahamsson et al 2007) *L. rhamnosus* GG (ATCC 53103) (Kalliomaki et al 2001, Rautava et al 2002, Kalliomaki et al 2003) *L. rhamnosus* GG (ATCC 53103); *L. rhamnosus* LC705 (DSM 7061); *Bifidobacterium breve* Bb99 (DSM 13692); and *Propionibacterium freudenreichii* ssp. *shermanii* JS (DSM 7076) (Kukkonen et al 2007) *L. rhamnosus* GG and *B. lactis* Bb12 (Huurre et al 2008) • Prophylactic enteral supplementation reduces the occurrence of necrotising enterocolitis and death in premature infants born weighing less than 1500 g (Alfaleh & Bassler 2008); this may be owing to normalisation of gut flora and stimulation of natural host defences (Hammerman & Kaplan 2006). • Vaginal application reduces the risk of vaginal infections in pregnancy (Othman et al 2007).	• Based on review of literature, prescription appears to be safe for internal and vaginal application.
Choline	• Choline status in pregnancy influences the development of the memory centre (hippocampus) in the fetal brain, and may have a life-long impact on memory (Zeisel 2004).	• The RDI is slightly increased at 440 mg/day, with an upper level of 3000 mg/day.

the offspring's blood pressure during childhood (Hatton et al 2003).

HERBAL MEDICINE

Herbal medicines are used in pregnancy as pharmacological agents. They are used as foods, such as ginger, in extract form (liquid and solid dose forms) and also as teas. In many developing countries, herbal medicines have been used as the dominant form of medicine and continue to play a major role in healthcare, reproductive health and midwifery (WHO 2002).

A traditional approach

Although conception is a problem for some women, a more common problem throughout the ages was contraception. Ethnobotanical studies conducted in many parts of the world reveal that herbal medicines have been used widely for generations to prevent conception and induce miscarriage, and in some parts of the world their use continues despite the availability of pharmaceutical contraceptive pills and devices. Besides this, herbal medicines have been used to enhance fertility, regulate menstruation, facilitate childbirth, help with the expulsion of the placenta and promote lactation.

In many cultures, herbal healers have special reverence for herbs that are thought to have abortifacient or emmenagogue properties. These concepts are foreign in Western medicine and deserve some discussion.

Abortifacients

Since ancient Egyptian times, plants have been used as a source of both contraceptives and early-term abortifacients (Riddle 1991) and in some parts of the world this practice still exists. The abortifacient effects of herbs are attributed to their inherent toxicity or ability to induce uterine contractions (Noumi & Tchakonang 2001). It is also suspected that abortifacient activity may be immune-mediated, hormonal or due to non-specific actions, such as the ability to reduce uterine blood flow. Examples of Western herbs with abortifacient potential due to suspected toxicity include wormwood (*Artemsia absinthium*), pennyroyal (*Mentha pulgeum*), poke root (*Phytolacca decandra*), pau d'arco (*Tabebuia avellanedae*), rue (*Ruta graveolens*) and tansy (*Tanacetum vulgare*) (Mills & Bone 2005).

Emmenagogues

The term 'emmenagogue' is used to describe a herb that will stimulate menstrual flow. Traditionally, such herbs have been indicated for delayed menstruation and have developed a reputation of being contraindicated in pregnancy for fear they may induce miscarriage. Herbalists consider emmenagogues to exert oxytocic-like effects that cause uterine contractions; however, this mechanism is unlikely to explain how they promote menses in a non-pregnant woman. Changes to lymph or blood flow and hormonal effects are more likely mechanisms. Examples of herbs thought to act as emmenagogues found on many traditional lists include aloe (*Aloe vera*), juniper (*Juniperus communis*), pennyroyal (*Mentha pulgeum*), goldenseal (*Hydrastis canadensis*), black cohosh (*Cimicifuga racemosa*), blue cohosh (*Caulophyllum thalictroides*), dong quai (*Angelica polymorpha*), rue (*Ruta graveolens*), tansy (*Tancetum vulgare*) and thuja (*Thuja occidentalis*). Some herbs considered to be emmenagogues are also regarded as potential abortifacients if used in sufficient quantities (e.g. oxytocin agonists); however, not all abortifacients may act as emmenagogues (e.g. potentially toxic herbs with no hormonal or uterine effects).

Historical perspectives

Medicinal plants have been used in Mexico since pre-Hispanic times. Nearly 10 million indigenous people speaking nearly 85 different languages inhabit the region, and many still depend for primary therapy upon plants from the diverse flora (almost 5,000 medicinal plants) (Andrade-Cetto 2009). An ethnobotanical study of the medicinal plants from Tlanchinol, Hidalgo, Mexico, identified several plants that are used as abortifacients (Andrade-Cetto 2009): *Galium mexicanum* var *mexicanum, Ruta chalepensis*, *Zaluzania triloba* and *Tanacetum parthenium*. The herb *Cinnamomum veru* is generally considered useful to induce childbirth and *Pedilanthus tithymaloides* to reduce ovarian pain.

The Criollo people of Argentina use a vast plant pharmacopoeia. To date, 189 species with 754 different medicinal applications have been recorded (Martinez 2008). The absence of a normal menstrual cycle and amenorrhoea are matters of concern among the Criollo and are treated with emmenagogue plants, the most common being *Anemia tomentosa*, *Tripodanthus flagellaris*, *Lippia turbinata* and *Trixis divaricata*. Contraceptive herbs used in the region include *Zea mays*, *Anemia tomentose*, and abortifacient herbs include *Artemisia absinthium*, *Cheilantes buchtienii*, *Chenopodium aff. hircinum*, *Cuphea glutinosa*, *Ligaria cuneifolia, Lippia turbinate* and *Pinus* spp (Martinez 2008).

Rama midwives in eastern Nicaragua currently use a diverse group of plants in the practice of midwifery: 162 species from 125 genera and 62 families (Senes et al 2008). This extensive ethnopharmacopoeia is employed to treat the many health issues of pregnancy, parturition, postpartum care, neonatal care and primary healthcare of women and children. The 22 most popular midwifery species are medicinals that are widely used by practitioners other than midwives, not only in eastern Nicaragua but elsewhere. Very few herbal species are used as contraceptives in this region, whereas abortifacients are well known and mostly made with bitter-tasting plants (the bitter taste is probably due to alkaloids and other bitter-tasting compounds). The most widely used abortifacients are decoctions made from the leaves and seeds of soursap and the roots of guinea hen. Others are decoctions made with the leaves and/or flowers of barsley, broom weed, trompet, sorosi and wild rice, and from the root of ginja.

Interestingly, midwives in other parts of the world use many Rama midwifery species for the same purpose: for example, sorosi and lime are both widely regarded as important in midwifery. Sorosi is one of the most widely used medicinals in eastern Nicaragua, where it is used as an abortifacient, with similar use in Africa, Australia, Brazil, India, Malaysia, the Philippines and the West Indies (Senes et al 2008). Lime is a domesticated crop used by the Rama and other indigenous groups of eastern Nicaragua as an abortifacient and to accelerate labour. It is also used to induce abortion by tribal people in India, Honduran midwives and the Tikunas of northwestern Amazonia.

In Europe, herbal medicine has a rich history and continues to be popular today. As in other parts of the world, plants were used for reproductive health, to prevent conception and induce abortion, with women and midwives as the main keepers of herbal knowledge. Savin (*Juniperus sabina*) was one abortifacient herb of choice and pennyroyal, sage, thyme and rosemary were considered powerful emmenagogues (Belew 1999). Unlike some other parts of the world, information exchange down the generations was interrupted during the 18th and 19th centuries because there was a major shift in the management of the birthing process (Schiebinger 2008). During this period, female practitioners with knowledge of herbal lore lost ground to obstetricians (men trained primarily as surgeons), and plant-based treatments were gradually replaced with surgical procedures (Schiebinger 2008). As a result, much knowledge about the use of herbal medicines in fertility and reproduction in Europe was lost.

The North American Indians used herbal medicines extensively throughout the reproductive life cycle and had many remedies for improving fertility, preventing miscarriage, treating symptoms during pregnancy and facilitating the birthing process. A large number of these treatments became known to European settlers in North America through careful study, observation and subsequent clinical use. If repeated use indicated the treatments were effective, the herbs were recorded and prescribed by the Eclectic physicians, who flourished from the mid-1800s to around 1920 in the United States (Belew 1999). Many of the herbal medicines used by the North American Indians and described by the Eclectic physicians are still in use today as part of the Western herbalists' and traditional midwives' cache of treatments.

The Eclectics considered black cohosh a 'remedy par excellence to stimulate normal functional activity of the uterus and ovaries' throughout the reproductive life cycle (Belew 1999). They reported that when used regularly at the end of pregnancy 'it will render labor easier and quicker, and give a better getting up'. Black haw was highly regarded by the Eclectic physicians, who used it both before and during pregnancy to prevent miscarriage, prepare for labour and relieve false labour pains and after-pains. The Eclectic physicians preferred to use cottonroot (*Gossypium*) as an oxytocin agonist rather than the newly available sublingual oxytocin preparation, because the herb was considered to have a gentler action and produce more predictable results. Squaw vine (*Mitchella repens*) was well considered when enhanced fertility was called for. It was extensively used to promote menstruation and alleviate physical discomfort in the latter months of pregnancy, and was thought to be a good preparative to labour, rendering the birth easier.

Contemporary use by Western herbalists

In Western herbal practice today, much knowledge about herbal safety and efficacy in pregnancy is drawn from North American and European traditions, and traditional applications are largely used as a basis for prescriptions. Herbal medicines may be prescribed to

regulate menstruation before conception, and to alleviate morning sickness and other symptoms related to pregnancy. A growing number of gynaecologists and obstetricians are working with herbalists to enhance patients' chances of conception and reducing miscarriage, sometimes in combination with IVF procedures.

Requests for abortifacient herbs in Western countries are virtually unheard of; however, some women still seek herbalists to provide '*partus* (birth) *preparatus* (prepare)' mixtures to prepare for childbirth and facilitate delivery. Traditionally, the Eclectic physicians called these preparations 'mother's cordial'. They tend to be recommended in very low doses, starting at 36 weeks' gestation, with the dose increasing each week until delivery. Herbs that have been used in *partus preparatus* preparations include: *Mitchella repens* (squaw vine), *Viburnum prunifolium* (black haw), *Rubus idaeus* (raspberry), *Chamaelirium luteum* (false unicorn), *Caulophyllum thalictroides* (blue cohosh) and *Cimicifuga racemosa* (black cohosh).

Today, Western herbalists are also asked for treatment to address pre- and postnatal depression, and to alleviate symptoms of dyspepsia, nausea and lower back pain, and sometimes for topical applications to reduce perineal discomfort and stretch marks associated with pregnancy. In addition, herbalists may be providing support for conditions unrelated to pregnancy, such as urinary tract or upper respiratory tract infections.

Unlike medical practitioners, Western herbalists are less concerned about teratogenicity than inducing miscarriage. To minimise the risk of harming the mother or fetus, several general guidelines are followed. Most importantly, traditional sources dictate that if known toxic herbs are avoided, then toxic side effects are unlikely to occur. In addition, other classes of herbs avoided during pregnancy include the following (Hess et al 2007):

- emmenagogues and abortifacients (discussed below)
- large quantities of herbs containing a high volatile oil content, especially during the first trimester (It is suspected that volatile oils contain constituents that could induce uterine contractions. Many kitchen spices contain volatile oils: they are not believed to be a problem when used in dietary amounts but could pose problems when used in concentrated preparations [e.g. rosemary, peppermint, thyme, sage]. This contraindication is likely to be derived from European tradition, as there is scant scientific evidence to support this concern.)
- stimulant laxative herbs containing anthraquinones (These herbal medicines stimulate peristalsis and can induce loss of water and electrolytes, intestinal cramps, loose bowels and dependency with chronic use. It is believed these harsh irritant effects may exert a reflex stimulating effect on the uterus, causing uterine contractions. This is a traditional understanding, as there is no scientific evidence to support this concern at present. Stimulant laxative herbs include buckthorn, cascara [*Rhamnus* sp.], rhubarb, castor, senna and aloe. Aloe gel is not a problem, as it contains a part of the plant that does not contain significant levels of anthraquinones.)
- herbs with hormonal actions such as *Trifollium pratense* (red clover) and *Vitex agnus-castus* (chaste tree), which may adversely influence fetal development
- thujone-containing herbs such as *Achillea millefolium* (yarrow), *Thuja occidentalis* (thuja) or *Artemisia absinthium* (wormwood) due to their inherent toxicity concerns.

This approach is based on traditional evidence and theoretical concerns, usually without any scientific evidence to confirm lack of safety. As such, a herbalist's approach to these herbs may be overly cautious and not borne out if scientific testing takes place in the future. For example, senna is traditionally avoided during pregnancy as it is an anthraquinone-containing herb, but it is widely recommended as a safe and effective short-term stimulant laxative for constipation by medical practitioners (Tytgat et al 2003). Some herbalists also recommend against the use of several aromatherapy oils during the first trimester, but there is no scientific evidence to suggest external use of such oils poses any serious danger.

PART 2: SAFETY IN PREGNANCY

All medicines have the potential to affect maternal health, and to cross the placenta and affect fetal development. The most serious risk associated with medicine use in pregnancy is the possibility of teratogenesis, which can manifest as a structural abnormality, dysfunctional growth in utero and/or long-term functional defects. Other risks include miscarriage and neonatal withdrawal.

Birth defects occur naturally in 2–4% of all newborns and in the vast majority of cases the

cause is unknown. Medication use is not considered a major contributor to the incidence of birth defects, as less than 1% of cases can be attributed to drug use (Webster & Freeman 2001). It is likely that the use of CMs in Western countries is a far less important factor.

CRITICAL PERIODS IN HUMAN DEVELOPMENT

The safe use of any medicine in pregnancy must take into account the safety of the treatment to be used, the seriousness of the patient's presenting problem and the timing of exposure.

In the first two weeks, prior to implantation, an insult is thought to have an all-or-nothing effect. Assuming the embryo survives, the risk of structural malformations to the fetus is greatest 17–70 days post-conception, a critical stage of organ development (Freyer 2008). After this time, organs continue to mature, so later adverse effects tend to be functional rather than structural and major birth defects are unlikely. Functional defects are less obvious than structural ones and may become obvious only when the child is older. The central nervous system, eyes, teeth and external genitalia are the last organs to fully develop and continue to mature until the baby reaches full term.

If practitioner and patient agree that medicinal treatment is warranted, then minimising exposure during critical developmental times (Fig 11.1) is essential. This means using the lowest effective dose of the least toxic substance for the shortest period of time.

TERATOGENESIS

Teratogens are agents that result in structural or functional defects in the development of fetal organs (Shehata & Nelson-Piercy 2000). Sources of exposure to these agents include: contaminated air, water, soil, food, beverages, household items, and medicines (including CMs) (Kovacic & Somanathan 2006). Teratogens can cause a variety of effects, including embryo/fetal death, intrauterine growth restriction and increased risk of malformations and carcinogenesis (Shehata & Nelson-Piercy 2000). The exact mechanisms responsible for teratogenicity are unknown but theories include damage to DNA, membranes, protein and mitochondria, enzyme inhibition and hormonal interference (Kovacic & Somanathan 2006). Despite the potential for teratogens to have devastating consequences, only a relatively small number of fetuses exposed to these agents experience adverse effects (Freyer 2008). This relates to factors such as the dose and duration of exposure, genetic susceptibility of the fetus/embryo, timing of exposure, specific mode of action of the teratogen (Miller et al 2007) and nutritional and disease status of the mother–baby unit (Shehata & Nelson-Piercy 2000).

Data on herbal teratogens is limited and largely based on animal studies, which are not completely reliable. Blue cohosh is an example of a herb for which there is some evidence to suggest a potential teratogenic effect, based on animal studies (Keeler 1976, Keeler et al 1976, Kennelly et al 1999). Other herbs that may increase the risk of fetal malformations (predominantly based on limited animal data) include aloe, andrographis, cat's claw, Jamaica dogwood, pau d'arco, pennyroyal, poke root, tribulus and white horehound (Mills & Bone 2005). There is very little evidence of teratogenic activity or adverse pregnancy outcomes from the use of nutritional supplements, with the notable exception of high-dose vitamin A. Interestingly, deficiencies of nutrients such as vitamin A, folate, vitamin B_{12}, vitamin D, iodine and zinc have been found to have adverse effects that include teratogenesis, emphasising the important role these nutrients have in normal embryonic and fetal development.

Neonatal withdrawal

While the fetus is in utero, the placenta supplies it with nutrients and other substances, as well as drugs. When the baby is born, placental supply ceases, which can lead to neonatal withdrawal syndromes for certain drugs such as beta-blockers, SSRIs and other antidepressants, opiates and alcohol (Freyer 2008, Sanz et al 2005). It is not known whether the use of CMs during the final trimester can also induce withdrawal syndromes.

HOW IS SAFETY EVALUATED IN PREGNANCY?

One of the hardest challenges a clinician faces is advising a pregnant patient about the safety of a treatment. A key factor to consider is the strength of evidence indicating the treatment is safe or, as so often happens in pregnancy, the lack of evidence indicating it is unsafe. More specific factors are the dose of medicine to be used, precise timing of exposure and duration of exposure.

When evaluating the effectiveness of a treatment, prospective randomised trials and

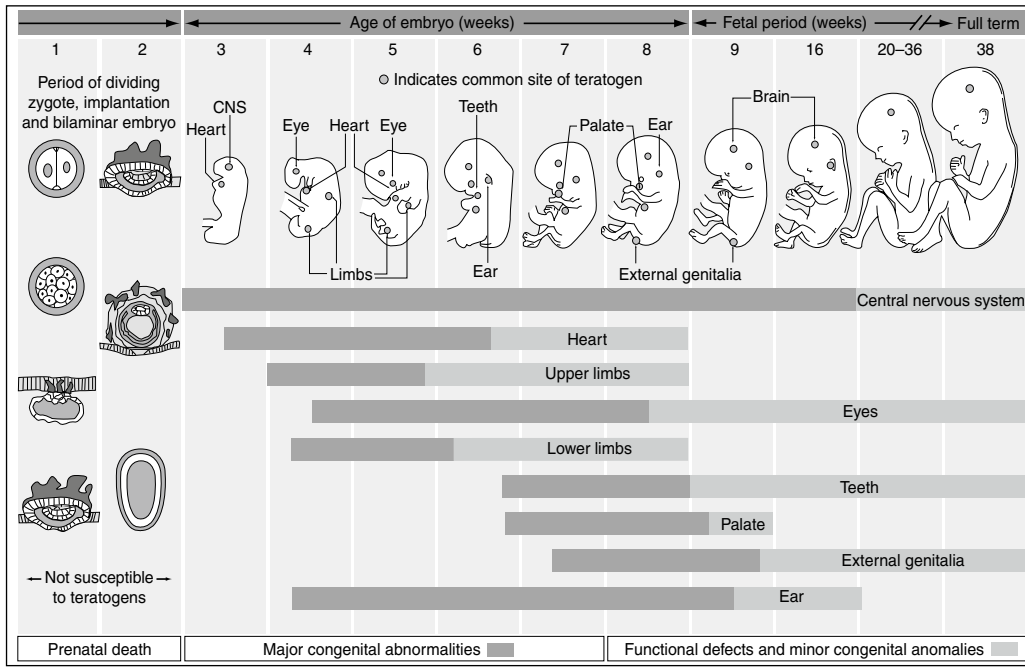

FIGURE 11.1 Critical periods in human development (From Moore KI, Persaud TVN. The developing human: clinically oriented embryology, 6th edn. Philadelphia: WB Saunders, 1998, p 548. With permission.)

meta-analyses are widely considered the gold standards. When evaluating safety in pregnancy, there is a paucity of such trials because pregnant women tend to be excluded, so other methods of information gathering are required. Epidemiological studies, tests with animal models, post-marketing surveillance systems, case reports and traditional use provide the main inputs into establishing safety, but each method has limitations and should not stand alone without corroborating evidence from another source.

Epidemiological studies

Epidemiological studies are also known as population studies. Owing to their large participant numbers, epidemiological studies can detect large and small size effects and sometimes rare outcomes, if the study population is sufficiently large and follow-up is sufficiently complete. As such, they may provide useful information regarding safety in pregnancy.

Considering the incidence of fetal malformations is already small (2–4%), extremely large participant numbers would be required to detect a slight increase above what may normally be expected. For example, a study would require 35,000 women in order to establish with a 95% confidence level that a medicine changes the naturally occurring frequency of a congenital malformation by 1% (Lee et al 2000). Unfortunately, most epidemiological studies have inadequate statistical power to detect this outcome because they lack sufficient patient numbers. This means that no medicine (pharmaceutical or complementary) has proven safety based on reliable epidemiological data involving sufficient numbers of women.

Animal studies

Animal studies of reproductive toxicity are required for all new drugs before they are licensed, but they are not required for CMs. While they can provide some assurance of safety, animal tests have limited usefulness because results do not always extrapolate accurately to humans. The problem of false positives is more common than false negatives, whereby medicines that produce defects in animals are later found to be relatively safe in humans (e.g. corticosteroids) (Lee et al 2000). It is likely that the excessive doses used in testing increase the risk of producing a false positive, as there is greater embryonic and maternal exposure to the medicine than would be expected in clinical practice. This should be kept in mind when interpreting the results of drug or herbal medicine testing in animal models.

Post-marketing surveillance systems

In many cases, more meaningful safety data becomes available only when a medicine is in widespread use and women knowingly

or inadvertently take it during pregnancy. Those medicines with high effect rates will be detected more quickly than less potent teratogens. For example, the teratogenic effect of isotretinoin was detected about one year after it came onto the market, whereas the antiepileptic drug valproic acid was available in Europe in the 1960s yet it took approximately 20 years of use by millions of women before its teratogenic potential was identified (Webster & Freeman 2001).

Post-marketing surveillance systems are set up to detect unfavourable outcomes and highlight adverse events rather than establishing safety, an inherently more difficult endpoint.

Adverse event case reports

Adverse event case reports are an account of an individual's suspected response to a treatment. Case reports are notoriously unreliable, as they tend to lack sufficient detail to clearly establish causality and fully eliminate the influence of confounding factors. Individual case reports become more convincing when a series of similar reports are collected.

Several factors should be considered when interpreting a case report; firstly, did the exposure to the medicine happen at the appropriate critical stage in pregnancy (usually first trimester) and was the dose used clinically relevant and similar for all cases? Additionally, if a complementary medicine is implicated, has the medicine been tested for contaminants and adulteration to exclude extrinsic factors and did the treatment involve a single entity or combination therapy (the norm in complementary medicine)? Finally, the traditional body of evidence that accompanies herbal medicines may provide further insights when interpreting cases.

The following three cases are presented as examples of the literature. They involve the herbs dong quai, Korean ginseng and blue cohosh. The reports indicate a probable link between herbal use and adverse outcome; however, none of the products implicated were tested for herbal authenticity or for the presence of contaminants or adulterants, an essential step towards drawing a definitive conclusion.

Case report 1

A 32-year-old woman, three weeks postpartum, developed acute headache, weakness, light-headedness and vomiting, with a blood pressure reading of 195/85 mmHg (Nambiar et al 1999). She reported using dong quai for postpartum weakness and had not been taking any other medicines. Her three-week-old son's blood pressure was also raised at 115/69. Within 48 hours of stopping herbal treatment, blood pressure normalised for both the mother and the breastfed child.

Case report 2

In 1990, a case report published in JAMA described a 30-year-old mother who had taken *Panax ginseng* (650 mg twice daily) throughout pregnancy and during lactation of her two-week-old baby (Koren et al 1990). The boy was noted to have signs of androgenisation, thick black pubic hair, hair over the entire forehead, swollen, red nipples and enlarged testes. After 2 weeks, his pubic and forehead hair began to fall out and was scant by 7.5 weeks. Excessive androgen production was ruled out and the authors suspected the effects were produced by hormonal activity of the herbal treatment. Letters to the editor were subsequently exchanged suggesting the product contained Siberian ginseng and not *Panax ginseng* (Awang 1991). The story does not end here, because Siberian ginseng has no significant androgenic activity in vivo that could account for the effects observed (Awang 1991, Waller et al 1992). It is now suspected that the herbal product did not contain Siberian ginseng but instead *Periploca sepium* (called wu jia or silk vine), as US herb companies importing Siberian ginseng from China have been known to be supplied with two or three species of *Periploca* (Awang 1991).

Case report 3

A newborn infant presented with acute myocardial infarction associated with profound congestive heart failure and shock (Jones & Lawson 1998). The mother had been ingesting blue cohosh (*Caulophyllum thalictroides*) in the month prior to delivery to facilitate the birthing process. She had been instructed to take one tablet daily but elected to take three times the recommended dose in the 3 weeks before delivery. During this time she noticed an increase in uterine contractions and a decrease in fetal activity. The infant eventually recovered after being critically ill for several weeks. Attending doctors excluded other causes of myocardial infarction and indicated that blue cohosh was responsible for the adverse event. On late follow-up at 2 years of age the child is doing well with good exercise tolerance, and

normal growth and development. However, cardiomegaly persists, left ventricular function remains mildly reduced, and he still receives digoxin therapy.

Clinical studies

While prospective clinical studies of herbal safety in pregnancy are problematic, retrospective studies are easier to conduct. Establishing cause–effect relationships beyond reasonable doubt is rare because of the myriad of confounding factors present; however these studies may identify common or palpable problems that could be investigated in appropriate models.

Example: echinacea

A Canadian study involving 412 pregnant women investigated the safety of echinacea in pregnancy (Gallo et al 2000). These women had contacted a teratogen information service (Motherisk Program) between 1996 and 1998 with concerns about the safety of ingesting echinacea during pregnancy. Half the group had already taken the herb, whereas the others decided against use and so were enrolled as a control group. Of the 206 women in the echinacea group, 112 (54%) used the herb in the first trimester and 17 (8%) used it throughout their pregnancies. No significant differences were seen between the groups for rates of major and minor malformations or any pregnancy outcome including delivery method, maternal weight gain, gestational age, infant birth weight or fetal distress.

Long-term use

Long-term use of a medicine by large populations of women without apparent increase in adverse events is considered to contribute towards evidence of safety. For example, the Australian Drug Evaluation Committee (ADEC) has classified the drug metoclopramide as relatively low risk because the 'drug has already been taken by large numbers of pregnant women and women of child-bearing age without proven increase in fetal harm' (Bryant et al 2003).

With regard to herbal medicine, 'long-term use' may actually refer to hundreds or even thousands of years of use, not just decades as is the case with pharmaceutical medicines. In fact, many herbal medicines such as ginger and garlic have been used as both foods and medicines since antiquity. This has allowed a large body of longitudinal and retrospective evidence to accumulate, which gives herbalists an extra dimension to consider.

Like all forms of evidence, traditional evidence has its limitations and must be interpreted carefully. It is likely that traditional healers would have found it easier to identify poisonous herbs and herbs that induce acute or obvious adverse effects than those that induce insidious, rare or delayed-onset adverse outcomes. There may also be significant differences in the way a herbal medicine is grown, prepared and used today compared with the practice in former times, thereby allowing larger doses to be taken and different herbal constituents to be absorbed (Tannis 2003).

WEIGHING UP THE EVIDENCE

For both pharmaceutical and complementary medicines, the evidence base is incomplete and insufficient to state with certainty that any medicine is safe in pregnancy. To build a case for safety, evidence from multiple sources must be considered to fill in as many gaps in knowledge as possible.

In the case of complementary medicines, any evidence supporting or contraindicating use during pregnancy must be based on the totality, quality and relevance of the evidence. In general, the greater the consistency of evidence from different sources, the stronger the evidence is overall.

In Australia, the ADEC has classified drugs on their potential to cause harm during pregnancy (Table 11.2, p 164). Eight categories are possible and each describes the evidence used to indicate safety or lack of safety. They rely on evidence gathered from animal models and post-marketing surveillance systems, and also consider the proven, suspected or expected potential of a drug to cause adverse outcomes (e.g. cytotoxic drugs).

Proposing a different system for complementary medicines

A similar grading system is required for complementary medicines, building a case for safety or harm based on considering multiple forms of evidence. Ideally, the new system should take into account the availability and credibility of various traditional evidence sources and the relative lack of data available from animal studies. It should also take into account the relative safety of over-the-counter complementary medicines in comparison to scheduled pharmaceutical drugs, and whether the association between exposure and proposed adverse outcome is biologically plausible.

TABLE 11.2 ADEC Pregnancy Categories (Australia)

Category	Description
A	Drugs that have been taken by a large number of pregnant women and women of childbearing age without any proven increase in the frequency of malformations or other direct or indirect harmful effects on the fetus having been observed.
B1	Drugs that have been taken by only a limited number of pregnant women and women of childbearing age, without an increase in the frequency of malformation or other direct or indirect harmful effects on the human fetus having been observed. Studies in animals have not shown evidence of an increased occurrence of fetal damage.
B2	Drugs that have been taken by only a limited number of pregnant women and women of childbearing age, without an increase in the frequency of malformation or other direct or indirect harmful effects on the human fetus having been observed. Studies in animals are inadequate or may be lacking, but available data show no evidence of an increased occurrence of fetal damage.
B3	Drugs that have been taken by only a limited number of pregnant women and women of childbearing age, without an increase in the frequency of malformation or other direct or indirect harmful effects on the human fetus having been observed. Studies in animals have shown evidence of an increased occurrence of fetal damage, the significance of which is considered uncertain in humans.
C	Drugs that, owing to their pharmacological effects, have caused or may be suspected of causing harmful effects on the human fetus or neonate, without causing malformations. These effects may be reversible. Accompanying texts should be consulted for further details.
D	Drugs that have caused, are suspected to have caused or may be expected to cause an increased incidence of human fetal malformations or irreversible damage. These drugs may also have adverse pharmacological effects. Accompanying texts should be consulted for further details.
X	Drugs that have such a high risk of causing permanent damage to the fetus that they should not be used in pregnancy or when there is a possibility of pregnancy.

Note: Based on ADEC 1999. For drugs in the B1, B2 and B3 categories, human data are lacking or inadequate and subcategorisation is therefore based on available animal data. The allocation of a B category does *not* imply greater safety than the C category. Drugs in category D are *not* absolutely contraindicated in pregnancy. Moreover, in some cases the D category has been assigned on the basis of suspicion.

The following examples are provided to give the reader some suggested questions to ask of the evidence and the types of evidence available to consider when evaluating safety in pregnancy.

Zingiber officinalis *(ginger)*

- Is traditional evidence available about the substance in general? — *Yes*
- Does traditional evidence caution or contraindicate against use in pregnancy? —*Yes*
- Is the reason for the traditional caution or contraindication biologically plausible? — *No*
- Is scientific evidence available in general about the substance? — *Yes*
- Does scientific evidence (from human or animal studies) provide information about pharmacological effects that may be of concern in pregnancy? — *Yes*
- Are there any studies suggesting that the substance may be safe in pregnancy? — *Yes*

Traditionally used as an antiemetic, ginger has encouraging research to support its use during pregnancy for nausea and vomiting (Borrelli et al 2005). No adverse effects have been reported in several studies examining ginger in the treatment of nausea and vomiting in pregnancy.

A systematic review of four double-blind RCTs (n = 449) and one prospective observational cohort study (n = 87) evaluated the effects of ginger on pregnancy outcomes. The preparation used in the trials was a ginger root powder or extract, taken 3–4 times daily (total dose ranged from 1.0–1.5 g) from 8 to 20 weeks' gestation. No dose was provided in the prospective study. No difference in the occurrence of spontaneous abortions, stillbirth, term delivery and caesarean deliveries, neonatal death, gestational age or congenital abnormalities was found between women who took ginger compared to those who took vitamin B_6 or a placebo, or to the general population (Borrelli et al 2005).

Unfortunately there is a lack of consensus regarding the safety of ginger during pregnancy. Soudamini et al (1995) suggest ginger contains possible mutagenic properties, but this effect appears to be counteracted by zingerone, another constituent present in the whole rhizome (Nakamura & Yamamoto 1982). Traditionally, ginger has been contraindicated in labour due to the possibility of increased postpartum haemorrhage, and in large doses ginger is traditionally thought to act as an emmenagogue (Grieve 1971). German Commission E

suggests that ginger is contraindicated in pregnancy, while more recent research suggests that doses up to 2 g/day of dried ginger root have been used safely. When considered in a comparison of recent research, the proposed notion of haemorrhage is unlikely (Lumb 1994). Even in very large doses (ginger tea up to 50 g/L), ginger had no impact on maternal toxicity or fetal malformations in an animal model, but embryo losses were double compared to the controls. No evidence of maternal toxicity was found for a patented extract of ginger (EV.EXT 33) given in doses of up to 1000 mg/kg/body weight daily to pregnant rats during the period of organogenesis (Weidner & Sigwart 2001).

Rubus ideaus *(Raspberry leaf)*

- Is traditional evidence available about the substance in general? — *Yes*
- Does traditional evidence caution or contraindicate against use in pregnancy? — *No*
- Is scientific evidence available in general about the substance? — *Yes (limited)*
- Does scientific evidence (from human or animal studies) provide information about pharmacological effects that may be of concern in pregnancy? — *Yes*
- Are there any studies suggesting that the substance may be safe in pregnancy? — *Yes*

Raspberry leaves appear to have a dual effect on the uterus, acting as both a stimulant and a relaxant to the uterine musculature (Bamford et al 1970). The use of this herb in concentrated form is traditionally recommended only in the second and third trimesters owing to its possible effects on the uterus. Traditional evidence and select pharmacological studies highlight that this herbal medicine has an effect on uterine contractions (Bamford et al 1970). Unfortunately, there is little research on either the efficacy or the safety of raspberry leaf. Two clinical studies evaluating the safety of raspberry leaf in pregnancy have reported no evidence of toxicity in either mother or child (Parsons et al 1999, Simpson et al 2001), although evidence from older animal studies is less clear (Burn & Withell 1941, Whitehouse 1941).

PART 3: ADVISING PATIENTS IN CLINICAL PRACTICE

At some stage of practice most clinicians have to consider the question, 'Is this treatment safe in pregnancy?' The answer to such a question is never straightforward, as establishing safety in pregnancy with any degree of certainty is difficult, partly because scientific methodologies to assess safety are inexact, the evidence base is incomplete and probably will remain so, and because birth defects occur spontaneously in 2–3% of all pregnancies for no known reason.

Over the years medical practitioners and pharmacists have generally held the view that all medicines should be avoided during pregnancy, where possible. This has referred to the use of pharmaceutical medicines and is wise counsel. With the increasing popularity and accessibility of complementary medicines, many have extended this caution to include herbal medicines under the assumption that the same safety issues apply. Indeed, the safety issues are similar and prudence is still required.

Naturopaths and herbal medicine practitioners hold a more targeted view and recommend a small number of herbal and nutritional medicines during different stages of pregnancy, while being mindful of many others that are considered to be contraindicated for various reasons.

Moving ahead, it is easy for clinicians to adopt the conservative view that all herbal medicines should be avoided throughout pregnancy. This is not useful in practice, however, especially as women will continue to take them in the belief that they are safe. In fact it could be argued that best practice means considering all treatment options for safety and efficacy in pregnancy, including herbs and natural supplements.

When medicinal treatments present unacceptable risks or are ineffective, complementary medicine as a treatment domain offers a broad range of non-medicinal treatment options that can be considered by clinicians. For instance, lifestyle prescriptions, dietary manipulation, massage, acupuncture and aromatherapy provided by appropriately trained practitioners can address a range of symptoms during this sensitive time.

FACTORS TO CONSIDER IN PRACTICE

It has been estimated that in the United States up to 50% of pregnancies are unplanned and about 5–10% of women are pregnant at any one time (Webster & Freeman 2001). As such, a large proportion of women may not be aware they are pregnant until well into their first trimester. This raises many issues regarding safety, as it is possible for a woman to be taking a complementary medicine during this period and potentially placing the fetus and pregnancy at risk. In Australia, the allocation of an AUST L

PRACTICE TIPS
GENERAL RULES FOR USING CMs IN PREGNANCY

- Use complementary medicine within the Quality Use of Medicines (QUM) framework.
- Consider the patient's presenting health status and comorbidities.
- Consider non-medicinal treatment options where appropriate. Is such a treatment available and likely to be successful?

Risk–benefit analysis

- If a complementary medicine is under consideration, what are the potential risks and benefits to the mother and fetus?
- What are the risks and benefits (to each) of not prescribing?

Timing of intervention

- Avoid all medicinal agents where possible, especially in the first trimester.
- Carefully consider the timing of the intervention in regards to gestational age of the fetus: the susceptibility of a fetus to toxic effects changes throughout gestation.
- Consider appropriate dose, dose frequency and duration of treatment.

Pharmacotherapy compared with complementary medicine

- If the patient's condition is sufficiently severe that pharmacotherapy is being considered, then clinicians should consider whether an appropriate complementary medicine treatment exists with lower risk of harm.
- If clinician and patient decide a complementary medicine is to be used, then the lowest possible dose should be used for the shortest period of time.
- CM is best prescribed by a qualified and appropriately trained health professional.

Counselling

- Counsel pregnant women to avoid exposure to unnecessary medicines and chemicals.

Education and communication

- If use of a complementary medicine is being considered, an open discussion about the potential benefits and potential risks must ensue, so that patients can make an informed decision. This includes providing information about what is known about the safety of the treatment and what remains unknown.
- Communication is essential between all health professionals involved in obstetric patient management and the patient.
- Encourage patients to disclose complementary medicine use to all health professionals in their obstetric team.

Special caution should be exercised with women due to have an elective caesarean section or other surgery. Presurgery recommendations should be considered.

ADDITIONAL RULES: TRADITIONAL UNDERSTANDING OF SAFE HERBAL USE IN PREGNANCY

- Avoid all known toxic and poisonous plants at all times, such as aconite, pennyroyal, tansy.
- Avoid all thujone-containing herbal medicines, such as *Achillea millefolium* (yarrow), *Thuja occidentalis* (thuja) or *Artemisia absinthium* (wormwood)
- Avoid internal use of pure volatile oils from herbal medicines, especially during the first trimester. Herbal teas and small concentrations of oils used as flavouring are the exception (e.g. peppermint oil or food quantities of essential oil containing herbal medicines).
- Avoid emmenagogue herbal medicines in the first trimester and use only under professional supervision at later stages.
- Herbs used to assist delivery should be used only under close professional supervision in the final 6 weeks of pregnancy.

number to an over-the-counter (OTC) product denotes general safety, even when taken without professional advice. Theoretically, it means all OTC-listed products should also be safe in pregnancy, but this remains to be established. To safeguard patients, it is recommended that all practitioners who wish to prescribe medicines with questionable safety in pregnancy should consider the risks in relation to possible benefits and discuss all safety concerns.

Individual prescribing

The decision to prescribe or withdraw a complementary medicine must be made on an individual case-by-case basis. The safe use of any medicine in pregnancy must take into account the safety of the treatment being considered, the seriousness of the patient's presenting problem, maternal age, gestational age of the fetus and timing of exposure. This includes a consideration of the dose to be used, dosing

interval and timing in respect to other medicines and food. Additionally, the patient's presenting health and nutritional status, comorbidities, kidney and liver function and personal attitude to treatment are important factors.

If practitioner and patient agree that a medicine is to be used, steps should be taken to reduce harm, such as recommending the lowest effective dose for the shortest period possible. While special cautions exist for the first trimester, care must be taken at all stages of pregnancy, as fetal growth and development continues for the full period of gestation.

Timing of the intervention

In practice, choosing the correct dose and administration form is essential, and in pregnancy there is the additional consideration of correct timing, which is important for achieving a desired clinical result with a minimum of risk. For example, folate supplementation has been shown to prevent neural tube defects when administered in the preconception period and continued during the first trimester (Berry et al 1999). Similarly, antioxidant supplements appear to be ineffective in reducing preeclampsia when started later in pregnancy (Rumbold et al 2008); however, positive results in preeclampsia were reported in a study that commenced treatment in the first trimester with a broad spectrum antioxidant supplement (including vitamin A 1000 IU, vitamin C 200 mg, vitamin E 400 IU, folic acid 400 mcg, selenium 100 mcg, zinc 15 mg, copper 2 mg, N-acetyl cysteine 200 mg, iron 30 mg) (Rumiris et al 2006).

Informed consent

Evidence-based patient-centred care means that all clinicians are required to present risk/benefit information to their patient, who can then make an informed choice. This means an honest discussion between patient and practitioner about what is known and what remains unknown about the safety and efficacy of a treatment. Patients will no doubt vary in their interest and ability to comprehend and recall the necessary information, so written information and assurance that the woman understands the issues during the time of consultation is useful.

CHAPTER 12
INTRODUCTION TO WELLNESS

WHAT IS 'WELLNESS'?

'Wellness' is a concept that has gained popularity in recent years but still has no rigorously developed definition, theory or philosophy. At a very simple level, wellness can be equated with health which, according to the World Health Organization, is 'a state of complete physical, mental and social well-being and not merely the absence of disease or infirmity' (WHO 1948). Wellness, however, can also be seen as distinct from health in that it is holistic and multidimensional. The notion of wellness includes not only physical, mental and social dimensions, but also emotional, cultural, spiritual, educational, sexual, occupational, financial, environmental, ethical and existential dimensions, with the assumption being that if any one of these dimensions is deficient, complete wellness cannot be achieved.

Wellness describes a quality of systems rather than isolated entities and, as such, it is dependent on relationships and must take into account both content and context. Because it describes systems, the notion of wellness can be applied to individuals as well as to communities, businesses and large-scale economies. The notion of wellness requires an ecological perspective that can be expanded to include the concepts of human security, corporate social responsibility, social justice, environmental impact and sustainability, together with subjective fulfilment and wellbeing.

In 1961, wellness pioneer Halbert Dunn defined wellness, in his book *High-level wellness*, as 'an integrated method of functioning which is oriented toward maximizing the potential of which the individual is capable' (Dunn 1961, p 4). He acknowledges that wellness is dependent on the relationship between individuals and their environment, stating that wellness 'requires that the individual maintain a continuum of balance and purposeful direction within the environment where he is functioning'. He also stated that 'wellness is a direction in progress toward an ever-higher potential of functioning' (Dunn 1961, p 6).

More recently the [US] President's Council on Physical Fitness and Sports proposed a uniform definition of wellness as 'a multidimensional state of being describing the existence of positive health in an individual as exemplified by quality of life and a sense of well-being' (Corbin & Pangrazi 2001). Yet another definition suggests that wellness is an 'active process of becoming aware of and making choices toward a more successful existence' (US National Wellness Institute 2009). Another proposed definition is:

> Wellness is the multidimensional state of being 'well', where inner and outer worlds are in harmony: a heightened state of consciousness enabling you to be fully present in the moment and respond authentically to any situation from the 'deep inner well of your being'. Wellness is dynamic and results in a continuous awakening and evolution of consciousness and is the state where you look, feel, perform, and stay 'well' and, therefore, experience the greatest fulfilment and enjoyment from life and achieve the greatest longevity. (Cohen 2008a, p 8)

This definition implies that the state of wellness allows the greatest flexibility to respond to situations and therefore provides the greatest resilience to stress and disease. Wellness in this context can be seen as the best preventative medicine. In this definition wellness is also seen as a state of consciousness that guides the quality of our relationships with the world and therefore cannot be viewed separately from the environment in which it occurs. Thus, if 'health' is 'wholeness', then wellness is the experience of an ever-expanding realisation of what it means to be whole (Cohen 2008a).

Travis and Ryan suggest that wellness is never a static state but rather a way of life, and that wellness and illness exist along a continuum: just as there are degrees of illness, there are also degrees of wellness. Travis and Ryan further see wellness as a choice, a process, a balanced channelling of energy, the integration of body, mind and spirit, and the loving acceptance of self (Travis & Ryan 2004).

If health and disease are considered to be at opposite ends of a spectrum, then it is possible to classify health into three broad areas: ill health (illness), average health and enhanced health (wellness) (Fig 12.1). The divide between ill health and average health is generally defined in Western medical terms, which classify diseases based on symptom patterns or other diagnostic parameters. Western medicine uses a bottom-up approach that aims to define and understand illness, and develop interventions such as drugs and surgery to treat or prevent the disease and control factors that reduce wellbeing ('stressors').

The divide between average health and enhanced health is less distinct. Enhanced health is more than just being disease-free: it assumes high levels of physical strength, stamina and mental clarity, as well as physical beauty and maximal enjoyment and fulfilment from life. This requires the holistic integration of multiple factors that determine physical, psychological, emotional, social, economic, environmental and spiritual health. In many Eastern philosophies, the idea of enhanced health can be extended to the concept of 'perfect health' or 'enlightenment', whereby a person is 'at one with the universe' and hence in a state of perfect bliss or 'nirvana' (Cohen 2003).

Moving up the spectrum from illness to wellness allows for greater flexibility of response and hence greater resilience; the best form of prevention is therefore to be as high on the spectrum as possible. Thus, while 'stressors' tend to reduce the ability to respond and create downward movement, upward movement can be facilitated by 'blissors', which create greater wellbeing. Throughout the spectrum, however, there is also a central axis that represents the core of our being. This central core, which may be termed the 'soul' or the 'essence', is an eternal and immortal aspect of the self that is naturally at one with the universe and blissful.

Bliss, or 'ananda' in Sanskrit, is considered by Vedic scholars to be the innermost level of the individual self, as well as the nature of the whole universe. It is the goal of the path to enlightenment and is found in the deepest experience of meditation and the innermost level of our being (Maharishi 1957–64). Bliss is also the ultimate aim of Eastern healing and spiritual practices, which adopt a top-down approach by attempting to elicit bliss through meditation and other practices that enhance wellbeing ('blissors') (Cohen 2008a).

The state of bliss can also be considered as the ultimate in achieving human potential. As the late anthropologist Joseph Campbell states:

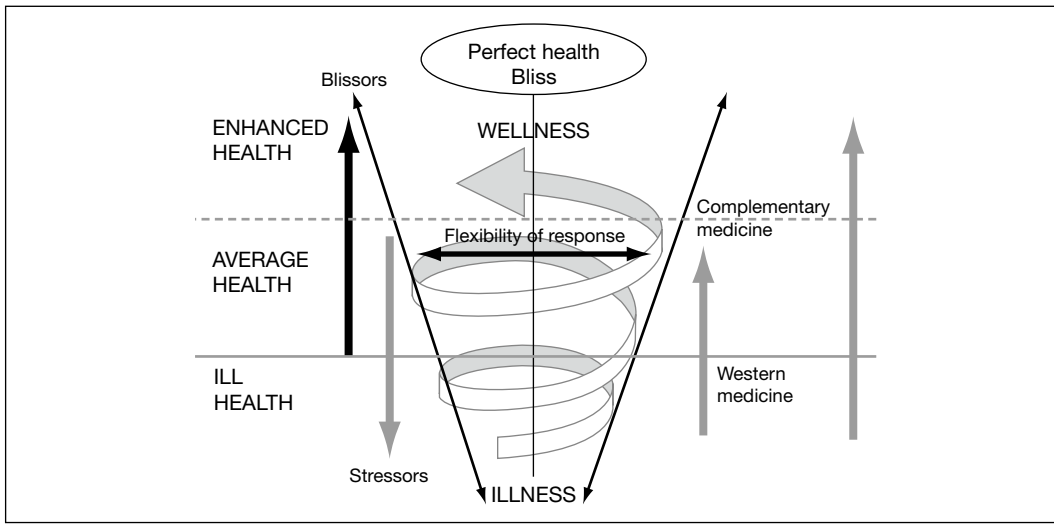

FIGURE 12.1 The illness–wellness spectrum (Cohen 2008a)

> I think that most people are looking for an experience that connects them to the ecstasy of what it could feel like to be totally alive. To know the unburdened state of total aliveness is the pinnacle of the human potential. (Campbell 1988)

This 'state of total aliveness' is what many people may consider to be 'wellness'.

THE WORLD IN CRISIS

It seems that all people at some time have tried to tackle the question of how to live well in the world. This single question has driven many different areas of human endeavour and has led to innovations that have created new technologies and ways of living that have allowed human populations to expand exponentially (Meadows et al 1976).

The world is currently facing a series of crises that are challenging the financial system, the climate and the environment. Increased global terrorism, pandemics, environmental pollution, general toxicity and natural disasters are breaching national boundaries and threatening human security. We also currently live in a world where one-third of the world's population is dying from diseases linked to malnutrition and starvation; another third is dying from obesity and diseases related to overconsumption; toxic chemicals are continuously being created and released into our environment and food supply, and people are becoming increasingly disconnected from their natural environment and one another.

Modern healthcare systems are also struggling to provide quality care to all in need, as the burden of illness-care reaches barely manageable proportions. It is becoming clear that the current illness-based medical model is not sustainable and is ill-equipped to meet the needs of the global population or deal with the consequences of an ageing population, increasing healthcare costs and an epidemic of lifestyle-related diseases such as obesity, diabetes, heart disease and cancer.

The disproportionate focus on illness has allowed unhealthy lifestyle practices to remain largely unchecked, thereby allowing them to expand across the globe to the point where they now represent the greatest threat to human health and survival. A 2005 report by the World Health Organization entitled *Preventing chronic disease: A vital investment* estimates that of the 58 million deaths in the world in 2005, 35 million (60%) were caused by chronic diseases such as heart disease, stroke, cancer, chronic respiratory diseases and diabetes. The report goes on to suggest that 80% of premature heart disease, stroke and type 2 diabetes and 40% of all cancers are preventable, concluding that the main modifiable risk factors for these diseases are lifestyle-related and include unhealthy diets, physical inactivity and tobacco use (WHO 2005).

It has been predicted that, as a result of unhealthy lifestyles, for the first time in history the lifespan of the next generation in the United States could be shorter than that of their parents (Olshansky et al 2005). In a PriceWaterhouseCoopers (PWC) report on the future of healthcare entitled *HealthCast 2020: Creating a sustainable future* (PWC 2005), it is suggested that 'There is growing evidence that the current health systems of nations around the world will be unsustainable if unchanged over the next 15 years' (PWC 2005, p 2), while 'preventive care and disease management programs have untapped potential to enhance health status and reduce costs' (PWC 2005, p 4).

IN SEARCH OF WELLNESS

It is becoming increasingly evident that the fate of all people is ultimately linked and that as a global species we must find sustainable ways to live well in the world together. It could be viewed that humanity has reached a 'tipping point', bringing the possibility of either substantial hardship or a breakthrough into new ways of living and a new phase in human evolution. This new phase represents a culmination of thousands of years of human history, during which different philosophies, traditions and technologies have attempted to address the questions of life, ageing, illness and death.

The search for wellness is a common goal for all people. It can be understood as a conscious extension of the basic animal instinct to avoid pain that has its origins at the dawn of humanity when consciousness first became self-reflective (Cohen 2000). This search has influenced the evolution of medicine, which has seen the elaboration of two distinct yet complementary approaches: Eastern medicine, which is based on holistic thinking that maintains a cosmological and systems perspective outlining a philosophy of life; and Western medicine, which is based on a reductionist approach, emphasising controlled scientific experimentation and mathematical analysis (Cohen 2002).

The different health paradigms that aim to improve health and wellness have attempted to address the same issues in different ways. The principle of consilience suggests that there is an underlying unity of knowledge whereby a small number of natural laws may underpin seemingly different conceptual frameworks (Wilson 1999). Indeed there are general concepts and principles that seem to recur as themes across different healthcare paradigms.

THE THERMODYNAMICS OF WELLNESS

Perhaps the most ubiquitous principle in medical thought is the idea that life is dependent on energy. The science of energy is well described in the field of thermodynamics, which proposes universal laws that give rise to precise mathematical equations that form the foundation for modern science and technology. However, while the field of thermodynamics purports to describe all energetic processes, it is seldom applied directly to the fields of health and medicine, despite 'energy' being a basic principle in virtually every healing tradition.

The concept of energy is described in different traditions as 'life energy', 'vital force', 'prana', 'chi' (or 'Qi'), and is said to flow along defined pathways and support the functioning of living systems. Traditional Chinese medicine has developed a sophisticated framework for conceptualising this energy: it is seen to encompass the concept of 'flow' and to move according to the dynamic interplay of the opposite yet complementary forces of 'yin' and 'yang', which guide the process of transformation whereby non-living things become animate. In this view, pain and disease are said to result when the energetic flow is disrupted, and healing is aimed at restoring the natural balance and flow (Cohen 2002).

As science does not recognise a form of energy specific to living systems, many concepts underlying Eastern medicine have been criticised as unscientific. There are parallels, however, between Eastern and Western concepts, which can be seen to be linked through the concept of information. Information can be measured in terms of energy or 'joules/degree Kelvin' (Tribus & McIrvine 1971), and there is a congruence between the concepts of 'Qi' in Eastern medicine and 'information' in thermodynamics.

Thus the Eastern concept of disease arising from a blockage of 'Qi' can be seen to parallel the second law of thermodynamics, which describes a tendency towards disorder or entropy in an isolated system. Disease and the adverse effects of ageing, which include progressive degeneration of tissues together with loss of function, can therefore be related to an increase in entropy as a consequence of blockages or isolation of different systems. In contrast, the ability of living systems to grow, evolve and learn appears to defy the second law and can be related to an open exchange between organisms and the environment. This can be extended to the concept of 'nirvana', or perfect bliss, whereby a person is 'at one with the universe' and there is no distinction between self and non-self, thus creating an open system that is no longer prone to the increase in entropy that occurs in isolated systems (Cohen 2002).

WELLNESS AND FLOW

While it may be true that life depends on energy, living systems must remain 'open', as it is the flow of energy through them that maintains their integrity. The concept of 'flow' is a powerful one that provides a bridge between Eastern and Western thought. The concept of flow applies to both thermodynamic processes and systems theory, as well as to the cyclic thinking of Eastern medicine. The concept of flow has also been applied to subjective psychological states that involve the integrated functioning of mind and body. This concept has been developed by Mihalyi Csikszentmihalyi who describes flow as 'a joyous, self-forgetful involvement through concentration, which in turn is made possible by a discipline of the body' (Csikszentmihalyi 1992).

The state of flow occurs when perceived challenges exactly match the skills and capacity to respond. Such a state is therefore a 'whole of consciousness' phenomenon that requires the integrated action of both physiological and psychological processes, and hence the involvement of the entire being. In requiring 'wholeness', the 'flow state' is aligned with health and wellness, and engenders positive feelings that include:

- being completely involved in what we are doing — focused, concentrated
- a sense of ecstasy — of being outside and beyond everyday reality
- great inner clarity — knowing what needs to be done and how well we are doing it (introspective, realistic feedback)
- knowing the activity is able to be done — that our skills are adequate to the task

- a sense of serenity — having no undue concerns or worries about oneself, and a feeling of growing beyond the boundaries of the ego
- timelessness — being thoroughly focused on the present so that hours seem to pass by in minutes
- intrinsic motivation — whatever produces flow becomes its own reward (Csikszentmihalyi 2004).

The idea that positive psychological states and wellbeing require 'open systems' is recognised in everyday common language in the phrases 'having an open heart' or 'open mind'. The concept of flow sustaining life is also a basic tenet of Chinese and other traditional medicine philosophies. A thermodynamic model that includes the concept of energy and flow can also be seen to include many parallels between Eastern and Western concepts and thus provide links between different conceptual systems (Fig 12.2).

For example, the process of flow leading to transformation and the maintenance of living systems parallels the concept of the five elements or phases of transformation that is common to Chinese medicine, Ayurvedic medicine and ancient Greek medicine (which considered quintessence as a fifth element in addition to air, water, fire and earth). The result of this transformation is represented by the concept of 'yin' and 'yang', which refers to interdependent yet mutually exclusive opposites and can be compared to the concept of 'complementarity' in quantum physics or the concept of homeostatic balance in physiology. The result of this balance leads to an increase or decrease in order as described by entropy or evolution, while the infinite nature of direct experience can be compared to the concept of 'Tao' or the mathematical concept of 'absolute infinity', both of which are defined as being inherently incomprehensible (Cohen 2002).

WELLNESS METRICS

Wellness is holistic and multidimensional, and involves content and context. As such it is both subjective and objective, and is difficult to quantify. As yet there are no agreed upon metrics by which wellness can be reliably measured, despite the existence of many potential indicators and proxy measures that may be applied to populations as well as individuals. Thus it is now possible to measure subjective states such as 'quality of life', 'happiness' and 'wellbeing' through instruments such as the Australian Quality of Life Index (Cummins et al 2008), as well as to use more objective and physiological measures such as anthropometric and biometric data. Objective indicators of wellness can also be obtained from tissue

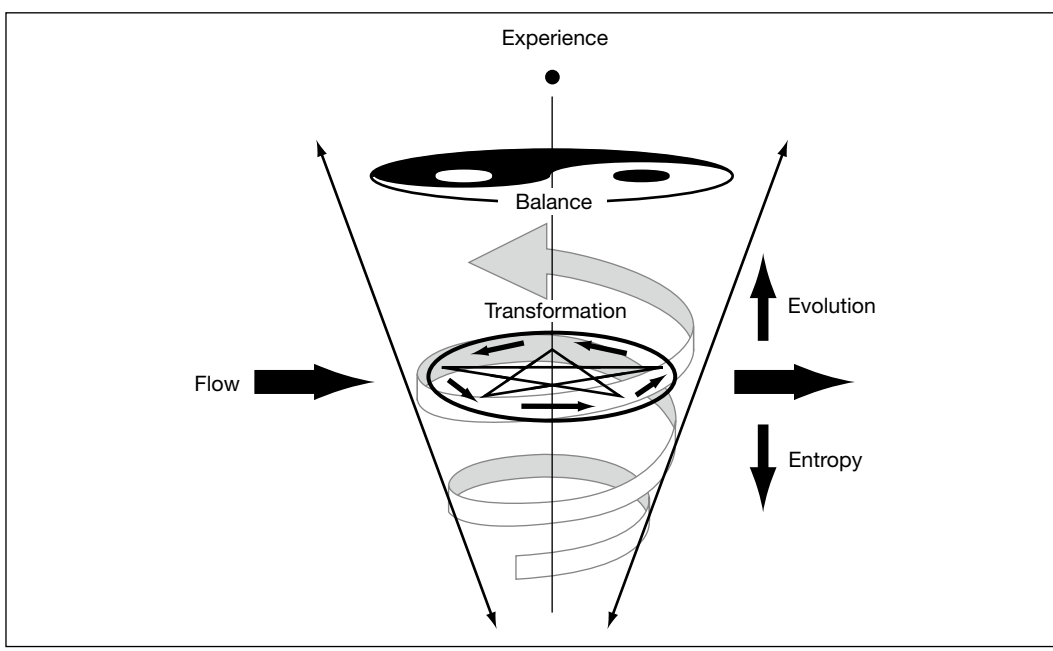

FIGURE 12.2 Pictorial conceptualisation of wellness concepts from traditional Chinese medicine (Cohen 2008a)

sampling and measuring biochemical, hormonal, genetic, haematological and toxological data, as well as by testing functional capacity and performance. Further indicators for wellness can be obtained from demographic, socioeconomic and epidemiological data, which can be used to appraise access to food, shelter, education, employment, healthcare and consumer goods, as well as to rate health risks, ecological footprint, morbidity, mortality and life expectancy (Cohen 2008a).

The multidimensional nature of wellness makes any single measure inadequate, and so attempts have been made to combine measures from the different domains. For example, the BankWest Quality of Life Index tracks Australian living standards across municipalities based on key indicators of the labour market, the housing market, the environment, education and health (BankWest 2008).

In attempting to measure 'full spectrum wellness', Travis and Ryan adopt the concept of a 'wellness energy system', which implies a thermodynamic model and measures wellness in terms of inputs and outputs. They acknowledge that 'we are all energy transformers, connected with the whole universe', and that 'all our life processes, including illness, depend on how we manage energy' (Travis & Ryan 2004). These authors further describe 12 aspects of wellness, which include inputs provided by breathing, eating, and sensing, and outputs described as self-responsibility and love, transcending, finding meaning, intimacy, communicating, playing and working, thinking, feeling and moving. These 12 aspects of wellness are the basis for the wellness inventory: evolved from health-risk appraisal techniques to become the first computerised wellness assessment tool, this inventory aims to provide a measure of wellness across the 12 dimensions through a self-reported questionnaire.

Perhaps the most comprehensive attempt to create a metric for wellbeing is the 'Happy Planet Index', which uses both subjective and objective data in an attempt to measure the ecological efficiency with which countries achieve long and happy lives for their citizens. The Happy Planet Index is a composite measure that is calculated by multiplying life satisfaction by life expectancy and then dividing by ecological footprint. It therefore takes a thermodynamic approach to the wellness of populations by dividing outputs (the length and happiness of human life) by inputs (natural resources) (Marks et al 2009). The finding that the average scores across nations are low, that all nations could do better and that no country does well on all three indicators or achieves an overall high score on the index has led the Happy Planet Index to be considered currently as the (Un)Happy Planet Index (Marks et al 2009).

THE WELLNESS REVOLUTION

Since the emergence of self-reflective consciousness, every culture at every point in history has maintained various practices that aim at achieving and maintaining the wellbeing of individuals and the wider community. These practices invariably include the use of the local environment, food, water and plants, as well as various indigenous healing practices, such as massage and traditional cultural practices that are performed to focus the mind and anchor the experience of being well in ritual, routine and direct sensual experience.

While every culture throughout history has had its own wellness practices and philosophies, a culture that is global or sustainable has never existed before (Cohen 2008a). In the current millennium, however, there is a need for global solutions that provide an integrated response to the many world crises and an orientation towards wellness promises to provide such solutions. Thus it is suggested that along with the current crises, the world is also experiencing the start of a 'wellness revolution' and the accompanying growth of a 'wellness industry'.

THE WELLNESS INDUSTRY

In his 2002 book *The wellness revolution*, economist Paul Zane Pilzer estimated that the value of existing items in the US wellness industry had reached approximately US$200 billion. This included US$70 billion for vitamins and US$25 billion for spas and fitness centres — about half the amount spent on automobiles in the USA (Pilzer 2002). Pilzer suggests that the US$200 billion is only the tip of the iceberg, and that wellness products and services represent the beginning of a new trillion-dollar sector of the US economy. In an updated edition of his book, Pilzer estimates that in 2007 the US wellness industry had expanded to over US$500 billion and that the untapped market for wellness had increased in size thanks to millions of new wellness consumers (Pilzer 2007).

The growth of the wellness industry is evidenced by the dramatic growth of the global spa industry (now considered by many to be the 'spa and wellness' industry), which has recently

emerged as a global phenomenon through a convergence of industries, traditions and therapeutic practices. While spa therapies have been around since ancient times in many different forms that reflect the cultural, social and political milieu in which they are embedded, these practices are now being rediscovered, integrated and branded to create a new global industry that draws from a range of aligned industries, including beauty, massage, hospitality, tourism, architecture, property development, landscape design, fashion, food and beverage, fitness and leisure, personal development, as well as complementary, conventional and traditional medicine (Cohen 2008a).

Fuelled by the merging of the travel dollar with the health dollar, spas are now springing up all over the world and have become a standard feature of luxury hotels and resorts. Spas are reported to be the fastest-growing leisure industry, and it is estimated that by 2001 revenues from spas had already overtaken revenues from amusement parks, box office receipts, vacation ownership and ski resorts (ISPA 2002). A more recent report on the global spa economy suggests that global revenue from spas in 2007 was worth more than US$255 billion globally and that the wider wellness industry was worth an additional US$1.1 trillion (SRI International 2008).

In offering to deliver on wellness, the spa industry is moving beyond luxury and pampering into the area of providing healthcare and, even further, raising consciousness. As such, the global spa industry is a melting pot for a whole host of products and services that encourage enhanced health and wellbeing and are drawn from a wide variety of traditions that include conventional, complementary and traditional medicine. Thus spas are adopting an integrative approach; they are taking holistic medical concepts out of clinics and combining them with the world of hospitality and leisure to place them in sustainable, enjoyable and nurturing environments.

Hotels certainly have a much greater appeal than hospitals. By combining hospitality with an integrative medicine model that emphasises lifestyle change and personal empowerment, the spa and wellness industry has the potential to transcend conventional medicine and create a globally sustainable health system. While most spas do not, as yet, create formal medical records, instigate diagnostic tests or perform medical procedures, these are all taking place in some medi-spas and destination spas, while some spas are beginning to integrate conventional and complementary medicine services with hospitality services such as accommodation, food and beverage to create hybrid hospital-spa-hotels ('hos-spa-tels'). As these are integrated into international hospitality chains, they create the potential for the delivery of a global integrated health service based on wellness principles (Cohen 2008a).

CONSCIOUS CONSUMPTION

The rise of the wellness industry is aligned with a move towards 'lifestyles of health and sustainability' (LOHAS). LOHAS is a demographic defining a particular market segment related to sustainable living and 'green' ecological initiatives, and is generally composed of a relatively upscale and well-educated population segment. In 2006 the LOHAS market segment was estimated at approximately US$209 billion for goods and services focused on health, the environment, personal development and sustainable living. The focus of LOHAS is conscious consumption and covers diverse market segments such as personal health, natural lifestyles, green building, alternative energy and transportation, and ecotourism (for more information about LOHAS, see www.lohas.com).

A strong component of the LOHAS movement is the trend for consumers to choose more holistic, prevention-based models of healthcare, and this is evidenced by the increasing use of complementary and alternative medicine (Tindle et al 2005). This trend may reflect a growing disenchantment with the medical profession's seemingly one-sided emphasis on science and technology, as well as a growing demand for autonomy in healthcare decisions. Certainly, the general population is now better informed than ever and has better access to health information. The public are subsequently demanding more from healthcare providers and are not interested only in treating illness. Instead they want to maximise their health, prevent or slow down the ageing process and achieve higher levels of functioning (Cohen 2001).

The LOHAS movement has arisen out of a growing awareness that rampant consumerism seems to be taking over and destroying the planet. Certainly, unchecked and unconscious consumption can be seen to be at the root of many of the world's problems. Thus while we as consumers currently have access to a seemingly unlimited choice of goods in every size

and colour, we remain disconnected from the products and services we purchase and often do not know where they come from, how they are produced, who produced them, what is in them, how they are disposed of or who benefits from their purchase.

In response to this, there is a growth in conscious consumer trends that include LOHAS, as well as a variety of trends badged with different labels such as; 'green', 'natural', 'organic', 'fair-trade', 'corporate social responsibility', 'eco', 'ethical investment', 'sustainable', 'barefoot luxury'. These have given rise to 'locovor' restaurants (those that source food within 160 kilometres/100 miles), carbon offset programs, green buildings, 'carbon neutral businesses', 'ecotourism', 'ethnotourism', 'voluntourism', 'downsizing', 'compacting', 'tree-change', 'social capital' and 'triple and quadruple bottom-line reporting'.

It is suggested that this range of conscious consumer trends can be integrated under the banner of 'conshumanism', which is a term that defines 'conscious and humane consumption' or 'consumption with maximal awareness, efficiency and enjoyment and minimal pain, energy, waste and pollution' (Cohen 2008a). Conshumanism embraces an overarching concept that can integrate multiple consumer trends towards greater transparency, equity, accountability, social responsibility, environmental sustainability and ethics. The common feature of these trends is increasing information and consciousness about consumption as well as incorporating an awareness of wellness into everyday lifestyle decisions.

TOWARDS A WELLNESS POLICY AGENDA

While treating illness has traditionally been the domain of the medical system, there is a growing realisation that wellness is holistic and multifaceted, and that implementing a wellness agenda requires wellness to become part of the fabric of our society so that it infiltrates the education system, workplaces and the consciousness of every individual. Thus action is required from all sectors, from individuals, government and non-government agencies to the corporate sector.

GOVERNMENT INITIATIVES

The year 2008 seems to have been a watershed year for Australian government wellness initiatives. The Australia 2020 Summit called for the development of a 'whole-of-life wellness model' and a 'wellness footprint' to evaluate, measure and resource services across portfolios (Good & Roxon 2008), while the National Health and Hospitals Reform Commission, the National Preventative Health Task Force, the Primary Health Care Strategy Reference Group and the Indigenous Health Equity Council were established, all with a mandate for health reform (Moodie et al 2008).

Established in February 2008, the National Health and Hospitals Reform Commission (NHHRC) came out with a set of guiding principles that include 'strengthening prevention and wellness', and acknowledged that a comprehensive and holistic approach is needed to reorient the health system, so that there is greater emphasis on helping people stay healthy through stronger investment in wellness, prevention and early detection and appropriate intervention to maintain people in as optimal health as possible (NHHRC 2008). In October 2008 the NHHRC commissioned an options paper on 'A national agency for promoting health and preventing illness' (Moodie et al 2008), which proposes the establishment of a National Health Promotion and Prevention Agency in order to provide education, evidence and research to make prevention a top priority. This options paper was followed by the publication of an interim report, *A healthier future for all Australians*, a major theme of which was 'Taking responsibility', calling for greater personal responsibility for improving health supported by policies that make healthy choices easier; health literacy in a national curriculum for all schools; better information about creating healthy local communities — 'wellness footprints'; and workplace health promotion and wellness programs (Bennett 2008).

In line with these developments, the National Preventative Health Taskforce was established in April 2008 to provide evidence-based advice to governments and health providers on preventative health programs and strategies, focusing on the burden of chronic disease currently caused by unhealthy lifestyles. This taskforce produced a discussion paper entitled 'Australia, the healthiest country by 2020', which acknowledges the need for a coordinated approach to wellness, stating that:

> Our health is not only determined by our physical and psychological make-up and health behaviours, but also by our education, income and employment; our access to services; the place in which we live in [sic] and

its culture; the advertising we are exposed to; and the laws and other regulations in place in our society (Preventative Health Task Force 2008).

WORKING TOWARDS WELLNESS

In addition to the above initiatives taken by the Australian government, 2008 saw a number of global initiatives with a call for a more proactive, wellness-oriented approach to be taken by the corporate sector. Illness places a huge burden not only on government health systems and communities, but also on industry, with the potential for catastrophic effects. While the costs to industry from illness due to absenteeism are clear, it is only recently that the costs of 'presenteeism' have been assessed. It has been estimated that presenteeism — when workers turn up for work but are unproductive because of an ongoing illness — involves a greater cost than absenteeism, and may represent up to 60% of an employee's total lost productivity and medical costs (Goetzel et al 2004). Presenteeism may also pose serious threats to workplace safety, lead to dissemination of infectious diseases and have hidden long-term costs as well as compounding other lifestyle and social issues.

There is therefore a clear advantage in addressing wellness in the workplace, as this may have a positive impact on a company's productivity, recruitment, retention and ultimate profitability. As many employees spend a significant portion of their life at work, workplace wellness programs are also well positioned to address the growing burden of chronic lifestyle-related disease.

At the World Economic Forum Annual Meeting in Davos, Switzerland, in January 2008, there was a call for action to raise the issue of employee health on the corporate agenda. At the meeting, the results of a collaboration between the World Economic Forum and the World Health Organization were released that suggested that workplace wellness programs are a real, but underexploited, opportunity to tackle the growing worldwide epidemic of chronic disease. This coincided with a PriceWaterhouseCoopers report entitled *Working towards wellness: accelerating the prevention of chronic disease*, which suggests that large multinational corporations are now looking for wellness strategies to implement in their workplaces and the communities in which they operate, and are rolling out comprehensive wellness programs in multiple countries, even though there are challenges in the implementation, evaluation and monitoring of such programs (PriceWaterhouseCoopers 2007).

As yet there is still no robust accounting for wellness, despite the evolution of triple and quadruple bottom-line reporting; however, the corporate sector appears to be taking workplace wellness programs beyond health screening and occupational health and safety programs, and there are moves to engage employees and the wider community in wellness and lifestyle initiatives through corporate social responsibility, environmental sustainability and community development agendas.

LIFESTYLE MEDICINE

Wellness impacts on every aspect of our lives, and experiencing wellness requires the holistic integration of multiple factors that determine physical, psychological, emotional, social, economic, environmental and spiritual health. Wellness is therefore ultimately an issue of lifestyle. In order to embrace wellness or enhanced health, the key 'life activities' that determine our health must be addressed. These life activities are summarised by the SENSE approach (see Ch 1). We all need to manage stress, move, eat, interact with other people, interact with the world, and learn. If we improve the way we do these activities, we will naturally improve our wellbeing. Wellness therefore involves the following:

- **stress management** — managing stressors (e.g. effective time management strategies and priority setting), and including everyday activities that enhance our ability to cope with stressors (e.g. meditation, breathing exercises, hobbies, and infusing life with creativity, humour and fun)
- **exercise** — engaging in regular physical activity that improves our aerobic capacity (e.g. walking), physical strength (e.g. resistance training) and flexibility (e.g. yoga)
- **nutrition** — receiving adequate nutrition through the consumption of a wide variety of fresh, seasonal, whole foods that are stored and prepared appropriately; minimising our exposure to toxins by using organic produce; and avoiding tobacco smoke and environmental toxins
- **social and spiritual interaction** — devoting ourselves to quality time with others and fostering love and intimacy in all our personal relationships; developing an ethic of service to others and a sense of

social responsibility (e.g. volunteering and community work); giving to charities (e.g. time, effort, money); ethical investing and purchasing

- **education** — learning about ourselves and others, our environment and our place in it, and attempting to avoid obvious hazards while living sustainable, ecological lifestyles.

In recognition of the impact that lifestyle has on illness, developments in health funding in Australia have enabled allied health professionals to become part of a team that can address lifestyle issues. This has led to the emergence of 'lifestyle medicine', which is deemed to be a new discipline that attempts to bridge the gap between health promotion and conventional medicine by applying 'environmental, behavioural, medical and motivational principles to the management of lifestyle related health problems in a clinical setting' (Egger et al 2008).

Managing lifestyle issues changes the emphasis from conventional treatment to one where patients need to be more involved in their own care, and which therefore requires the clinician to have considerable motivational knowledge and skills. It involves the therapeutic use of lifestyle interventions in the management of disease (Egger et al 2009). Lifestyle medicine may also involve health coaching, which is a practice in which health professionals apply evidence-based psychological, counselling and coaching principles and techniques to assist their patients to achieve positive health and lifestyle outcomes through cognitive and behaviour change (Gale 2009).

A NEW ACADEMIC DISCIPLINE

It appears that the wellness revolution has created the opportunity for wellness to be framed as a new academic discipline. The multidimensional and holistic nature of wellness, however, demands extensive collaboration and communication across diverse discipline areas of expertise to work on wellness-oriented teaching, learning and research projects.

Wellness seems to have an emerging research agenda, with one of the four Australian Government National Research Priorities being 'Promoting and maintaining good health'. This priority area aims to support preventative healthcare and enable people to make healthy choices, and includes the following key research themes: a healthy start to life, ageing well, ageing productively and preventive healthcare (Department of Education, Employment and Workplace Relations 2009). While this research priority area seems to target wellness-related research, wellness underpins many disparate research areas, ranging from theoretical and bench-top science to clinical research as well as social and policy research. A wellness agenda is therefore also inherent in other research priority areas, such as sustainability, frontier technologies and safeguarding Australia from terrorism, crime, invasive diseases and pests.

While a wellness research agenda is emerging, significant hurdles remain. Specific research into wellness and disease prevention is hindered by a lack of discrete outcome measures with which to measure wellness. Additional challenges include the design of programs that monitor and promote adherence, novel delivery models and the training, regulation and accreditation of suitable practitioners.

Although training and regulation pose challenges, wellness is a growing area in education and training and is increasingly becoming the focus of academic programs at undergraduate and postgraduate levels. International demand for a wellness-oriented academic program is located in three principal healthcare sectors: the conventional healthcare disciplines, which have an increasing emphasis on health promotion; the complementary and allied health sector including fitness, sports science, nutrition and psychology; and the rapidly growing hospitality, leisure and spa sector.

The need for wellness-related education is demonstrated by current health workforce shortages, the lack of experienced managers and therapists to work in spas, hospitality and leisure and the need for business professionals to embrace workplace wellness. A Productivity Commission report on Australia's health workforce suggested four broad approaches to overcome current health workforce shortages and distribution problems, and to address the future pressures facing the system. The first of these approaches involves strategies aimed at reducing the underlying demand for healthcare through 'wellness' and preventative strategies. This report also commented on the need for a health workforce with increased skills in health promotion (Productivity Commission 2006).

Creating a new academic discipline around wellness is a challenge, as there is a need to align the wellness industry with the professional and educational standards of the healthcare and business sectors. Such an alignment is evident in the continual increase in the

provision and standard of education programs in wellness-related areas such as naturopathy, massage, fitness, yoga and spa therapies. This has led to calls for wellness-education-related accreditation and standards. In answering this call, the US National Wellness Institute recently set up an Academic Accreditation Committee and developed a set of baccalaureate-degree-level standards and processes that will lead to accreditation of academic programs and graduate certification (US National Wellness Institute 2008).

In Australia, RMIT University has taken on a leadership role and established the world's first postgraduate Master of Wellness program (see www.rmit.edu.au/healthsciences/wellness). While no position descriptions currently require applicants to have a postgraduate wellness degree, this program provides core subjects and a suite of electives that include healthcare- and business-related courses so that students can choose their own path, build on their existing skills and become equipped to lead the wellness revolution in their respective disciplines. Thus the program is designed to provide graduate students from diverse backgrounds, including both health science and business graduates, with a holistic overview of wellness principles and practices. The program also aims to have a positive impact on students' personal health and wellbeing, and uses cutting-edge educational technology and the latest understanding about adult teaching and learning to deliver a fully online program with a global reach.

WELLNESS ONLINE

Wellness is a product of consciousness and it is said that 'the currency of wellness is connection' (Travis & Ryan 2004). With the advent of the internet as well as the development of information and communications technology (ICT), the world is certainly becoming more connected. Over the past two decades the development of the internet and ICT has progressed so rapidly that it is now possible for everyone on the globe to be linked via mobile communications technology that infiltrates almost every aspect of society.

It is clear that wellness-related technologies are converging in an online environment. Already ICT is used to support healthcare delivery, and electronic health-information systems promise to improve efficacy, safety and quality of care through the provision of alerts and reminders, diagnostic support, therapy critiquing and planning, prescribing decision support, information retrieval, image recognition and interpretation, as well as through the discovery of new phenomena and the creation of medical knowledge (Coiera 2003).

The advent of personal computing and modern consumer electronics has made technologies that were once accessible only to technical specialists available to the general population via home-based and mobile platforms. For example, online calculators can provide the basis for lifestyle advice and motivation for implementing positive lifestyle changes, and online tools can provide assessments via subjective questionnaires as well as by the direct testing of cognitive and other functional status.

Biometric monitors allow remote wellness monitoring by uploading data on various physiological parameters such as activity and sleep. These devices are being integrated into other personal electronic devices such as phones and digital music players. For example, Apple and Nike offer a kit in which a shoe sensor communicates with a wireless iPod receiver to transmit workout information such as elapsed time, distance travelled, and calories burned (see www.apple.com/ipod/nike) (Cohen 2008b).

Online data collection allows personal information to be analysed and interpreted with the assistance of online experts, who in turn have access to sophisticated knowledge-management technologies, including bibliographic databases and decision support systems. Furthermore, online education offers unprecedented opportunities to deliver education across the planet, and develop knowledge and skills wherever they are required.

THE FUTURE OF WELLNESS

While the worldwide web is only around 5000 days old, when considered as a single machine it represents the largest and most reliable machine ever built with information-processing power approaching the same order as a human brain. The size and power of the web is doubling every two years, and it is expected that its future evolution will lead to services and opportunities that are yet to be imagined (Kelly 2007). Its global reach provides a unique platform for connecting people, ideas and practices, essential parts of the wellness equation. How best to harness its capabilities to improve individual and global wellness is still unclear. Will initiatives such as Google

Health be able to provide everyone on the planet with a free online health record and provide continuity of care as well as opportunities for epidemiological research and public health initiatives? Will online access provide everyone with access to education and the wealth of the world's knowledge? Will 'augmented reality' become the norm and 'virtual reality' become indistinguishable from 'reality'? Will video games become better than real life? Will social networking provide a forum for meaningful connection and provide an end to loneliness and social isolation? Will online environments facilitate therapeutic and health enhancing experiences? Will the harnessing of global connectivity be able to enhance how we experience our environment and avert the many crises we are facing?

It seems clear that over the next few decades changing global demographics, accompanied by major societal changes brought about by climate change, and technological innovations will have an impact on personal, community and global wellbeing and will for ever change how humans live. The development of wellness as a key focus for research, education, healthcare, government policy and industry can only improve the outlook for present and future generations.

Adhatoda

HISTORICAL NOTE An important herb in Ayurvedic medicine for hundreds of years, adhatoda is used traditionally for cough, asthma, bronchitis and tuberculosis. Its common name, 'vasa', means perfume; it is an evergreen perennial shrub that grows all over the plains of India and Sri Lanka (Pole 2006).

COMMON NAMES
Adhatoda, Malabar nut tree

OTHER NAMES
Adhatoda zeylanica, arusha, bakash, Justicia adhatoda-Folium, vasaka, vasa, adusa, Baga-bahouk

BOTANICAL NAME/FAMILY
Adhatoda vasica (family Acanthaceae)

PLANT PARTS USED
Leaves and roots

CHEMICAL COMPONENTS
The leaves contain several different alkaloids, including vasicine, vasicinone, vasicinol, adhatodine, adhatonine, adhavasinone, anisotine, peganine, 7-methoxyvaicinone, desmethoxyaniflorine, 3-hydroxyanisotine, vasnetine (Claeson et al 2000, Mhaske & Argade 2006, Kamal et al 2006), betaine, steroids and alkanes. The root also contains alkaloids (vasicinol, vasicinolone, vasicinone, adhatonine), a steroid (daucosterol), carbohydrates and alkanes (Claeson et al 2000).

MAIN ACTIONS
Indigenous usage in India and Sri Lanka was as an antispasmodic, antiseptic, insecticide and antidote to fish poisoning. Current application focuses on the herb's antispasmodic, oxytocic and cough-suppressant activities (Gurib-Fakim 2006). It is an ingredient in the Rasayana preparation called chyavanprash, which is used widely as a health-promotive and disease-preventative tonic and is believed to be hepatoprotective and immunomodulating (Govindarajan et al 2007).

As with many Ayurvedic herbs, most investigation has been undertaken in India and locating original research from these sources is difficult.

Antitussive effects
Results from animal studies show that *Adhatoda vasica* extract exerts considerable antitussive activity when administered orally and is comparable to codeine when cough is due to irritant stimuli (Dhuley 1999). The antitussive activity may be due to the action of vasicinone and vasicinol, which have activity in the cerebral medulla. In Ayurvedic medicine, adhatoda is prescribed in combination with *Curcuma longa*, *Zingiber officinale*, *Glycyrrhiza glabra*, *Terminalia chebula*, *Ocimum sanctum* and *A. vasica* to control cough and shortness of breath, especially for lung cancer patients (Nayak 2002).

> ***Clinical note***
> One of the alkaloids found in the herb (vasicine) has been chemically modified and is referred to as RLX (6,7,8,9,10,12-hexahydroazepino-[2,1-b]-quinazoline-12-one) in the medical literature (Johri & Zutshi 2000). It has been shown in animal studies to inhibit antigen-induced mast-cell degranulation and histamine release and to exert bronchodilator activity. It is the lead molecule for Bromhexin and Ambroxol (Gurib-Fakim 2006).

Anti-inflammatory
Potent anti-inflammatory activity has also been demonstrated for the alkaloid fraction deoxyvasicinone (22), the naturally occurring quinazolinone alkaloid (Mhaske & Argade 2006). This has been shown to be equivalent to the anti-inflammatory effect of hydrocortisone in one study (Chakraborty & Brantner 2001).

Bronchodilator and anti-asthmatic activity
According to a 2002 review, both vasicine and vasicinone possess in vitro and in vivo bronchodilatory activity and inhibit allergen-induced bronchial obstruction in a manner comparable to that of sodium cromoglycate (Dorsch & Wagner 1991, Jindal et al 2002).

OTHER ACTIONS

Hepatoprotective
A. vasica leaf (50–100 mg/kg) was shown to protect against induced liver damage in rats (Bhattacharyya et al 2005); 100 mg/kg of *A. vasica* was comparable to the hepatoprotective ability of silymarin at 25 mg/kg. An earlier study showed that *A. vasica* (100–200 mg/kg) protected against carbon tetrachloride-induced liver damage in rats (Pandit et al 2004). The leaf extract significantly enhanced the protective enzymes superoxide dismutase and catalase in the liver: 200 mg/kg of

A. vasica was shown to be comparable to 25 mg/kg of silymarin. Traditionally adhatoda was used to treat liver disease—the juice of fresh leaves (5–10 g) was mixed with honey and orally ingested three times daily for 2–3 weeks (Kotoky & Das 2008).

Protection against radiation damage

Adhatoda vasica (800 mg/kg) protects hematopoietic stem cells against radiation damage by inhibiting glutathione (GSH) deletion, reducing lipid peroxidation and increasing phosphatase activity in mice (Kumar et al 2005). Animals pretreated with oral doses of adhatoda showed an 81.25% survival rate at 30 days as compared to control animals, who could not survive past 25 days. In additional studies on mice, adhatoda exhibited highly significant increases in GSH content and significant decrease in lipid peroxidation (Samarth et al 2008).

Enzyme induction

In vitro tests show that *A. vasica* acts as a bifunctional inducer, since it induces both phase I and phase II enzyme systems (Singh et al 2000). The clinical significance of this finding is unclear and remains to be tested.

Abortifacient

One of the traditional uses of the herb is as an abortifacient; however, inconsistent results from in vivo studies have made it difficult to determine whether adhatoda has significant abortifacient activity. One animal study investigating oral administration of leaf extracts showed 100% abortive rates at doses equivalent to 175 mg/kg of starting dry material (Nath et al 1992). Another study found that an *A. vasica* extract had anti-implantation activity in 60–70% of test animals (Prakash et al 1985).

Antispasmodic

The essential oil from the leaves exerts antispasmodic action, as demonstrated in an animal model of guinea pig tracheal chain (Claeson et al 2000).

Antioxidant activity

In vitro tests on mice also show the extract is effective in inducing glutathione S-transferase and DT-diaphorase in lungs and forestomach, and superoxide dismutase and catalase in kidneys (Singh et al 2000).

Nematocidal/anticestodal activity

In rat studies, Naga tribes in India have traditionally used adhatoda for curing intestinal worm infestations. Animal studies indicate that crude aqueous root extracts of 3 g/kg body weight exhibit 37.4% reduction of mixed gastrointestinal nematode infestations in sheep, as a result of the alkaloid and glycoside content of adhatoda (Lateef et al 2003, Githiori et al 2006). In one animal study, adhatoda exhibited significant anticestodal efficacy, greater than that of praziquantel (Yadav et al 2008).

Other

Deoxyvasicinone (22), the naturally occurring quinazolinone alkaloid, exhibits antimicrobial and antidepressant activities (Mhaske & Argade 2006). Antimicrobial activity was specific to certain strains of penicillin- and ciprofloxacin-resistant *Neisseria gonorrhoea* (Shokeen et al 2009).

CLINICAL USE

Adhatoda has not been significantly investigated in clinical studies, so information is generally derived from in vitro and animal studies and is largely speculative.

Cough

The antitussive activity of adhatoda extract has been compared to that of codeine in two different models of coughing and in two different animal species (Dhuley 1999). When administered orally, *A. vasica* extract produced antitussive effects comparable to those of codeine against coughing induced by peripheral irritant stimuli. When coughing was induced by electrical stimulation of the tracheal mucosa, adhatoda extract was only one-quarter as active as codeine. Intravenous administration was far less effective in both cough models. A double-blind, randomised, controlled trial of *Adhatoda vasica* in combination with *Echinacea purpurea* and *Eleutherococcus senticosus* was compared with an *Echinacea* and *Eleutherococcus* mixture and bromhexine (Narimanian et al 2005). Bromhexine is a semi-synthetic derivative of the alkaloid vasicine found in *A. vasica* (Grange & Snell 1996) and is found in some pharmaceutical cough mixtures. Compared with the other two formulas, the *A. vasica* combination reduced the severity of cough, increased mucus discharge and reduced nasal congestion. Both herbal mixtures reduced the frequency of cough compared with bromhexine. Furthermore, Grange and Snell (1996) identified pH-dependent growth inhibitory effects on *Mycobacterium tuberculosis*, which further supports its usage as a mucolytic.

Asthma

Although *A. vasica* is used for asthma in combination with other herbs, clinical evidence is limited. Evidence of bronchodilator activity from in vitro and animal studies provides a theoretical basis for use in treating asthma.

One 12-week randomised, double-blind, placebo-controlled clinical trial was undertaken to assess the efficacy of an Ayurvedic herbal formula in asthmatic patients. While the formula contained 15 different herbs, almost half the total weight consisted of adhatoda. Active herbal treatment increased the efficacy of medication (salbutamol and theophylline) in bronchodilation, thus increasing forced expiratory volume in the first second (FEV_1). In addition, the herbal combination significantly improved other clinical parameters, resulting in reductions in dyspnoea, wheezing, expectoration, disability and respiratory rate when compared to a placebo (Murali et al 2006). Although these results are promising, the role of adhatoda as a stand-alone treatment remains unclear.

OTHER USES

Adhatoda is traditionally used to treat cough, asthma, bronchitis and colds, but has also been used to treat fever, dysentery, diarrhoea, jaundice,

A

PRACTICE POINTS/PATIENT COUNSELLING

- Adhatoda is an important Ayurvedic medicine used in the treatment of cough, asthma, bronchitis and colds.
- Traditional use further includes fever, dysentery, diarrhoea, jaundice, tuberculosis and headache.
- Preliminary evidence suggests that adhatoda may have bronchodilator activity and inhibit allergen-induced bronchoconstriction; however, clinical studies are unavailable to determine clinical significance.
- Antitussive effects comparable to those of codeine have also been reported in animal studies in which cough has been peripherally induced.
- Adhatoda has been used to stimulate the birthing process and aid healing afterwards, and may have abortifacient activity.
- Overall, little clinical evidence is available. Much of the available information is therefore speculative and based on in vitro and animal research and traditional use.

tuberculosis and headache, to stimulate the birthing process and aid healing afterwards, and as an antispasmodic (Claeson et al 2000). It has also been used as an abortifacient in some Indian villages.

Leaves that have been warmed on the fire are applied topically in the treatment of joint pain, lumbar pain and sprains.

Use of the powder is reported as a poultice on rheumatic joints, a counterirritant for inflammatory swelling, a treatment for fresh wounds, and in urticaria and neuralgia (Dhuley 1999).

DOSAGE RANGE

As clinical research is lacking, the following dosages come from Australian manufacturers' recommendations.

- Liquid extract tincture (1:2): 1–3 mL/day (Pole 2006).
- Liquid extract tincture (1:5): 2.5–7.5 mL/day (Pole 2006).
- Dried herb/powdered leaf: 0.5–1.5 g/day (Pole 2006).

ADVERSE REACTIONS

Insufficient reliable information is available.

SIGNIFICANT INTERACTIONS

Controlled studies are not available, so interactions are based on evidence of activity and are largely theoretical and speculative.

Codeine and other antitussive drugs

Theoretically, adhatoda may increase the antitussive effects of these drugs—beneficial interaction may be possible under professional supervision.

CONTRAINDICATIONS AND PRECAUTIONS

Insufficient reliable information is available.

PREGNANCY USE

Adhatoda is contraindicated in pregnancy, as the herb may have abortifacient activity. In Ayurvedic medicine it is considered safe post-partum (Pole 2006), and is used in combination with *Bacopa monnieri* and 12 other herbal medicines in the treatment of vaginal discharge, pregnancy pain and pregnancy fever (Jadhav & Bhutani 2005).

PATIENTS' FAQs

What will this herb do for me?

Because adhatoda has been investigated mainly in animal and test-tube studies, its effects on humans are uncertain. Based on preliminary information and historical use, it may suppress cough and have some beneficial effects in asthma.

When will it start to work?

This is uncertain because insufficient research data are available.

Are there any safety issues?

Some research suggests that adhatoda may stimulate uterine contractions, so it is not recommended in pregnancy.

Albizia

HISTORICAL NOTE It is believed that albizia received its name because Filipo del Albizi, an 18th century Florentine nobleman, introduced the species into cultivation (The Plants Database 2004). It has been used in Ayurvedic medicine for many years and is still a popular treatment for asthma, allergy and eczema.

COMMON NAME
Albizia

OTHER NAMES
Pit shirish shirisha

BOTANICAL NAME/FAMILY
Albizia lebbeck (family Fabaceae)

PLANT PARTS USED
Leaves and stem bark

CHEMICAL COMPONENTS
These are poorly understood, but albizia has been reported to contain albiziasaponins A, B and C, epicatechin, procyanidins and stigmastadienone.

MAIN ACTIONS
Albizia has not been significantly investigated in clinical studies; therefore, information is generally derived from in vitro and animal studies and is largely speculative.

Stabilising mast cells
Both in vitro and in vivo tests have reported significant mast-cell-stabilisation effects similar to those of cromoglycate (Johri et al 1985, Tripathi et al 1979). One study found that degranulation was inhibited by 62% (Tripathi et al 1979). The saponin fraction is believed to be the key group responsible for activity. A more recent in vitro study compared the effects of albizia leaf, albizia stem bark and disodium chromoglycate on mast-cell stabilisation. All three compounds were found to be equally potent (Shashidhara et al 2008).

Altering neurotransmitter activity
Albizia has an influence on GABA, serotonin and dopamine levels, according to in vivo studies (Chintawar et al 2002, Kasture et al 2000). It appears that different fractions within the herb exert slightly different effects on neurotransmitters. In one study, a saponin-containing fraction from the extract of dried leaves of albizia was shown to decrease brain concentrations of GABA and dopamine, whereas serotonin levels increased. Another study that tested the methanolic fraction of an ethanolic extract of albizia leaves found that it raised brain levels of GABA and serotonin (Kasture et al 2000). Additionally, anticonvulsant activity has been demonstrated in vivo for this fraction.

Memory enhancement
Saponins isolated from albizia have been shown to significantly improve the memory retention ability of normal and amnesic mice, compared with their respective controls (Une et al 2001).

Reduces male fertility
Three studies using animal models have demonstrated that albizia significantly reduces fertility in males (Gupta et al 2004, 2005, 2006).

Albizia saponins A, B and C (50 mg/kg) isolated from the stem bark have been shown to significantly reduce the weight of the testis, epididymides, seminal vesicle and ventral prostate of male rats (Gupta et al 2005). A significant reduction in sperm concentration was also noted and albizia reduced fertility by 100% after 60 days. A follow-up study administered oral doses of methanolic bark extract (100 mg/day) for 60 days (Gupta et al 2006). Testis, epididymides, seminal vesicle and ventral prostate weights along with sperm motility and density

were all significantly decreased compared to controls, also resulting in a 100% drop in male fertility. The methanolic extract of albizia pods (50, 100 and 200 mg/kg) was also shown to significantly decrease fertility and arrest spermatogenesis in rats after 60 days (Gupta et al 2004).

OTHER ACTIONS

Other actions seen in vitro and in vivo include antioxidant, antifungal and antibacterial actions, antispasmodic effect on smooth muscle, positive inotropy and an immunostimulant effect (Barua 2000, Bone 2001, Kasture et al 2000, Resmi et al 2006). Cholesterol-lowering activity has been demonstrated in vivo (Tripathi et al 1979).

CLINICAL USE

Albizia has not been significantly investigated under clinical trial conditions, so evidence is derived from tradition, in vitro and animal studies.

Allergy and asthma

Albizia is mainly used to treat allergic rhinitis, urticaria and asthma in clinical practice. In vitro and in vivo evidence of mast-cell stabilisation provide a theoretical basis for its use in allergic conditions; however, the clinical significance is unknown.

OTHER USES

Traditionally, a juice made from the leaves has been used internally to treat night blindness. The bark and seeds have been used to relieve diarrhoea, dysentery and treat haemorrhoids, most likely because of their astringent activity. The flowers have been used as an emollient to soothe eruptions, swellings, boils and carbuncles. In Ayurvedic medicine, it is used to treat bronchitis, asthma, allergy and inflammation.

DOSAGE RANGE

As clinical research is lacking, the following dosages come from Australian manufacturer recommendations.

- Liquid extract (1:2): 3.5–8.5 mL/day or 25–60 mL/week.
- Dried herb: 3–6 g/day.

TOXICITY

This is unknown; however, research with the methanolic fraction of albizia extract has identified a median lethal dose of 150 mg/kg (Kasture et al 2000).

ADVERSE REACTIONS

Insufficient reliable information available.

SIGNIFICANT INTERACTIONS

Controlled studies are not available; therefore, interactions are based on evidence of activity and are largely theoretical and speculative.

Barbiturates

Additive effects are theoretically possible, as potentiation of pentobarbitone-induced sleep has been observed in vivo — use with caution.

Antihistamines and mast-cell-stabilising drugs

Additive effects are theoretically possible because both in vitro and in vivo tests have identified significant mast-cell-stabilisation activity similar to that of cromoglycate — potentially beneficial interaction.

Tricyclic and selective serotonin reuptake inhibitor antidepressant drugs

Increased risk of serotonin syndrome is theoretically possible, as albizia increases serotonin levels, according to in vivo studies — observe patient.

CONTRAINDICATIONS AND PRECAUTIONS

Significant reductions in male fertility have been reported in tests using animal models; however, it is not known whether the effects also occur in humans. Until further research is conducted, caution is advised.

PREGNANCY USE

Insufficient reliable information available. Based on animal studies indicating a significant effect on male fertility, males with low sperm counts or poor sperm motility should avoid this herb if attempting to father a child.

PRACTICE POINTS/PATIENT COUNSELLING

- Albizia is a traditional Ayurvedic herb used to treat allergies, asthma, eczema and inflammation.
- Preliminary research has shown that it has significant mast-cell-stabilisation activity comparable to cromoglycate, and has also identified memory enhancement activity and possible anticonvulsant effects.
- Overall, little clinical evidence is available; therefore, much information is speculative and based on in vitro and animal research.

PATIENTS' FAQs

What will this herb do for me?

Albizia is a traditional Ayurvedic medicine used to reduce allergic conditions, such as allergic rhinitis and urticaria. It is also used for atopic conditions, such as eczema and asthma, when indicated. Controlled trials have not been conducted, so it is uncertain whether it is effective.

When will it start to work?

This is uncertain because insufficient research data are available.

Are there any safety issues?

This is uncertain because insufficient research data are available. It is advised that people with asthma be monitored by a healthcare professional. Males with low sperm counts or poor sperm motility should avoid this herb if attempting to father a child.

Aloe vera

HISTORICAL NOTE *Aloe vera* has been used since ancient times as a medicinal plant. In fact, evidence of use has been found on a Mesopotamian clay tablet dating back to 2100 BC (Atherton 1998). It has been used as a topical treatment for wounds, burns and other skin conditions and internally as a general tonic, anti-inflammatory agent, carminative, laxative, aphrodisiac and anthelmintic by the ancient Romans, Greeks, Arabs, Indians and Spaniards. According to legend, Alexander the Great captured an island in the Indian Ocean in order to access the *Aloe vera* for his wounded army. Today aloe is used to soothe skin complaints and heal burns, and is one of the most common ingredients in many cosmetic products.

OTHER NAMES
Aloes, Barbados aloe, Curacao aloe

BOTANICAL NAME/FAMILY
Aloe vera (L.)/*Aloe barbadensis* (Mill.) (family Aloeaceae)

PLANT PARTS USED
The leaf, from which several different products are made; namely the exudate, gel, extract and juice. The exudate ('aloes' in older pharmacy texts) is a thick residue, yellow in colour and bitter in taste that comes from the latex that oozes out when the leaf is cut. The 'gel' refers to the clear gel or mucilage produced by the inner parenchymal cells in the central part of the leaf. Diluted aloe gel is commonly known as 'aloe vera extract' or 'aloe juice'.

CHEMICAL COMPONENTS
Aloe vera extract, or diluted aloe gel, is made of mostly water (99%) and mono- and polysaccharides, the most important of which are the monosaccharide mannose-6-phosphate and the polysaccharide gluco-mannans, which are long-chain sugars containing glucose and mannose. Gluco-mannan has been named acemannan and is marketed as Carrisyn. A glycoprotein with anti-allergic properties has also been isolated, and has been named alprogen. Recently, C-glucosyl chromone, an anti-inflammatory compound, has also been identified.

Aloe gel also contains lignans, saponins, salicylic acid, sterols and triterpenoids, vitamins A, C, E, B_{12}, thiamine, niacin and folic acid, and the minerals sodium, calcium, potassium, manganese, magnesium, copper, chromium, zinc and iron (Shelton 1991, Yamaguchi et al 1993).

The fresh gel contains glutathione peroxidase, isozymes of superoxide dismutase, and the proteolytic enzyme carboxypeptidase (Klein & Penneys 1988, Sabeh et al 1993). Recent in vitro bioassays identified three malic acid acylated carbohydrates from the gel, veracylglucan A, B and C, and determined that veracylglucan B exhibited potent anti-inflammatory and anti-proliferative effects; veracylglucan C exhibited significant cell proliferative and anti-inflammatory activities; and the third carbohydrate veracylglucan A was highly unstable and provided no biological effects. Of interest is that veracylglucan B and C proved to be highly competitive in their effects on cell proliferation (Esua et al 2006).

Ultimately, the types and levels of components present in aloe gel vary according to geographic origin, variety and processing method.

The exudate (latex layer) contains the pharmacologically active anthraquinone glycosides: aloin, aloe-emodin, barbaloin, emodin and aloectic acid (Choi & Chung 2003, Rodriguez-Fragoso et al 2008).

MAIN ACTIONS
The active ingredients, whether acting alone or in concert, include glycoproteins, anthraquinones, polysaccharides, and low-molecular-weight species such as beta-sitosterol (Choi & Chung 2003).

Assists in wound healing
Wound healing is associated with various mechanisms and constituents. Thromboxane inhibits wound healing and aloe has been shown to inhibit thromboxane in vitro (Zachary et al 1987). Enzymes in aloe have also been shown to break down damaged tissue, which can then be removed by phagocytosis (Bunyapraphatsara et al 1996). A glycoprotein fraction was found to increase proliferation of human keratinocytes and increase the expression of receptors for epidermal growth factor

and fibronectin in vitro (Choi et al 2001). The same research team then demonstrated that this glycoprotein enhanced wound healing by increasing cell proliferation in vivo. Beta-sitosterol appears to improve wound healing by stimulating angiogenesis and neovascularisation in vivo (Moon et al 1999). Aloe polysaccharides have been shown to ameliorate UV-induced immunosuppression (Strickland et al 1994).

Tests in animal models

Several animal studies support the application of aloe gel to skin damaged by frostbite as a means to maintain circulation and reduce the vasoconstrictive effects of thromboxane in the affected dermis (Heggers et al 1987, Klein & Penneys 1988, McCauley et al 1990, Miller & Koltai 1995). In combination with pentoxifylline, it will act synergistically to further increase tissue survival (Miller & Koltai 1995).

A study to test the effectiveness of topical application versus oral administration in rats with full-thickness wounds showed topical use of aloe gel to be slightly more effective than internal use. The collagen content in granulation tissue was measured to be 89% in the topical group compared with 83% in the oral group (Chithra et al 1998). Other studies have found that aloe gel not only increases collagen content, but also changes collagen composition, in addition to increasing collagen cross-linking, which in turn increases the breaking strength of scar tissue, making the seal stronger (Chithra et al 1998, Heggers et al 1996).

Full thickness hot-plate burns (3% total surface area) in test animals healed more quickly with the application of aloe gel compared to silver sulfadiazine (SSD) or salicylic acid cream (aspirin) (Rodriguez-Bigas et al 1988). Guinea pigs treated with aloe recovered in 30 days as compared to 50 days for control animals (dressing only) and wound bacterial counts were effectively decreased. *A. vera* was also found to promote healing and decrease inflammation in second-degree burns in vivo (Somboonwong et al 2000). A significant reduction in vasodilation and post-capillary venular permeability was recorded on day 7 in the aloe group. At day 14 arteriolar diameter had returned to normal and the size of the wound was greatly reduced as compared to controls.

Aloe gel prevented delayed hypersensitivity of UV-irritated skin as well as contact hypersensitivity in animal models with allergic reactions (Strickland et al 1994). Acemannan gel (beta-(1,4)-acetylated mannan) has demonstrably improved radiation burns in mice. Best results were obtained when the gel was applied during the first week after injury (Roberts & Travis 1995).

Use with pharmaceutical agents

Several topical pharmaceutical antimicrobial agents, such as SSD, inhibit wound contraction, thereby slowing the rate of wound healing. An experimental model was used to investigate whether co-administration of aloe could reverse this effect and improve wound-healing rate (Muller et al 2003). Full-thickness excised wounds were treated with placebo (aqueous cream or saline), SSD cream 0.5%, 1% or 1% with *A. vera* three times daily for 14 days, then observed until healed. *A. vera* was found to reverse the delayed wound healing produced by SSD, resulting in the shortest wound half-life and healing time.

A. vera (100 and 300 mg/kg daily for 4 days) blocked the ability of hydrocortisone acetate to suppress wound healing by up to 100% (Davis et al 1994a). Growth factors in *A. vera* were thought to mask sterols and certain amino acids that prevent wound healing. An earlier study identified the sugar mannose-6-phosphate to be one of the chief constituents responsible for wound healing (Davis et al 1994b).

Antioxidant

Studies have found that several compounds present in aloe gel protect tissues against oxidative damage caused by free radicals ('t Hart et al 1990, Singh et al 2000, Wu et al 2006, Yagi et al 2002, Zhang et al 2006). This is achieved by direct antioxidant activity and indirect activity through stimulation of endogenous antioxidant systems. Two aloe dihydroisocoumarins have been identified and have demonstrated free radical scavenging properties (Zhang et al 2006, Zhang et al 2008).

Treatment with aloe gel extract decreased lipid peroxidation and hydroperoxides in diabetic rats to near normal levels (Rajasekaran et al 2005). The extract also significantly increased superoxide dismutase, catalase, glutathione peroxidase and glutathione-S-transferase in the liver and kidney. In another study, data obtained 3, 7 and 10 days after exposure to radiation showed that aloe gel significantly reduced oxidative damage in the liver, lungs, and kidney tissues of irradiated rats (Saada et al 2003).

Three-year-old aloe plants appear to have the highest amounts of flavonoids and polysaccharides and hence the best free radical scavenging capacity, as compared to 2- and 4-year-old plants (Hu et al 2003). Interestingly, the 3-year-old plant demonstrated antioxidant activity of 72.19%, compared to alpha-tocopherol at 65.20%.

Immunostimulant

It has been suggested that aloe may have immune-stimulating capabilities. Much of the available research has been performed on mice or in vitro and aloe shows antiviral, antitumour and non-specific immunostimulant activity. An experiment in 1980 demonstrated that mice given aloe extract 2 days before exposure to pathogens were protected against a variety of fungi and bacteria (Brossat et al 1981). Later, the isolated compound acemannan (beta-(1,4)-acetylated mannan) was shown to increase the response of lymphocytes to antigens in vitro (Womble & Helderman 1988). In mice, acemannan stimulated cytokines, bringing about an immune attack on implanted sarcoma cells, leading to necrosis and regression of cancer cells (Peng et al 1991). A later trial investigated the effects of acemannan on mouse macrophages (Zhang & Tizard 1996). Acemannan stimulated macrophage cytokine production (IL-6 and TNF-alpha), NO release, surface

Clinical note — Wound-healing models
Acute wound healing occurs in four stages that tend to overlap: haemostasis, inflammation, proliferation and remodelling. Underlying metabolic disturbances and/or disease may disrupt the regenerative process, causing delayed healing. Much investigation is conducted with in vitro assays based on cell culture models of the various phases of healing, which provides information about possible mechanisms of action. Experimental models using animals are undertaken to determine the reduction of wound size (usually in terms of area) and hence the rate of healing. Histological examination of granulation and epidermal tissues provides a concurrent analysis at the molecular level. Human models of wound healing provide an opportunity to observe a variety of healing disorders that are less predictable than their cell or animal-based counterparts. *Aloe vera* is the only traditional wound healing herbal medicine that has been subjected to a variety of cell culture-based, animal and human-based studies (Krishnan 2006).

molecule expression, and cellular morphologic changes. Similarly, a polysaccharide fraction isolated from *A. vera* promoted human keratinocytes to secrete TGF-alpha, TGF-beta-1, IL-1-beta, IL-6, IL-8 and TNF, and inhibited the release of NO as compared to control (Chen et al 2005). The immune enhancing effects of acemannan may be due in part to the compound's ability to promote differentiation of immature dendritic cells (Lee et al 2001). These cells are crucial for the initiation of primary immune responses.

Multiple studies have highlighted the diverse immunomodulatory activities of aloe polysaccharides. Recent research has identified that immunomodulatory activity varies with the size of the polysaccharide entity. It appears that aloe polysaccharides that are of smaller molecular weight (specifically between 5 and 400 kDa) have the greatest immunological effects possibly because they are better absorbed than larger MW entities (Im et al 2005).

Three purified polysaccharide fractions (PAC-I, PAC-II and PAC-III) from *A. vera* stimulated peritoneal macrophages, and splenic T and B cells, and increased the ability of these cells to secrete TNF-alpha, IL-1-beta, IFN-gamma, IL-2 and IL-6 (Leung et al 2004). The compound with the highest mannose content, and therefore the highest molecular weight (PAC-I), demonstrated the most potential. This finding was again repeated by Liu et al (2006) whereby PAC-I exhibited potent stimulation of murine macrophages and produced tumouricidal properties of activated macrophages in vitro, thus providing evidence in support of its antitumour properties.

A 99% pure carbohydrate compound (purified acemannan) isolated from aloe demonstrated potent haematopoietic and haematologic activity in myelosuppressed mice (Talmadge et al 2004).

Specific manufacturing methods can be applied to enhance the extracts. For example, 1 g of extract obtained from leaves subjected to cold and dark treatment contained 400 mg of neutral polysaccharide compared with 30 mg in leaves not specially treated (Shida et al 1985).

Anti-inflammatory

A number of in vitro and in vivo studies confirm the anti-inflammatory activity of *A. vera*.

The gel reduces oxidation of arachidonic acid, thereby reducing PG synthesis and inflammation (Davis et al 1987). It inhibits the production of PGE_2 by 30% and IL-8 by 20%, but has no effect on thromboxane B2 production in vitro (Langmead et al 2004). Following burn injury in vivo, *A. vera* was also found to inhibit inflammation by reducing leukocyte adhesion and decreasing the pro-inflammatory cytokines TNF-alpha and IL-6 (Duansak et al 2003).

One study conducted on rats with croton oil-induced oedema reported a 47% reduction in swelling after the application of topical aloe gel (Davis et al 1989). Another study found aloe gel to reduce vascularity and swelling by 50% in the inflamed synovial pouch in rats, along with a 48% reduction in the number of mast cells in the synovial fluid within the pouch. When aloe gel was applied topically there was also an increase in fibroblast cell numbers (Davis et al 1992). C-glucosyl chromone, isolated from aloe gel extracts, is chiefly responsible for the anti-inflammatory effect, with activity comparable to hydrocortisone in experimental models (Hutter et al 1996). A study of streptozotocin-induced diabetic mice further confirmed the anti-inflammatory activity of *A. vera* and identified the isolated constituent gibberellin as also effective (Davis & Maro 1989). Both compounds inhibited inflammation in a dose-dependent manner. A recent in vitro assessment using human immune cells displayed aloe's potential to reduce bacteria-induced pro-inflammatory cytokine production, specifically TNF-alpha and IL-1-beta, by peripheral blood leukocytes stimulated with *Shigella flexneri* or lipopolysaccharide (LPS) (Habeeb et al 2007a).

Laxative

The aloe latex contains anthraquinones, which have a stimulant laxative activity. Studies in rats have shown that aloe latex increases intestinal water content, stimulates mucus secretion, and induces intestinal peristalsis (Ishii et al 1994). However, aloe as a laxative is more irritating than other herbs (Reynolds & Dweck 1999) and long-term use can cause an electrolyte imbalance through depletion of potassium salts. Alternatives are recommended if long-term treatment is required.

Anti-ulcer

The anti-ulcer activity of *A. vera* has been proposed to be due to anti-inflammatory, cytoprotective, healing and mucus stimulatory effects. According to an in vivo study, *A. vera* promotes gastric ulcer healing (Eamlamnam et al 2006). In contrast to these results, in another study a stabilised fresh aloe gel preparation

prolonged the effect of histamine-stimulated acid secretion but inhibited pepsin (Suvitayavat et al 2004).

Hypoglycaemic

Glucomannan slows carbohydrate absorption and slows the postprandial insulin response by up to 50% (McCarty 2002).

A. vera leaf gel has been investigated as a possible hepatoprotective and kidney protective agent in diabetes type 2 using animal models. In one study, the leaf gel and glibenclamide both decreased degenerative kidney changes, serum urea levels and creatinine levels, but only aloe further reduced kidney lipid peroxidation (Bolkent et al 2004). Can et al (2004) tested aloe pulp, aloe gel extract and glibenclamide, finding that all treatments decreased liver tissue damage compared to control animals. Aloe gel extract also increased glutathione levels and decreased non-enzymatic glycosylation, lipid peroxidation, serum alkaline phosphatase and alanine transaminase.

Antimicrobial

A. vera is active against a wide variety of bacteria in vitro, such as *Pseudomonas aeruginosa*, *Klebsiella pneumoniae*, *Streptococcus pyogenes*, *Staphylococcus aureus* and *Escherichia coli* (Heck et al 1981, Shelton 1991). More recent research indicates antimicrobial activity against *Shigella flexneri*, methicillin-resistant *Staphylococcus aureus* (MRSA), *Enterobacter cloacae* and *Enterococcus bovis* (Habeeb et al 2007a).

Antiviral

In vitro studies suggest that *Aloe vera* has antiviral activity due to its interference with DNA synthesis (Saoo et al 1996). The polysaccharide fractions of aloe gel inhibit the binding of benzopyrene to primary rat hepatocytes and thus prevent the formation of potentially cancer-initiating benzopyrene-DNA adducts in vitro. This was later confirmed by in vivo studies (Kim & Lee 1997). Moreover, in vitro experiments have shown the anthraquinones in aloe to be virucidal against HSV 1 and 2, vaccinia virus, parainfluenza virus and vesicular stomatitis virus (Anderson 2003).

Investigation with the acemannan component has identified antiviral activity, particularly against feline AIDS, HIV type 1, influenza virus, measles virus and herpes simplex (Kahlon et al 1991a & b, Sydiskis et al 1991).

CLINICAL USE

Although *A. vera* products are used for many indications, the chief use is treating skin conditions.

Skin conditions

Aloe is used in the treatment of wounds, burns, radiation burns, ulcers, frostbite, psoriasis and genital herpes, and is the only traditional wound-healing herbal medicine which has been subjected to a variety of cell culture-based, animal and human-based studies (Krishnan 2006). The healing properties may be attributed to antimicrobial, immune-stimulating, anti-inflammatory and antithromboxane activities. Allantoin has also been shown to stimulate epithelialisation, and acemannan has been shown to stimulate macrophage production of IL-1 and TNF, which are associated with wound healing (Liptak 1997).

Most human studies have found that topical application of aloe vera gel increases wound healing rate and effectively reduces microbial counts; however, there are some negative studies, most likely related to the fact that the composition of aloe vera gel varies, even within the same species. Chemical composition depends on source, climate, region, and the processing method used (Choi & Chung 2003).

Dry-coated aloe vera gloves were tested by 30 women suffering from dry, cracked hands, with or without contact dermatitis due to occupational exposure, in an open contralateral comparison study (West & Zhu 2003). Women wore a glove on one hand for 8 hours daily for 30 days followed by a rest period for 30 days and then 10 more days of treatment. Results indicated that the aloe vera glove significantly reduced dry skin, irritation, wrinkling, dermatitis, redness and improved skin integrity. It would be interesting to see this study repeated using a standard non-aloe fortified glove on the opposing hand.

The effects of aloe gel applied to skin following dermabrasion in humans are more controversial, with some patients responding well (Fulton 1990), while others have had severe adverse reactions, including burning sensations and dermatitis (Hunter & Frumkin 1991). A standard polyethylene oxide gel dressing saturated with stabilised aloe vera gel was compared to the standard oxide dressing alone in the study by Fulton and appears to exhibit the strongest evidence overall to support the beneficial effects of *A. vera*. The addition of *A. vera* produced a significant vasoconstriction and anti-inflammatory effect 24 and 48 hours after application. By the 4th day it produced less crusting and exudate and by the 5th and 6th day re-epithelialisation was almost complete (90% for aloe compared with 50% for the standard treatment). Overall, wound healing was quicker with *A. vera* and completed by an average of 72 hours before the oxide gel-treatment. In contrast, one study found that topical aloe vera gel actually slowed healing after caesarean delivery (Schmidt & Greenspoon 1991).

Burns

A recent systematic review of the efficacy of *A. vera* for healing of burns considered four controlled clinical trials involving 371 patients. Meta-analysis concluded that topical treatment with *A. vera* decreased healing time and was specifically more effective for first- and second-degree burns rather than third-degree. It was noted that due to variations in the aloe preparations and outcome measures used in the studies, more specific conclusions cannot be drawn (Maenthalsong et al 2007).

One study involving 27 patients with a partial-thickness burn injury found that topical aloe gel significantly increased the healing rate compared with controls who used a vaseline gauze. The mean healing time for the aloe gel group was 11.89 days compared with the control group, which was 18.18

days. Additionally, the aloe treatment brought about full epithelialisation after 14 days (Visuthikosol et al 1995).

Another study involving 18 outpatients with moderate to deep second-degree burns ranging from 2 to 12% of total body surface area showed that a commercial aloe vera ointment was as effective as SSD in regard to protection against bacterial colonisation and healing time. More specifically, the mean healing time with aloe vera treatment was 13 days compared with 16.15 days for SSD (Heck et al 1981).

Results are less encouraging for sunburn protection and healing. A randomised double-blind trial in 20 healthy volunteers evaluated the effect of aloe vera cream for both prevention and treatment of sunburn (Puvabanditsin & Vongtongsri 2005). The cream (70% aloe) was applied 30 minutes before, immediately after, or both before and after UV irradiation. The cream was then continually applied daily for 3 weeks. The results showed that the aloe vera cream did not protect against sunburn and was not an effective treatment.

Frostbite

In combination with other treatments, topical *A. vera* significantly enhances healing and has a beneficial effect in frostbite. One clinical study compared the effects of topical aloe vera cream in combination with standard treatment, such as rapidly rewarming the affected areas, analgesics, antibiotics and debridement ($n = 56$) with another group of 98 patients who did not receive *A. vera* treatment. Of those receiving *A. vera* in addition to usual treatment, 67% healed without tissue loss compared with 32.7% in the control group. Additionally, 7.1% of the total group of 56 required amputation compared with 32.7% in the control group. Although encouraging, this study is difficult to interpret because the groups were not well matched and combination therapies differed (Heggers et al 1987).

Radiation-induced dermatitis

A recent review concluded that aloe gel was as effective as mild steroid creams, such as 1% hydrocortisone, in reducing the severity of radiation burn, without the side-effects associated with steroid creams (Maddocks-Jennings et al 2005). In contrast, another review concluded that aloe was ineffective for the prevention or reduction of side-effects to radiation therapy in cancer patients (Richardson et al 2005). That review analysed 1 past review, 5 published RCTs and 2 unpublished RCTs. It is important to note that various preparations such as creams, juices, gels and fresh aloe had been tested, which makes it difficult to assess the evidence.

Ulcers

A number of case reports tell of a positive effect on leg ulcers with topical use of aloe gel, including cases that did not respond to standard medical interventions (Zawahry et al 1973). Application of water-based aloe-gel saline soaks, broad-spectrum antibiotics and antifungals allowed a wound, caused by necrotising fasciitis, to heal in 45 days in a 72-year-old woman. Aloe gel and saline-soaked sponges were also used to treat two large seroma cavities caused by deep vein thrombosis in a 48-year-old man (Ardire 1997).

Although aloe gel is commonly used as a topical agent for wound healing it is also used internally. A small study of six patients with chronic leg ulcers found that ingesting 60 mL aloe juice daily and applying aloe gel directly to the ulcer and surrounding area resulted in less exudate, odour and seepage through the bandaging (Atherton 1998).

Psoriasis

A double-blind placebo-controlled study found topical aloe vera extract 0.5% in a hydrophilic cream to be beneficial in the treatment of psoriasis. Sixty patients aged 18–50 years with slight to moderate chronic psoriasis and PASI (psoriasis area and severity index) scores between 4.8 and 16.7 (mean 9.3) participated in the study, which was scheduled for 16 weeks with 12 months of follow-up. Patients were examined weekly and those showing a progressive reduction of lesions, desquamation followed by decreased erythema, infiltration and lowered PASI score were considered healed. By the end of the study, the *A. vera* extract cream had cured 83.3% of patients compared with the placebo cure rate of 6.6% ($P < 0.001$). Psoriatic plaques decreased in 82.8% of patients versus only 7.7% in the placebo group ($P < 0.001$). PASI scores decreased to a mean of 2.2 (Syed et al 1996a). In contrast, a randomised, double-blind, placebo-controlled trial found no significant benefits with a commercial aloe vera gel in 41 patients with stable plaque psoriasis (Paulsen et al 2005). Following a 2-week washout period patients applied either the aloe gel or placebo twice daily for 1 month. Redness and desquamation decreased by 72.5% in the active treatment group as compared to 82.5% in the placebo group. It should be pointed out that 82.5% is an extremely high placebo responder rate. Fifty-five per cent of patients reported local side-effects, mainly drying of the skin on test areas.

Genital herpes

Two clinical studies have investigated the effects of *Aloe vera* 0.5% topical preparations in genital herpes, producing good results.

A double-blind, placebo-controlled study has demonstrated that *A. vera* extract 0.5% in a hydrophilic cream is more efficacious than placebo in the treatment of initial episodes of genital herpes in men ($n = 60$, aged 18–40 years). Each patient was provided with a 40 g tube, containing placebo or active preparation with instructions on self-application of the trial medication to their lesions three times daily for 5 consecutive days (maximum 15 topical applications per week). The treatment was well tolerated by all patients (Syed et al 1997).

The other study involving 120 subjects used a preparation containing 0.5% of whole aloe leaf extract in a hydrophilic castor and mineral oil cream base, which was applied three times daily for 5 days per week for 2 weeks. Treatment resulted in a shorter mean duration of healing compared with

placebo. Aloe cream also increased the overall percentage of healed patients and there were no significant adverse reactions reported (Syed et al 1996b).

HIV

The acemannan component of *Aloe vera* has been used as adjunctive therapy to antiretroviral therapy in HIV infection. A preliminary clinical trial found that acemannan may enhance the activity of the anti-HIV drug AZT. A dose of 800 mg acemannan daily significantly increased circulating monocytes (macrophages) in 14 HIV patients. Aloe increased the number and activity of the monocytes (McDaniel et al 1990). Subsequently, a randomised, double-blind placebo-controlled study of 63 male subjects with advanced HIV, taking zidovudine and didanosine, investigated the effects of 400 mg of acemannan taken four times daily for 48 weeks. Results showed a decrease in CD4 cell numbers in the acemannan group compared with placebo (Montaner et al 1996).

Gastrointestinal conditions

Oral *A. vera* is a popular treatment for a variety of gastrointestinal disorders. It has been shown to improve different parameters of gastrointestinal function in normal subjects, such as colonic bacterial activity, gastrointestinal pH, stool specific gravity and gastrointestinal motility (Bland 1986). Due to its anthraquinone content, the latex is used as a stimulant laxative.

Besides this indication, there is still a need for scientific validation to establish which gastrointestinal conditions are most receptive to treatment with aloe.

Irritable bowel syndrome

A. vera may be effective for patients with diarrhoea-predominant IBS, according to a randomised, placebo-controlled study ($n = 58$) (Davis et al 2006). Both treatments were administered for 1 month with a follow-up period of 3 months. Within the first month, 35% of the patients receiving *A. vera* responded compared to 22% receiving placebo. Overall, diarrhoea-predominant IBS patients had a more statistically significant responder rate than placebo (43% vs 22%).

Ulcerative colitis

A double-blind, randomised, placebo-controlled trial evaluated the efficacy and safety of *A. vera* gel (100 mL twice daily for 4 weeks) in ulcerative colitis (Davis et al 2006). Aloe induced clinical remission in 30% of subjects compared to 7% for placebo and symptom improvement in 37% compared to 7% for placebo. The Simple Clinical Colitis Activity Index and histological scores also decreased significantly for patients on the aloe treatment, but not for those receiving placebo.

OTHER USES

Asthma

According to a small open study ($n = 33$), long-term oral administration of aloe may have benefits for some people with chronic asthma, as one-third of subjects reported improvement (Afzal et al 1991, Shida et al 1985).

Diabetes

Glycaemic control

Three systemic reviews of herbal medicines for glycaemic control in diabetes found that *A. vera* can lower blood glucose levels in diabetic patients (Grover et al 2002, Vogler & Ernst 1999, Yeh et al 2003). In one trial aloe juice consisting of 80% gel or placebo was given in a trial of 40 patients who were recently diagnosed with type 1 diabetes at the dose of 1 tablespoon twice daily. From day 14 the blood sugar levels in the aloe group began to fall significantly compared with the control group and continued to steadily drop during the study period ($P < 0.01$). Blood triglyceride levels were also substantially reduced but cholesterol levels remained the same (Yongchaiyudha et al 1996). A single-blind, placebo-controlled trial found that glibenclamide when combined with oral aloe gel was more effective in reducing blood sugar levels than glibenclamide alone in 72 patients with type 2 diabetes. Patients took 5 mg of glibenclamide twice daily and 1 tablespoon aloe gel. Fasting blood glucose levels dropped appreciably after just 2 weeks of treatment, and were still falling after 42 days (Bunyapraphatsara et al 1996).

Cancer

There are some epidemiological studies suggesting that aloe may reduce the risk of certain cancers; however, further research is required to clarify its place in practice (Sakai et al 1989, Siegers et al 1993).

Recent pre-clinical research has identified that aloe-emodin (an anthraquinone compound) present in the leaves of *A. vera* shows promising anticancer effects in human gastric carcinoma cell lines AGS and NCI-N87. A.-emodin induced cell death in a dose-dependent and time-dependent manner and caused the release of apoptosis-inducing factor and cytochrome c from mitochondria followed by the activation of caspase-3 leading to nuclear shrinkage and apoptosis (AGS was more sensitive that NCI-N87 cells). In addition, casein kinase II activity was suppressed (time-dependent) and was accompanied by a reduced phosphorylation of Bid, a downstream substrate of casein kinase II and a pro-apoptotic molecule (Chen et al 2007).

Another study investigated the anticancer effect of aloe-emodin in T24 human bladder cancer cells and found that it induced apoptosis in T24 cells mediated through the activation of p53, p21, Fas/APO-1, Bax and caspase-3 (Lin et al 2006).

Chemotherapy-induced oral and gastrointestinal mucositis

Aloe gel may ameliorate chemotherapy-induced oral and gastrointestinal mucositis (Stargrove et al 2008), however, the evidence base is conflicting and further research is required.

DOSAGE RANGE

- Aloe vera gel: fresh from a living plant or as stabilised juice 25 mL (4.5:1) up to four times daily.
- Extracts standardised to acemannan: preparation containing up to 800 mg/day.
- Topical application: gel, cream or ointment as needed.
- 1.5–4.5 mL daily of 1:10 tincture of resin (latex).

ADVERSE REACTIONS

Although adverse reactions are rare, hypersensitivities and contact dermatitis to aloe have been reported (Morrow et al 1980, Nakamura & Kotajima 1984). Hypersensitivity manifested by generalised nummular eczematous and papular dermatitis, and presumably by contact urticaria, developed in a 47-year-old man after 4 years of using oral and topical aloe. Patch tests for aloe were positive in this patient (Morrow et al 1980).

SIGNIFICANT INTERACTIONS

Hypoglycaemic agents

Oral *A. vera* may have hypoglycaemic activity, therefore additive effects are theoretically possible—observe patients taking this combination.

Laxatives

Additive effects are theoretically possible with oral aloe latex inducing griping pains. Use with caution.

Topical cortisone preparations

In addition to its own anti-inflammatory effects, animal studies have shown that *A. vera* increases the absorption of hydrocortisone by hydrating the stratum corneum, inhibits hydrocortisone's suppressive effects on wound healing and increases wound tensile strength — possible beneficial interaction.

Vitamins C and E

Concurrent prescription of oral *A. vera* (both gel and latex) with vitamins C and E shows improved absorption and increased plasma life of vitamin concentration for both vitamins when taken together (Vinson et al 2005).

CONTRAINDICATIONS AND PRECAUTIONS

Strong laxatives such as aloe latex are contraindicated in children. Avoid in patients with known hypersensitivity to aloe or with nausea, vomiting or signs and symptoms of gastrointestinal obstruction. Avoid excessive use and long-term use (more than 2 weeks), as potassium losses may occur, which may alter cardiac electrophysiology.

Use with caution in people with thyrotoxicosis.

A case study of depression of thyroid hormones in a woman taking *A. vera* juice has been reported (Pigatto & Guzzi 2005). The patient consumed 10 mL daily for 11 months and laboratory testing showed reduced levels of thyroxine and triiodothyronine. Levels returned to normal progressively after discontinuing the aloe juice and the patient achieved full clinical remission after 16 months. Reduced serum levels of the thyroid hormones T_3 and T_4 have been reported for *A. vera* in vivo (Kar et al 2002).

PRACTICE POINTS/PATIENT COUNSELLING

- Different parts of the *Aloe vera* plant are used therapeutically. The gel is used topically and the latex is used internally.
- The gel may be beneficial in the treatment of skin conditions (wounds, burns, radiation burns, ulcers, frostbite, psoriasis and genital herpes). There is good scientific evidence for these indications.
- Traditionally, aloe latex is also used internally for gastrointestinal ulcers, dyspepsia and what is known today as IBS. Aloe is also used in conditions such as food allergies and disturbed bowel flora.
- Aloe may be a useful adjunct in the treatment of chronic poor immunity, HIV, cancer and chronic fatigue. There is preliminary scientific support for these indications.

Caution is suggested with topical applications that contain *A. vera* as they may enhance sensitivity to ultraviolet light (Xia et al 2007).

PREGNANCY USE

Strong laxatives such as aloe latex are traditionally contraindicated in pregnancy. Scientific evidence is unavailable to conclusively support the safe use of orally administered aloe.

PATIENTS' FAQs

What will this herb do for me?

Aloe gel is traditionally used for burns, wounds and inflammatory skin disorders. There is good scientific evidence that aloe may be of benefit in these conditions; however, the chemical composition of *A. vera* products will vary depending on geographical and processing factors. Traditionally, aloe is also used internally for dyspepsia, gastrointestinal ulcers and IBS.

When will it start to work?

Aloe has an immediate effect on burns and inflammatory skin diseases. Improvement occurs within several weeks with the condition continuing to improve with use. Chronic conditions may require long-term use. Internal use of *A. vera* as a laxative can produce results within 12–24 hours.

Are there any safety issues?

Aloe gel is safe and non-toxic when used topically. Avoid chronic use of laxative preparations that contain highly irritant compounds, known as anthraquinone glycosides, in the latex.

Andrographis

HISTORICAL NOTE Andrographis has long been used in traditional medicine systems in numerous countries. It has been included in the pharmacopoeias of India, Korea and China, possibly because it grows abundantly in India, Pakistan and various parts of Southeast Asia. In TCM, andrographis is considered a 'cold' herb and is used to rid the body of heat, as in fevers and acute infections, and to dispel toxins from the body. In Ayurvedic medicine it is used as a bitter tonic, to stimulate digestion and as a treatment for a wide range of conditions such as diabetes and hepatitis. It is still a common household remedy and found in more than half the combination tonics used to treat liver conditions in India. Also used to treat the common cold, it is sometimes called Indian echinacea.

COMMON NAMES
Andrographis, chirayata, chiretta, green chiretta, Indian echinacea, kalmegh, king of bitters. *Andrographis paniculata* is often studied as the herbal combination known as Kan Jang.

BOTANICAL NAME/FAMILY
Andrographis paniculata (family Acanthaceae)

PLANT PARTS USED
Leaves, aerial parts

CHEMICAL COMPONENTS
The main active constituent group is considered to be the bitter diterpenoid lactones known as andrographolides. This group consists of andrographolide (AP1), 14-deoxy-11,12-didehydroandrographolide (AP3) and neoandrographolide (AP4). Other constituents include diterpenoid glucosides, diterpene dimers, flavonoids (Koteswara et al 2004, Rao et al 2003) and xanthones (Dua et al 2004).

Clinical studies show that andrographis is well absorbed, with peak plasma concentrations reached after 1.5–2 hours and a half-life of 6.6 hours (Panossian et al 2000).

MAIN ACTIONS
The mechanism of action of andrographis has not been significantly investigated in clinical studies, so results from in vitro and animal tests provide most of the evidence for this herbal medicine.

Immunomodulating
According to in vivo research, andrographis stimulates both antigen-specific and non-specific immune responses (Puri et al 1993). One of the main constituents responsible for the immunostimulant activity is andrographolide, which has an effect on the stimulation and proliferation of immunocompetent cells and the production of key cytokines and immune markers in vitro (Panossian et al 2002). Although important, other pharmacologically active constituents are also present, as demonstrated by a study that found that the immunostimulant activity of the whole extract is greater than that of the isolated andrographolide constituent alone. Investigation with a combination of the whole extract and *Eleutherococcus senticosus* in the formula Kan Jang demonstrated a more profound effect.

Andrographolide was found to decrease IFN-gamma and IL-2 production and was therefore shown to have an immunosuppressive effect. Burgos et al (2005) concluded that andrographis may be useful for autoimmune disease, especially where high levels of IFN-gamma are present, for example in multiple sclerosis and RA. In vitro and in vivo data has recently shown that andrographolide has the ability to interfere with T-cell proliferation, cytokine release and maturation of dendritic cells, as well as to drastically decrease the antibody response in delayed-type hypersensitivity (Iruretagoyena et al 2005). Additionally, andrographolide demonstrated a capacity to inhibit T-cell and antibody responses in experimental autoimmune encephalomyelitis in mice, and to protect against myelin sheath damage.

Anticancer
In vitro experiments have demonstrated the possible benefits of andrographolide on various cancer cells. The compound has been shown to increase apoptosis of prostate cancer cells and human leukaemic cells and to increase cell-cycle arrest (Cheung et al 2005, Geethangili et al 2008, Kim et al 2005, Zhao et al 2008, Zhou et al 2006). It also inhibits the proliferation of human cancer cells and increases IL-2 induction in human peripheral blood lymphocytes in vitro (Kumar et al 2004, Rajagopal et al 2003). In vivo results show that andrographolide increases IL-2, interferon-gamma and T-cell activity (Sheeja et al 2007). In certain circumstances, andrographolide has been found to decrease IFN-gamma and IL-2 and may have an immunosuppressive effect (*see Immunomodulating* above).

Andrographis and andrographolide may also inhibit angiogenesis and cancer cell adhesion (Sheeja et al 2007, Jiang et al 2007).

Antimicrobial
Aqueous extract of *A. paniculata* has demonstrated significant antibacterial and antifungal activity in vitro when compared with standard antibiotics (Singha et al 2003). The andrographolides from andrographis have displayed antiviral activity against herpes simplex virus type 1 in vitro (Wiart et al 2005).

Antimalarial
In vitro and in vivo studies have identified considerable antimalarial effects (Najib et al 1999, Siti Najila et al 2002). Administration of andrographis immediately after infection and for an additional 4 days extended the life span of mice infected with *Plasmodium berghei* strain ANKA (Rahman et al 1999). Four xanthones recently isolated from *A. paniculata* have demonstrated antimalarial activity against *Plasmodium berghei* in vivo (Dua et al 2004). Treatment with 30 mg/kg for 4 days produced a 62% decrease in parasites in infected mice.

Cardiovascular effects
Several in vivo studies have suggested a potential role for andrographis in cardiovascular disease.

- **Prevention of atherosclerotic arterial stenosis and restenosis after angioplasty.** According to two animal studies, andrographis significantly improved atherosclerotic iliac artery stenosis induced by both de-endothelialisation and a high-cholesterol diet, and reduced the re-stenosis rate after experimental angioplasty (Wang & Zhao 1993, 1994).
- **Prevention of myocardial reperfusion injury and postoperative malignant arrhythmias.** Using an animal model, pretreatment with intravenous andrographis significantly protected the myocardium from ischaemic reperfusion injury and eliminated malignant arrhythmia development after reperfusion, compared with controls (Guo et al 1996). As a result of treatment, infarct size was also smaller and myocardial damage was lessened.
- **Hypertension.** Andrographis produced significant dose-dependent falls in mean arterial blood

pressure and heart rate when administered as an intraperitoneal infusion in one animal study (Zhang et al 1998). This study suggests a mechanism of action involving adrenoceptors, autonomic ganglia receptors and a reduction in circulating ACE. One constituent that appears to be primarily responsible for the herb's hypotensive effects is 14-deoxy-11,12-didehydroandrographolide (AP3) which induces relaxation of vascular smooth muscle and decreases heart rate (Yoopan et al 2007).

Hypoglycaemic

Andrographis has a strong dose-dependent action on insulin production in vitro (Wibudi et al 2008). Another in vitro study indicates that inhibition of alpha-glucosidase may contribute to the hypoglycaemic effects (Subramanian et al 2008). A recent in vivo study in alloxan-induced diabetic rats demonstrated significantly reduced blood glucose levels as compared to placebo (Reyes et al 2006). The authors commented that andrographis may restore impaired oestrous cycle in this model. A previous animal trial concluded that andrographolide (1.5 mg/kg) lowers plasma glucose by enhancing glucose utilisation in diabetic rats (Yu et al 2003). Andrographis may also alter glucose absorption from the gut (Borhanuddin et al 1994). Other in vitro data suggest that andrographolide may also lower plasma glucose by increasing glucose uptake in cultured myoblast cells via the phospholipase C/protein kinase C pathway (Hsu et al 2004).

Hepatoprotective

The hepatoprotective activity of andrographis has been investigated using several different experimental rat models, in which galactosamine, paracetamol and carbon tetrachloride were given to rats to test toxicity (Handa & Sharma 1990a & b, Rana & Avadhoot 1991). In all models, treatment led to complete normalisation of toxin-induced increases in the levels of key biochemical parameters, and significantly reduced toxin-induced histopathological changes to the liver. Andrographolide is one of the key active constituents responsible for this activity (Handa & Sharma 1990b, Rana & Avadhoot 1991). Results from animal studies suggest that the hepatoprotective effect of andrographolide is at least comparable and possibly more potent than that of silymarin, from the herb St Mary's thistle (Rana & Avadhoot 1991, Singha et al 2007, Visen et al 1993).

Analogous to silymarin, the activity is a result of several similar mechanisms working together. Andrographis increases liver superoxide dismutase, glutathione peroxidase, glutathione reductase and catalase concentrations, thereby increasing endogenous antioxidant production by the liver (Trivedi & Rawal 2001, Trivedi et al 2007, Tripathi & Kamat 2007). A hepatocyte cell-membrane-stabilising activity has also been observed (Puri et al 1993, Upadhyay et al 2001).

Digestive stimulant/choleretic

Andrographolide produces a significant dose-dependent increase in bile flow and in bile salt and acid production (Shukla et al 1992).

Antipyretic and anti-inflammatory

Testing in different animal models has identified antipyretic activity (Mandal et al 2001). Clinical testing in randomised double-blind trials involving volunteers with the common cold suggests that this activity is clinically relevant. The mechanism of action is unlike that of NSAIDs, as andrographis does not influence the biosynthesis of any lipoxygenase pathways, but may involve promoting ACTH production and enhancing adrenocortical function (Amroyan et al 1999).

A. paniculata extract completely inhibited inflammation in a carageenan model in vivo (Sheeja et al 2006). In vitro data from the same study showed that andrographis inhibited superoxide (32%), hydroxyl radicals (80%), lipid peroxidation (80%) and nitric oxide (42.8%). These antioxidant mechanisms are likely to contribute to the herb's anti-inflammatory effect.

Antiplatelet and antithrombotic activity

Several compounds found in andrographis inhibit platelet-activating-factor-(PAF)-induced human blood platelet aggregation. These have been identified as andrographolide and AP3; more recently four flavonoids have been isolated that inhibit thrombin and PAF-induced platelet aggregation (Amroyan et al 1999, Wu et al 2008, Thisoda et al 2006). Andrographolide and AP3 inhibit the extracellular signal-regulated kinase 1/2 pathway in vitro. Results from in vivo studies suggest that andrographis prevents the formation of thrombi and reduces the size of myocardial ischaemia by promoting synthesis of prostaglandin I_2, inhibiting production of thromboxane A2, stimulating synthesis of cyclic AMP in platelets, and inhibiting platelet aggregation (Zhao & Fang 1990, 1991). Clinical research in humans has confirmed the observed antiplatelet effect (Zhang et al 1994).

CLINICAL USE

Upper respiratory tract infections (URTI) and the common cold

Although sometimes investigated as a sole treatment, andrographis is also tested as part of a herbal combination known as Kan Jang. This is a standardised formula of *A. paniculata* extract 85 mg, containing 5.25 mg andrographolide and deoxyandrographolide per tablet, and *Eleutherococcus senticosus* extract 9.7 mg, containing total eleutheroside B and eleutheroside E 2% (Melchior et al 2000). Although more representative of real-life practice, results obtained with Kan Jang make it difficult to assess the individual role of andrographis.

Common cold — symptom relief and reduced incidence

In 2004, two different systematic reviews that investigated whether andrographis is a suitable treatment in acute respiratory infections were published (Coon & Ernst 2004, Poolsup et al 2004). The one conducted by Coon and Ernst from the Peninsula Medical School, Universities of Exeter and Plymouth, Exeter, UK, was a review of seven double-blind,

controlled trials (n = 896), from which the authors concluded that *A. paniculata* is more effective than placebo in treating uncomplicated URTI and is associated with relatively few adverse events. They also concluded that preliminary data suggested a protective effect. In five of the seven trials, the daily dose was equivalent to 60 mg of andrographolide, which was administered for 3–8 days.

The second systematic review conducted by Poolsup et al from the Department of Pharmacy, Faculty of Pharmacy, Silpakorn University, Nakhon-Pathom, Thailand, was a review of four randomised controlled trials (n = 433); they came to a similar conclusion, finding that *A. paniculata*, either by itself or in combination with *Eleutherococcus senticosus* (Kan Jang), is effective for uncomplicated acute URTI.

In 2006 another systematic review was released by the Natural Standard Research collaboration (Kligler et al 2006). This review evaluated seven clinical trials (n = 879) that were deemed to be of acceptable quality. Once again, clinical trial evidence was found to be positive but researchers commented that most of the studies have been done in conjunction with a major manufacturer of the product and further independent testing was required.

Symptoms responding

Double-blind studies show that numerous symptoms respond to treatment with andrographis. According to two trials that used a dose of 340 mg andrographis taken three times daily, total symptom scores improved, with throat signs and symptoms responding most strongly (Melchior et al 2000). A third study observed a decrease in rhinitis, sinus pain and headache compared with a placebo (Hancke et al 1995). A fourth study using a treatment dose of 1200 mg andrographis daily found a significant reduction in tiredness and sleepiness, as well as in sore throat and nasal secretions, by day 4 (Caceres et al 1999).

A double-blind placebo-controlled study (n = 185) that tested Kan Jang in the treatment of acute URTI and sinusitis showed it effectively reduced headache, nasal and throat symptoms and general malaise, but had no significant effects on cough and ocular symptoms. Additionally, fever was moderately reduced with active treatment (Gabrielian et al 2002).

Comparisons with echinacea

Although no direct head-to-head study could be located, one study was found that compared the effects of Kan Jang to a product known as Immunal (containing *Echinacea purpurea* [L.] extract) when both were used as adjuncts to standard treatment in children with the common cold. One hundred and thirty children were divided into three groups and received either of the combination treatments or solely standard treatment over a 10-day period (Spasov et al 2004). The addition of Kan Jang was shown to be significantly more effective than Immunal when started at an early stage and produced better symptomatic relief. The amounts of nasal secretion and congestion were particularly improved. With regard to altering recovery time, Kan Jang was also superior to Immunal, and children who received Kan Jang required less standard medication than in the other two groups. Additionally, Kan Jang treatment was well tolerated and no side effects or adverse reactions were reported.

Mediterranean fever

A combination of andrographolide and *Eleutherococcus senticosus*, *Schisandra chinensis* and *Glycyrriza glabra* inhibited neutrophil adhesion and transmigration (Shen et al 2002) and stabilised NO and IL-6 in functional Mediterranean fever according to a randomised, double-blind trial (Panossian et al 2003). The study involved 14 people (aged 3–15 years) with the fever and found that the herbal combination significantly reduced the frequency, severity and duration of attacks (Amaryan et al 2003). The daily dose of andrographolide was 48 mg, divided into 3 doses for 1 month.

Cancer (in combination)

Twenty patients with various end-stage cancers were given 500 mg twice daily for 6 months. After 6 months, 16 patients were still alive with a statistically significant increase in both NK function and TNF-alpha levels. Haemoglobin, haematocrit and glutathione levels were all greatly increased (See et al 2002). Although these results are interesting, it is difficult to examine the direct effect of *A. paniculata*, as many other nutritional supplements were given concurrently.

Pharyngotonsillitis

One randomised double-blind study involving 152 volunteers compared the effects of paracetamol with two different doses of andrographis (3 g and 6 g) taken daily for 7 days (Thamlikitkul et al 1991). By day 3 the symptom-relieving effects of both paracetamol treatment and high-dose *A. paniculata* were significant, and by day 7 andrographis was as effective as paracetamol.

Spermatogenesis

A phase 1 clinical study investigated the effects of Kan Jang (combination of andrographis and *Eleutherococcus senticosus*) on spermatogenesis and fertility in 14 healthy men aged between 18 and 35 years to ensure there were no ill effects (Mkrtchyan et al 2005). The men were randomised into one of five groups to receive either Kan Jang equivalent to 60 mg andrographolide, Kan Jang equivalent to 120 mg andrographolide, Kan Jang equivalent to 180 mg andrographolide, ginseng mixture or valerian extract. They found that Kan Jang was safe if taken at the highest dose, which was three times the therapeutic dose. The researchers discovered that the mixture in fact improved semen quality by increasing the number of healthy, active sperm in the ejaculate.

OTHER USES

Traditional uses

The herb is traditionally given as a restorative and tonic in convalescence and used as a choleretic to stimulate bile production and flow, which improves appetite and digestion. It is often used in combination with aromatic herbs, such as peppermint, for

stronger digestive effects and to prevent gastrointestinal discomfort at higher doses.

Snake bite
Prolonged survival has been reported with intraperitoneal administration of andrographis before administration of cobra venom (Martz 1992).

HIV infection
A phase 1 clinical trial involving non-medicated HIV-positive patients and healthy controls found that oral andrographolides taken for 6 weeks at increasing doses produced no significant benefits and a high incidence of adverse effects, causing the trial to be stopped prematurely (Calabrese et al 2000).

DOSAGE RANGE

URTI
Prevention dose
1200–3000 mg andrographis (standardised to contain no less than 11.2 mg andrographolides) or 4–6 mL of 1:2 liquid extract, daily in divided doses, taken for at least 3 months for preventive effects to become established.

Treatment dose for infection
1200–6000 mg/day or fluid extract (1:2): up to 12 mL/day or equivalent in solid dose form.

Dyspepsia
Andrographis can be taken as a tea before meals: 5 g of herb in 1 cup of hot water, which should be allowed to stand for 10 minutes before drinking.

Toxicity
Animal tests suggest low toxicity (Mills & Bone 2000).

ADVERSE REACTIONS
Generally well tolerated, but high doses may cause vomiting, anorexia and gastrointestinal discomfort. One source states that urticaria is also possible (Ernst 2001).

SIGNIFICANT INTERACTIONS
Controlled studies are not available; therefore, interactions are theoretical and based on evidence of pharmacological activity with uncertain clinical significance.

Anticoagulants
Increased risk of bruising and bleeding is theoretically possible, because andrographolide and other constituents in andrographis inhibit PAF-induced platelet aggregation. However andrographis used together with warfarin did not produce any significant effects on the pharmacokinetics of warfarin, and had even less effect on its pharmacodynamics in vivo (Hovhannisyan et al 2006). Caution should still be exercised until further research is available.

Antiplatelet drugs
Additive effects are possible, because the herb exhibits antiplatelet activity — observe the patient.

Barbiturates
Additive effects are possible, according to an animal study (Mandal et al 2001) — observe the patient. Beneficial interaction is theoretically possible under professional supervision.

Hepatotoxic drugs (paracetamol, tricyclic antidepressants)
Hepatoprotection is possible, according to studies in various experimental models — interaction is beneficial.

Hypoglycaemic agents
Additive effects are theoretically possible — andrographis has hypoglycaemic activity comparable to that of metformin in vivo. Use together with caution; however, interaction may be beneficial.

Drugs metabolised chiefly via the cytochrome p450 system
It is currently unclear whether there is a significant interaction between andrographis and these medications, as in vivo evidence is suggestive of enzyme induction, but this observation has not yet been investigated in clinical studies (Singh et al 2001). Recently andrographolide was shown to strongly induce the CYP 1A1 induction pathway; however, the clinical significance of this is unknown (Jaruchotikamol et al 2007). Another in vitro study has demonstrated an inhibitive effect of andrographis extract and andrographolide on CYP3A and 2C9 pathways (Pekthong et al 2008). It is recommended that patients be observed to ensure that drug effectiveness is not compromised.

Immunosuppressants
Reduced drug activity is theoretically possible, as immunostimulant activity has been demonstrated in vivo (Puri et al 1993) — use caution in the immunosuppressed.

CONTRAINDICATIONS AND PRECAUTIONS
Suspend use of concentrated extracts 1 week before major surgery.

PREGNANCY USE
Not recommended for use in pregnancy. There is conflicting evidence about the safety of andrographis in pregnancy.

PATIENTS' FAQs
What will this herb do for me?
Andrographis has been traditionally used to improve digestion, as a liver tonic and to fight off infection. Clinical studies confirm that it is an effective symptom reliever for the common cold, uncomplicated URTIs and pharyngotonsillitis. It has also been used to reduce the risk of developing the common cold in winter.
When will it start to work?
During an acute infection, effects may be seen within 3–4 days of starting the correct dose. Used in lower doses for prevention, effects are seen after 3 months' continual use.

Are there any safety issues?

Andrographis is not recommended in pregnancy and may interact with a range of pharmaceutical drugs, so advice from a health professional is required.

PRACTICE POINTS/PATIENT COUNSELLING

- Several clinical studies suggest that andrographis, both as a stand-alone treatment and in combination with Siberian ginseng, is a useful treatment in cases of common cold, pharyngotonsillitis and uncomplicated URTIs, with significant symptom relief experienced after 3 days' use.
- Clinical studies are lacking, but animal experiments suggest that andrographis may be useful in cases of hepatotoxicity (paracetamol), to reduce myocardial reperfusion injury, improve blood glucose management in diabetes, and in hypertension.
- Traditionally, the herb is used to increase bile production and relieve symptoms of dyspepsia and flatulence, loss of appetite and general debility.
- Because of the extreme bitterness of the herb, solid-dose forms may be better tolerated than liquid preparations.
- Andrographis is not recommended for use in pregnancy.
- There are several theoretical drug interactions with this herb — check interaction data for more details.

L-Arginine

BACKGROUND AND RELEVANT PHARMACOKINETICS

L-Arginine is a basic, semi-essential amino acid that was discovered in 1886 in lupin seedlings and then in 1895 in mammalian protein (Boger & Bode-Boger 2001). For humans L-arginine is considered to be a semi-essential amino acid or a conditionally essential amino acid, as requirements may increase during metabolic stress or when there is insufficient endogenous L-arginine for optimal growth or tissue repair; for birds and carnivores it is an essential amino acid. It is also the most abundant nitrogen carrier in animals and humans.

Ingested arginine is rapidly cleared from the plasma, and arginine metabolism occurs via a number of pathways although not all pathways are well defined. Arginine is involved in two major metabolic pathways: the nitric oxide synthase (NOS) pathway and the arginase pathway.

In the nitric oxide synthase (NOS) pathway, L-arginine is converted to nitric oxide (NO) and L-citrulline. Three isoforms of NOS (neuronal, inducible and endothelial) have been discovered, each with a different function. Nitric oxide (NO) is a free radical that has vasodilatory and angiogenic characteristics. It regulates nutrient metabolism, plays a role in the circulatory and respiratory systems, especially endothelial function, and exerts numerous other effects in the body.

In the arginase pathway, conversion of L-arginine into L-ornithine and urea is catalysed by the activity of arginase, with the subsequent production of polyamines such as putrescine, spermidine and spermine. Polyamines are essential for cell proliferation and differentiation, tissue growth, and development, and are involved in neurogenesis (Yi et al 2009).

L-Arginine is an essential component in the urea cycle, which is the only pathway in mammals that allows elimination of continuously generated toxic ammonia. Arginine can be synthesised endogenously, mostly in the kidneys and to some degree in liver from the amino acids aspartate and citrulline by arginine synthase.

Arginine is incorporated in the synthesis of proteins, and L-arginine is also required for the production of creatine, which in its phosphorylated form plays an essential role in the energy metabolism of muscle, nerve and testis. Creatine degrades into creatinine, which is removed from the body by the kidneys. Homeostasis of plasma L-arginine is regulated by dietary arginine intake, arginine synthesis, and metabolism and protein turnover.

Ingested arginine is rapidly absorbed and metabolised in the gastrointestinal tract. There is little urinary arginine excretion because it is mostly reabsorbed.

CHEMICAL COMPONENTS

2-amino-5-guanidino-pentanoic acid

FOOD SOURCES

Free arginine is found in dietary protein, commonly in meat, fish, poultry, milk and dairy products, and nuts and seeds (King et al 2008). Other dietary sources include barley, brown rice, buckwheat, chocolate, corn, oats, raisins, and soy. It has been estimated that each gram of dietary protein provides 54 mg of L-arginine, and that 3–6 g of L-arginine is absorbed each day in adults who ingest a normal Western diet (Boger & Bode-Boger 2001, Visek 1986). Dietary lysine competes with arginine for uptake, so low lysine diets are recommended for enhanced arginine absorption (Stargrove et al 2008).

DEFICIENCY SIGNS AND SYMPTOMS

A deficiency of arginine may affect growth and development, insulin production, lipid and protein metabolism, or glucose tolerance. Arginine deficiency may be associated with poor wound healing, hair loss or breakage, liver disease, constipation or skin rash.

MAIN ACTIONS

Arginine is involved in numerous important and diverse biochemical pathways. L-Arginine and its metabolites produce a myriad of effects in the body including pH regulation, depolarisation of endothelial cell membranes, macronutrient metabolism, cell-mediated immunity and antitumour activity, and it is an essential intermediate in the urea cycle (Wahlqvist 2002). L-Arginine also influences the release of such hormones as corticotrophin-releasing factor, insulin, glucagon, prolactin, aldosterone and somatostatin.

Growth hormone and immune function

Arginine triggers the release of growth hormone, which then increases the cytotoxic activity of macrophages, natural killer cells, cytotoxic T cells and neutrophils (Wahlqvist 2002).

Nitric oxide (NO) production

Although the arginine–NO pathway represents only a fraction of the total arginine metabolism, it has attracted considerable interest because of the many roles that NO plays in almost all organ systems. Nitric oxide is a free radical molecule that is synthesised in all mammalian cells from L-arginine by NO synthase (NOS) (Tapiero et al 2002). NO is recognised as an ubiquitous mediator, produced by many cell types, that has diverse and complex actions in multiple organ systems (Rawlingson 2003).

As a precursor of NO, L-arginine influences functions as varied as neurotransmission, vasodilation, inflammation, host defence, cytotoxicity, airway and vascular smooth muscle relaxation, mucociliary clearance and airway mucus secretion, and regulation of gene expression (Chionglo Sy et al 2006).

Cardiovascular disease

Arginine seems to exert its effects in the cardiovascular system mostly through the formation of NO, although it has NO-independent haemodynamic effects as well.

Through NO-dependent actions, arginine can increase smooth-muscle cell relaxation and endothelial cell proliferation, as well as promote angiogenesis and decrease platelet aggregation, leukocyte adhesion, superoxide production, endothelin-1 release and smooth-muscle proliferation (Chionglo Sy et al 2006). NO has also been known as endothelium-derived relaxing factor (EDRF), which is responsible for maintaining vasomotor tone and systemic blood pressure. It also controls intravascular volume by enhancing renin secretion and natriuresis (Rawlingson 2003).

NO-independent actions include: increased plasmin generation or fibrinolysis; augmented release of insulin, growth hormone and glucagon; decreased blood viscosity and formation of fibrin; and decreased angiotensin-converting enzyme activity (Chionglo Sy et al 2006).

CLINICAL USE

Arginine can have one of two forms, the L-form and the D-form, as do most other amino acids. The majority of research literature focuses on oral L-arginine because it has a longer half-life and better long-term effects than systemic forms and would be the preferred route (Blum et al 1999). The role of arginine in NO production has formed the basis of its application in various disease states such as cardiovascular disease, sexual dysfunction, peripheral arterial disease, asthma and interstitial cystitis.

Cardiovascular disease

In the management of cardiovascular disease, arginine supplementation is noted to improve endothelial function, particularly in hypercholesterolaemia and atherosclerosis (Boger & Bode-Boger 2001). Under- or over-production of NO is considered to be a contributing factor to cardiovascular disease, or it may be a consequence of disease, leading to active investigations into the potential for the L-arginine–NO system as a therapeutic target for a variety of conditions such as hypertension, atherosclerosis and ischaemic stroke (Rawlingson 2003).

Numerous animal studies have investigated the effects of L-arginine supplementation on measures of atherosclerotic lesion formation and on several markers of endothelial health and function, such as macrophage function, platelet aggregation and adhesion, and response to injury. L-Arginine supplementation appears to be of benefit regarding many parameters of vascular health: in particular, experimental models indicate slowed progression of the atherosclerotic disease process (Preli et al 2002; Boger & Bode-Boger 2001), although there is controversy as to whether pre-existing lesions are affected by L-arginine supplementation.

Human clinical trials have shown mixed results. A review of oral L-arginine supplementation identified 17 clinical studies that investigated its effects on vascular health (Preli et al 2002). The duration of supplementation varied from 3 days to 6 months, and doses used varied from 6 g to 36 g daily, usually in divided doses. Studies were grouped into those investigating effects on small vessels, large vessels, coronary blood flow, adhesion molecule expression and monocyte adhesion, platelet aggregation and adhesion, limb ischaemia, exercise tolerance and myocardial infarction.

Of the 17 studies reviewed, 12 produced positive results and showed inhibition of platelet aggregation and adhesion, decreased monocyte adhesion resulting in decreased atherogenesis, improved endothelium-dependent vasodilation, or greater pain-free and total walking distance in intermittent claudication. In chronic heart failure patients, improvements in forearm blood flow, walking distance and subjective symptoms were reported. In hypercholesterolaemia, all four studies reviewed produced positive results, suggesting that this subgroup may be particularly responsive to therapy with oral L-arginine. The studies showing favourable effects involved subjects with or at risk of vascular disease, whereas two of the five studies showing no beneficial effect on vascular health were conducted with healthy volunteers who did not have endothelial dysfunction. Overall there are subgroups of patients who may gain vascular health benefits from supplementary arginine, particularly patients with less advanced disease (Boger 2008).

Hyperlipidaemia

Treatment with 9 g arginine daily for 6 months improved endothelial function and patient symptom scores in 26 adults with coronary artery disease (Lerman et al 1998). Similarly in a study of 27 young hypercholesterolaemic adults, improved endothelial dilation was reported as a result of arginine supplementation (21 g/day) for one month (Clarkson et al 1996). Decreased serum total cholesterol levels were reported in a study of 45 healthy elderly adults who were treated with 30 g Arg-aspartate/day (equivalent to 17 g arginine) for 2 weeks (Hurson et al 1995).

Hypertension

Both oral and intravenous administration of L-arginine may reduce blood pressure. Intravenous administration of L-arginine reduces blood pressure in both healthy subjects and in patients with vascular disease. In a randomised, placebo-controlled, crossover study by West et al (2005), the benefit of oral arginine supplementation (12 g per day for 3 weeks) was investigated in 16 middle-aged men with hypercholesterolaemia. In contrast to the results of other studies where arginine was administered intravenously, L-arginine supplementation did not affect lipids, glucose or inflammatory biomarkers; however, there was a reduction in homocysteine and blood pressure.

Myocardial infarction

Some studies have reported that orally administered arginine improves cardiovascular function and reduces myocardial ischaemia in coronary artery disease, whereas others have noted increased

mortality. In a randomised, controlled study by Schulman et al (2006) 153 patients with acute ST-segment elevation myocardial infarcts were given 9 g arginine (as arg-HCL) a day or a placebo for 6 months; however, this study was terminated while in progress, as a significant increase in death rate was noted (8.6% in the group given arg versus zero in the placebo group; $P = 0.01$). The supplementary arginine was implicated by the authors but this assumption was not verified.

In a large, multicentre, randomised, double-blind, placebo-controlled study, 792 patients with coronary artery disease were included within 24 hours of the onset of acute MI; the arginine group received 3 × 3 g L-arginine a day for 1 month. The results showed very little difference between the two groups with respect to various metabolic and clinical markers, although the arginine-supplemented group had favourable trends. However, positive results were seen in a subgroup of patients with hypercholesterolaemia (Bednarz et al 2005).

Angina

Not all studies report efficacy of arginine supplementation for the treatment of angina. A randomised, controlled study of 40 men with stable angina receiving 15 g arginine on a daily basis for 2 weeks did not show benefits for endothelium-dependent vasodilation, oxidative stress or exercise performance (Walker et al 2001). However, in a randomised controlled study 10 patients with stable angina who were given 12 g arginine daily for 6 weeks demonstrated increased exercise tolerance benefits, decreased lactate accumulation and decreased heart rate (Doutreleau et al 2006).

Congestive heart failure

Studies report mixed findings regarding the benefits of supplemental arginine in congestive heart failure, although taking L-arginine orally, in combination with conventional treatment, seems to improve glomerular filtration rate (GFR), creatinine clearance, and sodium and water elimination after saline loading.

A study of 21 patients with congestive heart failure who were given 9 g arginine daily for 7 days reported prolonged exercise capability (Bednarz et al 2004). However, in general, improvements in exercise tolerance, quality of life and peripheral vascular resistance are not consistently obtained. Oral arginine treatment did not have beneficial effects in endothelial function for 20 heart-failure patients who received 20 g per day for 4 weeks (Chin-Dusting et al 1996).

Peripheral arterial disease

Dietary supplementation of L-arginine has been reported to improve endothelium-dependent vasodilation, limb blood flow and walking distance in peripheral arterial disease (PAD). In a recent study (Oka et al 2005), 80 patients with PAD and intermittent claudication were randomly assigned oral doses of L-arginine in 3 g increments up to 9 g daily in three divided doses over a period of 12 weeks. No major differences were noted, although there was a trend for an improvement in walking speed in patients receiving L-arginine, and the group that was treated with 3 g L-arginine daily also demonstrated a moderate improvement in walking distance. On the other hand, in a recent randomised, controlled study of 133 patients with peripheral arterial occlusive disease who received L-arginine supplementation of 3 g daily for 6 months, no benefit was reported regarding vascular function and there was a significant decrease in the absolute walking distance (Wilson et al 2007).

Diabetes

Reduced arginine plasma levels have been noted in patients with diabetes mellitus (DM), and reports indicate that endothelial function may be improved in such patients by supplementary arginine. Arginine may also counteract lipid peroxidation, thus reducing the long-term complications of DM. In a small study of 10 women with type 2 DM, improved endothelial function was noted after they were given 9 g arginine daily for 1 week (Regensteiner et al 2003).

Erectile dysfunction

Supplementary arginine has been investigated for its effect on erectile function, given the role of NO in the corpus cavernosum; the research in this area has mixed findings. In a large prospective randomised, double-blind placebo-controlled study, a high dose of arginine (5 g/d) was administered for 6 weeks to 50 men with organic erectile dysfunction (ED) and significant improvement in sexual function was reported only in men with abnormal nitric oxide metabolism (Chen et al 1999). However, in a randomised, placebo-controlled, crossover oral study of 32 patients with mixed-type impotence who were treated with 3 × 500 mg L-arginine/day for 17 days, the results showed the supplement was no more effective than the placebo (Klotz et al 1999). Taking L-arginine orally in high doses, 5 g daily, seems to improve subjective assessment of sexual function in men with organic ED, but taking lower doses might not be effective. A combination of arginyl aspartate (equivalent to 1.7 g of L-arginine a day) with pycnogenol was administered to 40 men, aged 25–45 years for 3 months; by the third month up to 92% of the men reported improved erectile function without any side effects (Stanislavov & Nikolova 2003).

Chemotherapy adjunct

There are conflicting reports about the value of arginine supplementation during chemotherapy. As some studies have also used other supplementary constituents, it is difficult to attribute any benefits solely to arginine (Appleton 2002). Importantly, arginine has been implicated in promoting cancer growth, since polyamines can act as growth factors for cancers, and this might be of concern in long-term arginine treatment. Precautionary measures regarding L-arginine administration should be considered in cancer patients, although in recent years immunomodulating (IM) formulas containing supplementary

arginine have been used safely (Aiko et al 2008, Marik & Zaloga 2008).

Interstitial cystitis

The results of taking L-arginine for the management of interstitial cystitis (IC) are mixed. In a double-blind placebo-controlled crossover study (Cartledge et al 2000), 16 patients were randomised to receive L-arginine (2.4 g/day) or a placebo for 1 month. Although some patients reported improvement in their symptoms the effects were only small and probably not clinically significant. A randomised, double-blind, placebo-controlled study with 53 patients who received 1500 mg L-arginine or a placebo orally for 3 months reported less pain and urgency in some of the patients (Korting et al 1999). A small study in which patients were treated with either 3 g or 10 g of supplementary arginine did not report any symptom improvements (Ehrén et al 1998). Overall, taking L-arginine orally may reduce symptoms, especially pain associated with interstitial cystitis, in only some patients.

Enhancing immune function

The results of the utility of supplemental arginine in immunonutrition are mixed. Numerous enteral formulas contain additional arginine for use in catabolic conditions and critical illness; most enteral feeds provide about 12–13 g per 1000 kcal.

A recent systematic review investigated the impact in critical illness of IM formulas containing various supplementary nutrients such as arginine (ranging from 6.5 to 15 g arginine/L) and glutamine compared with a control diet. Analysis of 24 studies (3013 patients) found that IM diets with supplementary arginine, with or without various supplementary nutrients, did not result in improved outcomes in intensive care, trauma and burn patients (Marik & Zaloga 2008).

Wound healing

A number of studies have reported that dietary L-arginine supplementation enhances wound healing and immunity. A randomised, controlled study with 29 older adults receiving 15 g arginine daily for 4 weeks reported improved immune function (Moriguti et al 2005). Similarly, improved wound healing was reported in another randomised, controlled study, in which 17 g arginine as arginine-aspartate (30 g/day) was administered daily for 14 days to 30 healthy elderly people (Kirk et al 1993). Improved wound healing was noted in a randomised controlled trial of experimental surgical wounds in 36 healthy adults who were given 17–25 g oral arginine per day (Barbul et al 1990).

Renal failure

There are mixed reports about the benefit of supplemental L-arginine in the management of chronic renal failure. There was no improvement in renal function in a randomised, double-blind, placebo-controlled study of 24 patients who were given 200 mg/kg (14 g/70 kg) arginine daily for 6 months (De Nicola et al 1999). A study of 76 renal transplant patients who were given 9 g arginine a day and canola oil as a source of omega-3 fatty acids for 3 years noted reduced infections and transplant rejections (Alexander et al 2005).

OTHER USES

HIV — general support

Supplementary arginine may have a beneficial role in the care of human immunodeficiency virus (HIV) infection and acquired immunodeficiency syndrome (AIDS). A few studies have already been conducted investigating the effects of a combination of arginine with vitamins, minerals and glutamine; body weight was reported to increase, but other findings were mixed (Appleton 2002).

Asthma

Arginine supplementation may be beneficial to patients with asthma, although there are reports that such supplementation may also cause exacerbation of airway inflammation (Coman et al 2008). At present, it is unclear whether L-arginine supplementation results in any clinically significant benefit to patients with asthma.

Cystic fibrosis

In a small, double-blind, placebo-controlled crossover study of 10 patients with cystic fibrosis, arginine supplementation of 200 mg/kg administered for 6 weeks resulted in increased NO production (Grasemann et al 2005).

Dementia

Increased cognitive function and reduced lipid peroxidation was noted in 16 elderly patients with senile dementia who were administered arginine (1.6 g/day) (Ohtsuka & Nakaya 2000).

Subfertility

It has been well documented that arginine-deficient diets in adult men result in markedly decreased sperm counts. Infertile men given 500 mg arginine-HCL per day for 6–8 weeks were reported to have increased sperm counts, although such supplementation had no effect if the baseline sperm counts were less than 10 million/mL (Appleton 2002). Results of a single study note that supplementation of 16 g of arginine per day improved ovarian response and pregnancy rate in poor responders to 'in vitro fertilisation' (Battaglia et al 1999).

DOSAGE RANGE

General guide

- Overall L-arginine is well tolerated in doses < 30 g administered orally, intravenously or via the intra-arterial route (Boger & Bode-Boger 2001). It is best taken in divided doses to improve overall absorption, reaching 1.5–6 g daily.
- In a recent risk assessment by Shao and Hancock (2008) the following recommendations have been made: NOAEL and LOAEL >42 g/day l-arginine; observed safe level (OSL) 20 g/day. ULS 20 g/day.

According to clinical studies

- Angina pectoris: oral 12 g/day (uncertain efficacy).
- Coronary artery disease: 9 g/day.
- Erectile dysfunction: 5 g/day (in men with abnormal NO metabolism).
- Hyperlipidaemia: 30 g/day (uncertain efficacy).
- Wound healing: 17 g/day.

TOXICITY

Overall, arginine administration is considered safe for humans and animals (Wu & Meininger 2000). However, it must be noted that vasodilation and hypotension can result from the overproduction of NO due to excess administration of arginine.

ADVERSE REACTIONS

L-Arginine supplementation has been used safely and has been associated with only minor side effects in clinical studies lasting from a few days to months (Shao & Hathcock 2008). Orally, L-arginine can cause abdominal pain and bloating, diarrhoea and gout. Gastrointestinal disturbances have been reported as a result of arginine supplementation, although the studies have been of a mixed nature and involved a range of patients (Grimble 2007) whereas these effects have not been reported in controlled studies.

There has been only limited consideration of safety aspects of supplemental arginine, even though numerous animal studies have been conducted examining a wide range of diseases (Shao & Hathcock 2008). In humans only one study has used a high oral arginine dose of 42 g on a daily basis without any adverse effects being noted (Shao & Hathcock 2008).

SIGNIFICANT INTERACTIONS

No controlled studies are available to determine the significance of the proposed interactions, so they remain speculative.

Antihypertensive medicines

Theoretically, additive hypotensive effects may occur — use with caution. Potential benefits under professional supervision.

Nitrates

Theoretically, additive vasodilation and hypotensive effects may occur — use with caution.

L-Lysine

A limited number of research studies report that high doses of arginine could be unfavourable, as arginine may compete with lysine uptake by tissues; caution is needed if considering the administration of both amino acids, since supplemental arginine has been reported to affect proliferation of the herpes simplex virus (Griffith et al 1981).

Sildenafil

Theoretically, additive vasodilation and hypotensive effects may occur — use with caution. Potential benefits under supervision.

CONTRAINDICATIONS AND PRECAUTIONS

Intravenous arginine needs to be administered with care, as overdose may result in adverse consequences such as severe hyponatraemia (Shao & Hathcock 2008), and high doses with high osmolality can cause local irritation and phlebitis (Boger & Bode-Boger 2001).

Other side effects that can occur as a result of administering arginine are metabolic acidosis associated with arrhythmias, and hyperkalaemia and increases in blood nitrogen urea in patients with liver disease and/or renal impairment (Boger & Bode-Boger 2001).

Hyperkalaemia and hypophosphataemia in patients with diabetes has also been reported (Boger & Bode-Boger 2001). Supplementary arginine may also be contraindicated in patients with systemic septic shock and hypotension due to NO production (Feihl et al 2001).

Caution is necessary in using high doses of 30 g/d in cancer patients, as even short-term use for 3 days may be linked to increased tumour growth.

PREGNANCY USE

At present there is insufficient reliable information available about the safety of L-arginine during pregnancy and for nursing mothers. Dietary intake levels are likely to be safe.

PRACTICE POINTS/PATIENT COUNSELLING

- L-Arginine is a conditionally essential amino acid for humans; requirements may be increased during metabolic stress or when there is insufficient endogenous L-arginine for optimal growth or tissue repair.
- Arginine deficiency can affect growth and development, insulin production, lipid and protein metabolism, and glucose tolerance. Clinical symptoms include poor wound healing, hair loss or breakage, liver disease, constipation and skin rashes.
- The role of arginine in NO production forms the basis of its application in cardiovascular disease, peripheral arterial disease, sexual dysfunction, asthma and interstitial cystitis.
- Oral arginine supplementation shows promise in the treatment of angina, hyperlipidaemia, congestive heart failure, improving vascular health (reducing atherogenesis) and interstitial cystitis; however, results are not consistent.
- Oral arginine supplementation has shown benefits in erectile dysfunction and promoting wound healing
- Arginine supplementation should be used with caution in people with cancer, kidney and/or liver impairment, schizophrenia, herpes simplex virus or a history of myocardial infarction.

PATIENTS' FAQs

What will this supplement do for me?

Arginine supplementation is used in cardiovascular disease, peripheral arterial disease, sexual dysfunction, wound healing and several other conditions. Its effects will depend on the dose used and indication for use.

When will it start to work?

This depends on the dose used and indication for use.

Are there any safety issues?

Arginine supplementation should be used with caution in people with cancer, kidney and/or liver impairment, schizophrenia, herpes simplex virus or a history of myocardial infarction. There are also several drug interactions that should be considered before use.

Astragalus

HISTORICAL NOTE Astragalus was first recorded in *Shen Nong's Materia Medica* about two thousand years ago and was believed to stimulate immune function, have antioxidant effects and other benefits in the treatment of viral infections and cardiovascular disease (Zhang et al 2007). The roots of astragalus are still considered among the most important and popular Chinese herbs for invigorating vital energy, health promotion and strengthening Qi. Western herbalists began using astragalus in the 1800s in various tonics and the gummy sap (tragacanth) is still used as an emulsifier, food thickener and antidiarrhoeal agent. Today, Western herbalists use astragalus as an immunomodulating agent, adaptogen and in the management of cardiovascular disease.

COMMON NAME
Astragalus

OTHER NAMES
Astragali, beg kei, bei qi, hwanggi, huang-qi, milk vetch, goat's horn, green dragon, Mongolian milk, ogi, Syrian tragacanth

BOTANICAL NAME/FAMILY
Astragalus membranaceus (family Fabaceae)

PLANT PART USED
Root

CHEMICAL COMPONENTS
Astragalus is a chemically complex herb and contains over 60 components including beta-sitosterol, glycosides (astragalosides I through VII, soyasaponin, daucosterin), polysaccharides (astroglucans A through C), saponins such as cycloastragenol, astragalosides, isoflavones and other flavonoids, plant acid, choline, betaine, rumatakenin, formonetin, amino acids (including gamma-aminobutyric acid) and various microelements (Duke 2003, Li & Wang 2005, Mills & Bone 2000).

MAIN ACTIONS
Evidence about mechanisms of action is mainly derived from in vitro and animal studies.

Immune modulation
Studies using various experimental models indicate that astragalus has immune-modulating activity. Astragalus stimulates macrophage activity and enhances antibody responses (Chu et al 1988, Jin et al 1994, Sugiura et al 1993). Astragalus enhances lymphocyte blastogenesis in vitro (Sun et al 1983). Immunostimulant effects have also been observed in the presence of immunosuppressive therapy in vivo (Jin et al 1999).

Although usually administered in the oral form, research has also been undertaken with injectable forms. A study conducted with both normal and immunosuppressed mice found that astragalus administration increased antibody responses and T helper cell activity (Zhao et al 1990). A flavonoid identified in the stem and leaves of astragalus is believed to be one of the main constituents responsible for immune modulation (Jiao et al 1999) and more recently, several studies have identified that astragalus polysaccharide (APS) also exerts significant biological effects, including increasing cellular and humoral immune responses in vivo (Guo et al 2004).

Studies in animal models have found APS stimulates B cells and macrophage activity, but not T cells (Shao et al 2004). More specifically, APS stimulates macrophages to produce nitric oxide (NO) through induction of NO synthase transcription leading to increased macrophage cytolytic function (Lee & Jeon 2005). Other in vitro and animal studies reveal that APS increases beneficial gut flora and decreases harmful gut bacteria, suggesting beneficial immune effects within the gastrointestinal tract (Guo et al 2003).

Cardiovascular effects
The effect of astragalus on heart function has been the subject of several investigations and, most recently, a Cochrane Systematic Review, which analysed studies of Chinese herbs used in viral myocarditis and concluded that astragalus significantly improves

Clinical note — Polysaccharides and immunity
One of the most promising recent alternatives to antibiotic treatment is the use of immunomodulators for enhancing host defence responses. Several types of immunomodulators have been identified, most recently botanically sourced polysaccharides isolated from mushrooms, algae, lichens and higher plants. These polysaccharides tend to have a broad spectrum of therapeutic properties and relatively low toxicity. One of the primary mechanisms responsible for immunomodulation involves non-specific induction of the immune system, which is thought to occur via macrophage stimulation and modulation of the complement system. According to one report, polysaccharides isolated from 35 plant species among 20 different families have been shown to increase macrophage cytotoxic activity against tumour cells and microorganisms, activate phagocytic activity, increase reactive oxygen species (ROS) and nitric oxide (NO) production, and enhance secretion of cytokines and chemokines, such as TNF-alpha, IL-1beta, IL-6, IL-8, IL-12, IFN-gamma and IFN-beta2 (Schepetkin & Quinn 2006). These effects have a major influence on the body's ability to respond rapidly and potently to a diverse array of pathogens, giving the polysaccharides wide clinical application.

cardiac function, arrhythmia and creatinine kinase levels (Liu, Yang & Du 2004). The review assessed data from 10 randomised clinical trials that used a single preparation of astragalus and one that used a combination containing mainly astragalus; however, the authors stated that the trials had poor quality in terms of design, reporting and methodology.

Several constituents from *Astragalus* spp. have demonstrated effects on heart contractility, heart rate and blood pressure. In particular, 3-nitropropionic acid (NPA) has been shown to decrease blood pressure and induce bradycardia when administered as an IV preparation in normotensive rats or renal hypertensive dogs (Castillo et al 1993). Another compound, astragaloside IV, demonstrated positive inotropic activity in patients with congestive heart failure (Luo et al 1995).

Recent research indicates that astragalus improves endothelial function by increasing the bioavailability of NO and decreasing reactive oxygen species production (Zhang et al 2007).

Antioxidant

In vivo studies have found that astragalus raises superoxide dismutase activity in the brain and liver, thus demonstrating an indirect antioxidant activity (Jin et al 1999). The constituent astragaloside IV (20 and 40 mg/kg) prevented the formation of cerebral infarction after induced focal ischaemia in an animal model, most likely due to its antioxidant and anti-inflammatory actions (Luo et al 2004).

Anticarcinogenic effects

Both in vitro and animal studies indicate that astragalus may have a role as adjunctive therapy in the treatment of some cancers. In vivo studies have shown that astragalus extract exerts anticarcinogenic effects in carcinogen-treated mice, mediated through activation of cytotoxic activity and the production of cytokines (Kurashige et al 1999). An extract of the root (90 and 180 mg/kg) prevented the development of preneoplastic lesions and delayed hepatic cancer in chemically-induced hepatocarcinogenesis in a rat model (Cui et al 2003). The saponin, astragaloside IV, can increase the fibrinolytic potential of cultured human umbilical vein endothelial cells by downregulating the expression of plasminogen activator inhibitor type 1 (Zhang et al 1997). Another constituent (astragalan) increased the secretion of TNF-alpha and TNF-beta (Zhao & Kong 1993).

An animal study using a combination of *Astragalus membranaceus* and *Ligustrum lucidum* demonstrated antitumour effects by augmenting phagocyte and lymphokine-activated killer cell activities (Lau et al 1994).

Digestive effects

Astragalus strengthens the movement and muscle tone of the small intestine (especially the jejunum) in animal tests, which may account for its clinical application in a variety of common digestive symptoms (Yang 1993).

Improved sperm motility

An aqueous extract of *Astragalus membranaceus* was tested in vitro and found to have a significant stimulatory effect on sperm motility (Hong et al 1992). Astragalus has shown a significant effect on human sperm motility in vitro when compared with controls (Liu et al 2004).

Hepatoprotective actions

Astragalus has hepatoprotective qualities against paracetamol, carbon tetrachloride and D-galactosamine poisoning (Zhang et al 1990). Increases in liver glutathione levels observed as a result of the herbal treatment may be partly responsible. Studies have identified the constituent betaine as an important contributor to this activity.

OTHER ACTIONS

Astragalus is also thought to have adaptogenic activity. It has shown weak oestrogenic activity in vitro when compared with other Chinese herbs and controls (17-beta-oestradiol) (Zhang et al 2005). This could partially explain its traditional use in menopause.

CLINICAL USE

Astragalus is a popular Chinese herbal medicine and has been the subject of many clinical trials, mainly published in foreign language peer-reviewed journals. To provide a more complete description of the evidence available, secondary sources have been used when necessary. As a reflection of clinical practice, astragalus is sometimes tested in combination with other herbal medicines, and such instances are stated as such in this review.

Viral infection

Owing to its immunomodulatary actions, astragalus is widely used for preventing and treating various viral infections. A popular use is as a preventive treatment against common colds and influenza. To date, scientific evidence is scant to confirm effectiveness, although one review stated that astragalus has been tested in clinical trials in China, reducing the incidence and shortening the duration of the common cold (Murray 1995).

Viral myocarditis

Astragalus has been investigated in viral myocarditis in several clinical studies. It was found to significantly improve cardiac function, arrhythmia and creatinine kinase levels according to a Cochrane review of randomised trials (Liu, Yang & Du 2004). Although this result is encouraging, the authors noted that trials were generally of poor quality in terms of design, reporting and methodology. Despite these limitations, the studies identified activity on heart contractility, heart rate and blood pressure for several constituents in astragalus, providing support for clinical observations. Recent research showed that astragalus also improves endothelial function, achieved by increasing the bioavailability of NO and decreasing reactive oxygen species production (Zhang et al 2007).

Several in vivo and in vitro studies have found some antagonistic effects on the enterovirus coxsackie B and a reduction in myocardial injury (Lu et al 1999, Peng et al 1995, Rui et al 1993, Yang et al 1990), thought to be due to the astragalosides in the herb (Lu et al 1999).

Cardiovascular disease

Congestive heart failure

Some of the clinical signs and symptoms recognised as indicators for this medicine by TCM practitioners suggest that the herb may be useful for congestive heart failure. Recent positive results obtained in clinical studies have reinforced this possibility.

The two clinical trials investigated continuous intravenous administration of astragalus. One study involving 19 patients found that after 2 weeks continuous administration of astragaloside IV, major symptoms were alleviated in 15 patients. Treatment produced a positive inotropic effect, improved left ventricular modelling and ejection function (Luo et al 1995).

The second study, involving 38 patients with congestive heart failure who were administered astragalus 24 g intravenously for 2 weeks, found that 13.6% had significantly shortened ventricular late potentials (Shi et al 1991).

Angina pectoris

Two clinical studies have suggested that astragalus may be an effective treatment for angina pectoris. One study used Doppler echocardiography to study the action of astragalus on left ventricular function in 20 patients with angina pectoris. Treatment resulted in increased cardiac output after 2 weeks, but no improvement in left ventricular diastolic function (Lei et al 1994). One Chinese study reported 92 patients with ischaemic heart disease who were successfully treated with astragalus as measured by electrocardiogram readings. Results obtained with the herb were considered superior to those obtained with nifedipine (Li et al 1995).

Cancer

Astragalus is used in cancer patients to enhance the effectiveness of chemotherapy and reduce associated side-effects. It is additionally used to enhance immune function.

Few details are available of clinical studies looking at the potential for astragalus to alter patient survival outcomes, as most information has been published in non-English journals. However, two clinical studies are worth mentioning which suggest that intravenously administered astragalus may have potential benefit as adjunctive therapy when given with chemotherapy. One randomised study of 120 cancer patients receiving chemotherapy administered IV astragalus extract daily (20 mL in 250 mL normal saline), which slowed tumour growth compared to controls (Duan & Wang 2002). Four treatment cycles were administered lasting 21 days each. Unfortunately, no further details are available about this study.

Another randomised study investigated IV astragalus in 60 patients with advanced non-small cell lung cancer (Zou & Liu 2003). This time 2–3 treatment cycles were given of 21–18 days each. The mean remission rate was 5.4 months in the herbal treated group versus 3.3 months in the untreated group, and the 1 year survival rate was 46.75% with herbal treatment versus 30.0% without. All differences were considered statistically significant. Once again further details are not available in English.

Colorectal cancer

According to a 2005 Cochrane systematic review, astragalus may be a useful adjunct to chemotherapy in colorectal cancer as it reduces treatment side effects. The review assessed various Chinese herbal medicines taken in combination with chemotherapy for colorectal cancer for their ability to reduce common side effects of chemotherapy such as nausea, vomiting, sore mouth, diarrhoea, hepatotoxicity, myelosuppression and immunosuppression (Taixiang et al 2005). Four trials were analysed: adjunctive treatment with astragalus was compared with chemotherapy alone in three trials, and with two other Chinese herbal treatments in the fourth trial. Overall, herbal treatment resulted in a significant reduction in the proportion of patients who experienced nausea and vomiting when decoctions of huang-qi (astragalus) compounds were given in addition to chemotherapy. There was also a decrease in the rate of leucopenia (WBC $< 3 \times 10^9$/L) and increased proportions of T-lymphocyte subsets: CD3, CD4 and CD8 with no significant effects on immunoglobulins G, A or M. The authors concluded that astragalus may stimulate immunocompetent cells and decrease chemotherapy side effects, however a definitive conclusion could not be made because of the studies' methodological limitations. Additionally, no evidence of harm was identified with use of the Chinese herbal treatment in these studies.

Reducing adverse effects of treatment (in combination)

Zee-Cheng screened and evaluated 116 Kampo formulas and identified 15 that potentiated therapeutic effects, reduced the adverse toxicity of various anticancer drugs, and exhibited immune-modulating effects in cancer patients. Among these, shi-quan-da-bu-tang (SQT) was selected as the most effective and studied further. SQT is a popular TCM herbal combination consisting of 10 medicinal herbs, including *Astragalus membranaceus*. Using both animal models and clinical studies, the herbal combination produced several promising results (Zee-Cheng 1992).

Prostate cancer (in combination)

Although no human studies could be located, encouraging results were obtained from an in vitro study investigating the effects of a proprietary product known as Equiguard™ on prostate cancer cells. It is prepared according to TCM principles and contains standardised extracts of nine herbs: herba epimedium brevicornum maxim (stem and leaves), radix morindae officinalis (root), fructus rosae laevigatae michx (fruit), rubus chingii hu (fruit), *Schisandra chinensis* (Turz.) Baill (fruit), *Ligustrum lucidum* Ait (fruit), *Cuscuta chinensis* Lam (seed), *Psoralea corylifolia* L. (fruit), and *Astragalus membranaceus* (root). It is used in TCM to restore Qi in the urogenital region. The product was shown to significantly reduce cancer cell growth, induce apoptosis, suppress expression of the androgen receptor and lower intracellular and secreted prostate-specific antigen (Hsieh et al 2002).

Clinical note — The concept of an adaptogen is foreign to Western medicine but often used in traditional medicine

The term 'adaptogen' was first coined by N. Lazarev in the Soviet Union in the mid-20th century, although the concept has been used for centuries in traditional herbal systems. Adaptogens are considered natural bioregulators that increase the ability of the organism to adapt to environmental factors and to avoid damage from such factors. Herbal medicines with adaptogenic activity are used when extremes of physical or emotional activity are present, environmental influences are severe, or allostatic load has developed over time. The aim of treatment is to improve the patient's endurance and ability to deal with these changes in a healthy way, and for abnormal parameters to shift towards normal. The best-known example of a plant adaptogen is ginseng (*Panax ginseng*), but others are also well established such as *Schisandra chinensis*, *Eleutherococcus senticosus* (Siberian ginseng), *Astragalus membranaceus* and *Withania somnifera* (see also Siberian ginseng and Glossary).

Chronic kidney disease

Astragalus is one of the most commonly prescribed Chinese herbs in chronic kidney disease (CKD). Pharmacological studies have confirmed that different constituents in the herb have effects which could be valuable in CKD such as anti-oxidant, diuretic and anti-inflammatory effects, and studies in rat models indicate that astragalus decreases glomerular hyperperfusion and improves kidney function (Li & Wang 2005). A meta-analysis of 14 randomised controlled trials involving 524 Chinese patients with primary nephrotic syndrome showed that treatment with astragalus for 1 to 3 months could increase the therapeutic effect of prednisone and immunosuppressants (reported in Li & Wang 2005). Herbal treatment decreased proteinuria and increased levels of total cholesterol and albumin. Although further details are unavailable, these results are encouraging.

OTHER USES

Traditional uses

Within traditional Chinese herbal medicine, astragalus is used to invigorate and tonify Qi and the blood, as an adaptogen, for severe blood loss, fatigue, anorexia, organ prolapse, chronic diarrhoea, shortness of breath, sweating and to enhance recuperation (Mills & Bone 2000).

Cholesterol reduction (in combination with other herbs)

A randomised, double-blind clinical trial compared the effects of a traditional Chinese herbal medicine combination known as jian yan ling (which includes astragalus as a main ingredient) to a placebo in 128 hyperlipidaemic patients. After 3 months' treatment it was found that total cholesterol, triglyceride, apoproteins and lipoprotein-a levels were significantly reduced in the treatment group, compared with a placebo (Lu et al 1994).

Asthma (in combination with other herbs)

A herbal combination of *Astragalus membranaceus, Codonopsis pilulosa* and *Glycyrrhiza uralensis* was investigated in an open study for effects on airway responsiveness. Twenty-eight patients with asthma were treated with the herbal combination for 6 weeks, after which values for FVC, FEV_1 and PEF were all higher than at baseline (Wang et al 1998).

Memory deficits (in combination with other herbs)

In TCM, invigorating Qi and warming Yang are believed to have a beneficial therapeutic effect on some brain diseases, such as senile dementia. Some studies have been conducted to determine the outcome of following this ancient principle.

A decoction of astragalus produced neuroprotective effects in rats with experimentally induced cerebral ischaemia (Quan & Du 1998), and memory enhancement has been observed in vivo (Jin et al 1999).

One article reports on 100 cases of children with minimal brain dysfunction and compared the effects of a TCM combination (*Bupleurum chinense*, *Scutellaria baicalensis*, *Astragalus membranaceus*, *Codonopsis pilulosa*, *Ligustrum lucidum*, *Lophatherum gracile* and thread of ivory) to the Western medical approach (methylphenidate (Ritalin™) 5–15 mg/day). A collation of results found that the herbal treatment produced a clinically effective rate of 87.5% compared with 90% in the Ritalin group, with the herbal treatment group reporting fewer side-effects (Zhang & Huang 1990).

DOSAGE RANGE

- Dried root: 2–30 g/day.
- Liquid extract (1:2) or solid dose equivalent: 4.5–8.5 mL/day.
- Decoction: 8–12 g divided into two doses daily on an empty stomach.

TOXICITY

Animal studies have shown that the herb has a wide safety margin.

ADVERSE REACTIONS

None known.

SIGNIFICANT INTERACTIONS

Interactions are theoretical and based on the herb's pharmacodynamic effects, therefore clinical significance is unclear and remains to be confirmed.

Acyclovir

Possibly enhances antiviral activity against herpes simplex type 1 (Stargrove et al 2008) — adjunctive use may be beneficial.

Immunosuppressant medication

Reduced drug activity is theoretically possible, as immunostimulant activity has been demonstrated — use caution.

Positive inotropic drugs

Additive effects are theoretically possible with intravenous administration of astragalus, based on positive inotropic activity identified in clinical studies. The clinical significance of these findings for oral dose forms is unknown — observe patients using high-dose astragalus preparations.

Cyclophosphamide

Adjunctive treatment with astragalus may have beneficial effects in regards to improving patient well-being and reducing adverse effects associated with treatment such as nausea and vomiting — only use combination under professional supervision.

CONTRAINDICATIONS AND PRECAUTIONS

According to the principles of TCM, astragalus should not be used during the acute stages of an infection.

PREGNANCY USE

Safety is unknown although no evidence of fetal damage has been reported in animal studies (Mills & Bone 2005).

PRACTICE POINTS/PATIENT COUNSELLING

- Astragalus is widely used as an immunostimulant medicine to reduce the incidence of the common cold and influenza and is sometimes used to improve immune responses to other viral infections such as herpes simplex type 1.
- It is also used to enhance recuperation and reduce fatigue, and reduce the side effects of chemotherapy whilst improving immune function.
- Astragalus is a commonly prescribed Chinese herb in chronic kidney disease.
- According to TCM practice it is widely used to invigorate and tonify Qi and the blood, and as an important adaptogen.
- Some evidence suggests it enhances digestion, improves heart function in viral myocarditis, and may improve sperm counts and have hepatoprotective activity.
- Under the TCM system of use, astragalus is not used during periods of acute infection.
- In clinical practice it is often used in combination with other herbs such as *Bupleurum chinense*, *Scutellaria baicalensis* and *Codonopsis pilulosa*. As such, most clinical trials have tested combination formulas.

PATIENTS' FAQs

What will this herb do for me?

Astragalus appears to have numerous biological effects, such as digestive and immune system stimulation and heart muscle stimulation. Early research suggests that it may have a role in the treatment of asthma, memory deficits, elevated cholesterol levels and as an adjunct to chemotherapy treatment for cancer.

When will it start working?

This will depend on the indication and dose; some studies have shown that effects can begin within 2 weeks.

Are there any safety issues?

Overall the herb appears to be safe, although it has the potential to interact with some medicines. Professional supervision is advised for people receiving chemotherapy and considering using this herb.

Baical skullcap

HISTORICAL NOTE Baical skullcap is a TCM herb used to clear 'heat and dry dampness'. Diseases with heat are associated with symptoms such as fever, irritability, thirst, cough and expectoration of thick, yellow sputum. Damp diseases may be associated with diarrhoea, a feeling of heaviness of the chest and painful urination (Bensky & Gamble 1986). From a modern perspective this suggests that baical may be useful for infection and inflammation of the respiratory, digestive and urinary systems. Scientific investigations have indeed shown that baical skullcap and its constituents have antibacterial, antiviral, anti-inflammatory, hepatoprotective and diuretic actions (Zhang et al 2001).

OTHER NAMES

Baical skullcap, Chinese skullcap, huang qin (Mandarin), ogon (Japanese), scute

BOTANICAL NAME/FAMILY

Scutellaria baicalensis Georgi (family Lamiaceae)

PLANT PART USED

Root

CHEMICAL COMPONENTS

Baical skullcap contains numerous flavonoids and their glycosides. The main flavonoids are baicalin and its aglycone, baicalein, and wogonin. Resin and tannins are also present.

Baical also contains melatonin. It has been shown that dietary melatonin directly contributes to the circulating level of the hormone. The clinical effects of plant-derived melatonin remains to be investigated (Hardeland & Poeggeler 2003). Baicalin itself is poorly absorbed from the gut, but is hydrolysed to its aglycone, baicalein, by intestinal bacteria and then restored to its original form from the absorbed baicalein in the body (Akao et al 2000).

MAIN ACTIONS

The actions of baical skullcap, some of its individual constituents, and combination formulations have been studied in various models.

Anti-inflammatory

The anti-inflammatory activity of baical skullcap has been well documented by in vitro and in vivo studies. The main constituents responsible are baicalein and wogonin (Chang et al 2001, Chi et al 2001, Chung et al 1995, Huang et al 2006, Krakauer et al 2001, Li et al 2000a, Park et al 2001, Wakabayashi 1999).

In a study using mice, baicalein 50 mg/kg has been shown to ameliorate the inflammatory symptoms of induced colitis, including body weight loss, blood haemoglobin content, rectal bleeding and other histological and biochemical parameters (Hong et al 2002). Pretreatment with wogonin also significantly reduced ethanol-induced gastric damage in vivo (Park et al 2004) and reduced immunoglobulin E, IL-4, IL-5 and IL-10 secretion in a colitis-induced mouse model (Lim 2004). The methanolic extract of the baical skullcap root and its flavonoids wogonin, baicalein and baicalin have been shown to inhibit lipopolysaccharide-induced inflammation of the gingivae (gums) in vivo. The three flavonoids exerted an anti-inflammatory effect similar to prednisolone. In addition, the flavonoids exerted a moderate inhibition (33–36%) of collagenolytic activity, comparable to the 40% inhibition by tetracycline. Meanwhile, the cellular activity of fibroblasts was augmented remarkably (40%) by baicalein and slightly by baicalin and wogonin. Consistent with the cellular activation, the flavonoids enhanced the synthesis of both collagen and total protein in fibroblasts in vitro (Chung et al 1995).

The anti-inflammatory mechanisms are varied and summarised below.

Chemokine binding

It has been proposed that the anti-inflammatory activity is partly caused by limiting the biological function of chemokines.

Excessive release of pro-inflammatory cytokines mediates the toxic effect of superantigenic staphylococcal exotoxins. In vitro data suggest that baicalin may be therapeutically useful for mitigating the pathogenic effects of staphylococcal exotoxins by inhibiting the signalling pathways activated by superantigens (Krakauer et al 2001).

Baicalin inhibited the binding of a number of chemokines to human leukocytes or cells expressing specific chemokine receptors, with an associated reduced capacity of the chemokines to induce cell migration. Based on these results, it is possible that the anti-inflammatory mechanism of baicalin is to bind a variety of chemokines and limit their biological function (Bao et al 2000, Li et al 2000a).

Four major flavonoids from baical have been shown in vitro to suppress eotaxin. Eotaxin is an eosinophil-specific chemokine associated with the recruitment of eosinophils to sites of allergic inflammation. Eotaxin is produced by IL-4 plus TNF-alpha-stimulated human fibroblasts. This may explain why it has been used traditionally in the treatment of bronchial asthma (Nakajima et al 2001). Various flavonoids, including wogonin and baicalein, have been shown to inhibit chemically induced histamine release from rat mast cells in vitro (Kubo et al 1984).

COX-2 inhibition

Wogonin is a direct COX-2 inhibitor. Wogonin inhibits both inducible nitric oxide synthase and cyclo-oxygenase 2 induction (Chen et al 2001 & 2008, Chi et al 2001, Wakabayashi & Yasui 2000). Wogonin has been shown to inhibit inducible PGE_2 production in macrophages by inhibiting COX-2 (Wakabayashi & Yasui 2000). Additionally baicalein, but not baicalin, has been shown to inhibit COX-2 expression in lipopolysaccharide induced RAW 264.7 cells (a murine leukaemic macrophage-like cell line) (Woo et al 2006). Both compounds also suppressed inducible NO synthase (iNOS) protein expression, iNOS mRNA expression, and NO production in a dose-dependent manner.

Wogonin may be beneficial for COX-2-related skin disorders. When applied topically to the dorsal skin of mice, it inhibited COX-2 expression and PGE_2 production (Byoung et al 2001, Chi et al 2003, Park et al 2001).

Lipoxygenase inhibition

The inhibition of the 5-lipoxygenase pathway of arachidonic acid metabolism may be one of the mechanisms of baicalein's anti-inflammatory activity according to an in vivo study (Butenko et al 1993).

Nitric oxide synthase inhibition

Baicalein and wogonin attenuate lipopolysaccharide-stimulated nitric oxide synthase induction in macrophages, which helps to explain the anti-inflammatory action of these flavonoid compounds (Cheng et al 2007, Wakabayashi 1999).

Antioxidant activity

The anti-inflammatory activity of baicalein may be associated with inhibition of leukocyte adhesion by the scavenging of reactive oxygen intermediates (Shen et al 2003).

Nuclear factor kappa B inhibition

Baicalin has been shown to inhibit nuclear factor kappa B (NFkB) in vitro (Cheng et al 2007, Hsieh et al 2007, Kim et al 2006, Wang et al 2006).

Antifibrotic

A methanolic extract of baical skullcap has been shown to inhibit fibrosis and lipid peroxidation induced by bile duct ligation or carbon tetrachloride in rat liver. Bile duct ligation in rodents is an experimental model for extrahepatic cholestasis caused by, for example, cholelithiasis (gall stones). Liver fibrosis was assessed by histological observation and by measuring levels of liver hydroxyproline, lipid peroxidation based on malondialdehyde production, and serum enzyme activities. Treatment with baical skullcap significantly reduced the levels of liver hydroxyproline and malondialdehyde, with improved histological findings (Nan et al 2002).

Hepatoprotective

Baicalein, baicalin and wogonin have been shown to have hepatoprotective effects in vivo. The flavonoids decrease the toxicity produced by a variety of chemicals. Significant protective effects were seen by comparing the serum levels of AST and ALT and by histopathologic examination (Lin & Shieh 1996). Two different dried root preparations of baical skullcap (1% of total feed) were added to the diet of animals that were subsequently exposed to aflatoxin-B1 (de Boer et al 2005). Mix A contained 3.13 microgram/g baicalin, 1.5 microgram/g baicalein, 0.021 microgram/g wogonin and 65.3 nmol/g melatonin compared to 0.94 microgram/g baicalin, 0.41 microgram/g baicalein, and 0.003 microgram/g wogonin and 1176 nmol/g melatonin in mix B. The addition of mix A and B reduced hepatic damage by approximately 60 and 77%, respectively. The feed mixtures also increased the expression of the gene for glutathione S-transferase A5 by 2.5 to 3.0-fold. Interestingly the mix with the lower concentration of flavonoids was the more protective. The authors explain this by stating that it was probably due to the much higher (18-fold) amount of melatonin which has been shown to enhance aflatoxin detoxification pathways in animals.

Baicalein, baicalin and wogonin have also been shown to inhibit hemin-nitrite-H_2O_2 induced liver injury in a dose-dependent manner by inhibiting oxidation and nitration (Zhao et al 2006). In other in vitro and in vivo studies baicalin reduced tert-butyl hydroperoxide hepatic damage, attenuated glutathione depletion, ALT and AST levels and reduced oxidative stress (Hwang et al 2005). Additionally, further histopathological examination showed a significant reduction in the incidence of hepatic lesions and swelling.

In combination

The combination Sho-saiko-to (a Japanese herbal supplement containing baical skullcap, also known as Minor Bupleurum Combination and Xiao Chai Hu Tang in Mandarin) has been shown to inhibit chemical hepatocarcinogenesis in animals, act as a biological response modifier and suppress the proliferation of hepatoma cells by inducing apoptosis and arresting the cell cycle. These effects may be due to baicalin, baicalein and saikosaponins (from *Bupleurum falcatum*), which have the ability to inhibit cell proliferation (Shimizu 2000). Further testing is required to determine the role of baical skullcap in achieving these effects.

Antioxidant

Several studies have shown baical skullcap constituents to be antioxidant in vitro and in vivo. Flavones produced a concentration-dependent protection of liposome membrane against UV-induced oxidation. The ability to scavenge free radicals and protect against the effects of lipid peroxidation (in this case caused by sunlight irradiation) may in part account for the herb's underlying mechanism of action (Gabrielska et al 1997).

Fourteen flavonoids and flavone glycosides have been demonstrated to possess good free radical scavenging properties in vitro (Gao et al 1999, Lin & Shieh 1996). Baicalin has been found to have the most potent antioxidant effect (Bochorakova et al 2003).

Baicalin's antioxidant effect is based on scavenging superoxide radicals, whereas baicalein is a good xanthine oxidase inhibitor. Xanthine oxidase inhibitors are known to be therapeutically useful for the treatment of hepatitis and brain tumours (Gao et al 2001).

Oxidative stress plays an important role in the pathological process of neurodegenerative diseases including Alzheimer's disease. The protective effects of baical flavonoids on the oxidative injury of neuronal cells have been demonstrated in vitro (Choi et al 2002, Gao et al 2001).

Anti-allergic

Flavonoids have anti-allergic activities and are known to inhibit histamine release from basophils and mast cells. Luteolin and baicalein have been shown to inhibit IgE antibody-mediated immediate and late phase allergic reactions in mice. In an in-vitro study, luteolin and baicalein inhibited IgE-mediated histamine release from mast cells. The compounds also inhibited IgE-mediated TNF-alpha and IL-6 production from mast cells. However, the compounds did not affect the histamine, serotonin or platelet-activating factor-induced cutaneous reactions in rats (Kimata et al 2000). Wogonin, wogonoside and 3,5,7,2',6'-pentahydroxyl flavanone isolated from baical skullcap decrease histamine, leukotriene B4 and IgE in vitro (Lim 2004).

Baicalein is 5–10-fold more potent than the anti-allergic drug azelastine. Baicalein significantly suppressed leukotriene C4 release by polymorphonuclear leukocytes obtained from asthmatic patients compared with healthy subjects (Niitsuma et al 2001).

Neuroprotective

Many in vitro and in vivo trials have demonstrated the neuroprotective effects of flavonoids derived from baical skullcap (Cho & Lee 2004, Heo et al 2004, Piao et al 2004, Shang et al 2006a, Son et al 2004).

Cerebral ischaemia can cause a significant elevation in the concentrations of amino acid neurotransmitters in the cerebral cortex. Baicalin administration can attenuate the elevations of glutamic acid and aspartic acid induced by cerebral ischaemia. This research demonstrates that baicalin may act as a neuroprotectant during cerebral ischaemia. Wogonin has been shown to exert a neuroprotective effect by inhibiting microglial activation, which is a critical component of pathogenic inflammatory responses in neurodegenerative diseases. Wogonin inhibited inflammatory activation of cultured brain microglia by diminishing lipopolysaccharide-induced TNF-alpha, IL-1-beta and NO production. Wogonin inhibited NO production by suppressing iNOS induction and NF-kappa-B activation in microglia. The neuroprotective effect of wogonin has also been shown in vivo using two experimental brain injury models (Lee et al 2003).

An in vivo study in rats induced with permanent global ischaemia demonstrated that daily oral doses of baical skullcap flavonoids (35 mg/kg) for 19–20 days statistically increased learning and memory ability and attenuated neural injury (Shang et al 2005). A follow-up in vivo study demonstrated that the flavonoid fraction also reduced neural damage and memory deficits after permanent cerebral ischaemia (Shang et al 2006b).

Another in vivo study investigated the neuroprotective effects of baicalein in a Parkinsonian experimental model and demonstrated improved motor coordination and a reduction in spontaneous motor activity (Cheng et al 2008). This was thought to be the result of increased dopamine and serotonin levels in the striatum, leading to increased dopaminergic neurons and an inhibition of oxidative stress. Baical skullcap is used in TCM for the treatment of stroke. Methanol extracts from the dried roots (0.1–10 mg/kg IP) significantly protected neurons against 10 min transient forebrain ischaemia. The extract inhibited microglial TNF-alpha and NO production, and protected cells from hydrogen peroxide-induced toxicity in vitro (Kim et al 2001).

Hypotensive

Treatment with baicalein lowered blood pressure in hypertensive but not in normotensive rats according to one study (Takizawa et al 1998). Baical extract and baicalein have also been shown to lower blood pressure in rats and cats (Kaye et al 1997, Takizawa et al 1998). The exact mechanisms underlying the hypotensive action are unclear. One in vivo study has shown that *Scutellaria baicalensis* extract produces peripheral vasodilatation (Lin et al 1980). A 2005 review concluded that baical skullcap is effective for renin-dependent hypertension and that in vivo effects may be due to the inhibition of lipoxygenase, reducing the production and release of arachidonic-acid derived vasoconstrictor substances (Huang et al 2005).

Vascular activity

Monocyte chemotactic protein-1 (MCP-1), a potent chemoattractant for monocytes, plays a crucial role in cases of early inflammatory responses, including atherosclerosis. Wogonin has been shown to inhibit MCP-1 induction by endothelial cells in a dose-dependent manner. Wogonin and baical skullcap may be potentially beneficial in inflammatory and vascular disorders (Chang et al 2001). Baicalein significantly suppressed intimal hyperplasia and cell proliferation in a vascular injury study in vivo (Peng et al 2008).

Antiplatelet

Baical flavonoids have been shown to inhibit platelet aggregation in vitro (Kubo et al 1985). Baicalein inhibited the elevation of calcium induced by thrombin and thrombin receptor agonist peptide. These findings suggest a potential benefit of baicalein in the treatment of arteriosclerosis and thrombosis (Kimura et al 1997).

Cholesterol reduction

Flavonoids are known to reduce cholesterol. A 30-day study of induced hyperlipidaemia in rats found that baicalein, quercetin, rutin and naringin reduced cholesterol, with baicalein the most potent. Baicalein was also the most effective flavonoid in reducing triglyceride levels (De Oliveira et al 2002). In another in vivo study, rats were fed a cholesterol-laden diet and half were also given *S. baicalensis* radix extract (Regulska-Ilow et al 2004). The treatment rats displayed a significant reduction in plasma triglycerides and total cholesterol compared with control animals. The mechanism may be due to the increased activity of lecithin cholesterol acyltransferase (You et al 2008).

Anxiolytic

Wogonin, baicalein, scutellarein and baicalin (in reducing order of potency), which all contain a certain flavonoid phenylbenzopyrone nucleus, have been shown in vitro to bind with the benzodiazepine site of the GABA-A receptor (Hui et al 2000).

Oral administration of wogonin (7.5–30 mg/kg) has been shown to interact with GABA-A receptors and produce an anxiolytic response that was similar to diazepam in the elevated plus-maze. Unlike benzodiazepines, wogonin was able to reduce anxiety without causing sedation or myorelaxation (Hui et al 2002, Kwok et al 2002).

Baicalin (10 mg/kg IP) and baicalin (20 mg/kg IP) have also been shown in vivo to produce an anxiolytic effect, mediated through activation of the benzodiazepine binding sites of GABA-A receptors (Liao et al 2003).

Two other flavones, 5,7-dihydroxy-6-methoxyflavone (oroxylin A) and 5,7,2'-trihydroxy-6,8-dimethoxyflavone (K36), also act as antagonists at the GABA-A recognition site and have demonstrated anxiolytic activity in vivo (Huen et al 2003a, b).

A water-extract of baical skullcap demonstrated anticonvulsant activity against electroshock-induced tonic seizures in vivo. Interestingly, the authors suggest that the effect might not be via the activation of the benzodiazepine binding site of GABA-A receptors, but probably via the prevention of seizure spread (Liao et al 2003, Wang et al 2000). A more recent study has shown that wogonin has anticonvulsive effects mediated by GABA (Park et al 2007).

Antimicrobial

Numerous studies have found that baical extract and flavonoids exert antibacterial, antiviral and antifungal actions. The antimicrobial effect of baical extract is mild and the clinical efficacy of baical in infectious diseases may be more associated with its anti-inflammatory rather than its antimicrobial activities.

Antibacterial

Baical skullcap decoction was investigated for bacteriostatic and bactericidal activity against a selection of oral bacteria, including suspected periodontopathogens. At a concentration of 2%, the decoction was bacteriostatic for 8 of 11 bacteria tested, but a

concentration of 3.13% or greater was required for bactericidal effect (Tsao et al 1982).

Baical aqueous-extract, but not its flavonoids, baicalin and baicalein, demonstrated antibacterial effects against the enteric pathogen *Salmonella typhimurium*. The effect was compatible with commercial antibiotics including ampicillin, chloramphenicol, and streptomycin. In contrast, the growth of a non-pathogenic *Escherichia coli* strain was unaffected by baical (Hahm et al 2001). One study demonstrated that the addition of baical skullcap in vitro improved the responsiveness of antibiotics for the treatment of MRSA (Yang et al 2005).

Baicalin has been shown to reduce the pathogenic effects of superantigenic staphylococcal exotoxins by inhibiting the signalling pathways activated by superantigens (Krakauer et al 2001).

Antiviral

Antiviral effects have been demonstrated for baical in numerous in vitro and in vivo tests. Baical extract significantly inhibits hepatitis C RNA replication in vivo (Tang et al 2003) and in vitro studies have found that:

- Intraperitoneal and intranasal administration of baical flavonoids significantly inhibits influenza virus in vivo and in vitro (Nagai et al 1989, 1992a, 1992b, 1995a, 1995b).
- Baicalein inhibits HIV-1 infection at the level of viral entry (a process known to involve interaction between HIV-1 envelope proteins and the cellular CD4 and chemokine receptors) (Li et al 2000b).
- Baicalin inhibits human T-cell leukaemia virus type I (HTLV-I) (Baylor et al 1992).
- Aqueous extract inhibits HIV type-1 protease (Lam et al 2000).
- Baicalin inhibits HIV-1 infection and replication (Li et al 1993).
- Baical flavonoids inhibit Epstein-Barr virus early antigen activation (Konoshima et al 1992).
- Wogonin suppresses hepatitis B virus surface antigen production without evidence of cytotoxicity (Huang et al 2000).
- 5,7,4'-trihydroxy-8-methoxyflavone inhibits the fusion of influenza virus with endosome/lysosome membrane (Nagai et al 1995a).
- Virus replication is suppressed, partly by inhibiting the fusion of viral envelopes with the endosome/lysosome membrane which occurs at the early stage of the virus infection cycle (Nagai et al 1995b).
- The flavones in baical have potent influenza virus sialidase inhibitory activity and anti-influenza virus activity in vivo (Nagai et al 1992b).
- Baicalin may selectively induce apoptosis of HIV-infected human T-leukaemia (CEM-HIV) cells, which have a high virus-releasing capacity, and stimulate proliferation of CEM-HIV cells, which have a relatively lower capacity of HIV-production (Wu et al 1995).

Antifungal

Antifungal activity has been demonstrated by several studies (Blaszczyk et al 2000, Yang et al 1995). Baical extract showed clear fungistatic activities in vitro against some cutaneous and unusual pathogenic fungi, and particularly against strains of *Candida albicans*, *Cryptococcus neoformans* and *Pityrosporum ovale*. The antifungal substance was isolated and found to be baicalein (Yang et al 1995). Of 56 Chinese antimicrobial plants, baical root extract had the highest activity against *C. albicans* (Blaszczyk et al 2000).

Anti-ulcerogenic

Extracts prepared from grass and roots of *S. baicalensis* showed high anti-ulcerogenic activity in vivo (Amosova et al 1998).

Antidiabetic

5-alpha-aldose inhibition

Diabetic patients may accumulate intracellular quantities of the sugars sorbitol and dulcitol, because of an increase in the polyol pathway involving the enzyme 5-alpha-aldose. Oral baicalin and liquid extract of licorice (also rich in flavonoids) reduced the sorbitol levels in the red blood cells of diabetic rats (Lin et al 1980, Zhou & Zhang 1989).

Alpha-glucosidase inhibition

Alpha-glucosidase inhibitors (e.g. acarbose) are a class of oral medicine for type 2 diabetes, which blocks the enzymes that digest starches in food. The result is a slower and lower rise in blood glucose throughout the day, especially immediately after meals. Methanol extracts of *S. baicalensis*, *Rheum officinale* and *Paeonia suffruticosa* showed potent inhibitory activity against rat intestinal sucrase. The active principles were identified as baicalein and methyl gallate (from the latter two plants). In addition to its activity against the rat enzyme, baicalein also inhibited human intestinal sucrase in vitro (Nishioka et al 1998).

Anti-emetic

Pretreatment with baical root extract has been shown to decrease cisplatin-induced pica in rats (animal models use the level of kaolin [type of clay] intake as a measure of the intensity of nausea). This suggests that baical may help to reduce cisplatin-induced nausea and emesis during cancer therapy (Aung et al 2003, Mehendale et al 2004, Wu et al 1995), although clinical testing is required to confirm significance.

Two in vivo trials found that *S. baicalensis* significantly attenuated ritonavir-induced pica, and demonstrated possible efficacy for the management of ritonavir-induced nausea in HIV treatment (Aung et al 2005, Mehendale et al 2007).

Renal–urinary tract activity

Baicalein inhibited angiotensin II-induced increases in the cellular protein content of aortic smooth muscle cells in vitro (Natarajan et al 1994). In another in vitro study, baicalein prevented the angiotensin II-induced increase in renal vascular resistance by 50% and promoted glomerular filtration rate (Bell-Quilley et al 1993). Pretreatment with baicalein significantly inhibited a decrease in nephrotoxin-induced

glomerular filtration rate and renal blood flow in vivo (Wu et al 1993). Oral intake of baical flavonoids and extract has been shown to produce a diuretic effect.

Anticancer

Immunostimulation (in combination)

Sho-saiko-to has been shown to stimulate granulocyte colony-stimulating factor (G-CSF), which may explain its use in infectious diseases and cancer (Yamashiki et al 1992). Like growth hormone, IL-2 and -4 and interferon, G-CSF is a signalling ligand that stimulates immune function. G-CSF, a glycoprotein produced mainly by macrophages, induces proliferation of neutrophil colonies and differentiation of precursor cells to neutrophils. It also stimulates the activity of mature neutrophils (Hill et al 1993).

Sho-saiko-to is known to significantly suppress cancer development in the liver. Moderate regulation of the cytokine production system in patients with hepatitis C by using Sho-saiko-to may be useful in the prevention of disease progression (Yamashiki et al 1997). One possible mechanism for the beneficial effects of this formula in patients with liver cirrhosis may be the improvement in production of IL-12, which is an important cytokine for maintenance of normal systemic defence and bioregulation. This effect of Sho-saiko-to is attributed to two of its seven herb components, baical and licorice root (Yamashiki et al 1999).

Patients who were given baical skullcap showed a tendency towards an increase in the relative number of T-lymphocytes and their theophylline-resistant population during antitumour chemotherapy. The immunoregulation index in this case was approximately twice the background value during the period of investigation. The inclusion of baical skullcap in the therapeutic complex promoted an increase in the number of immunoglobulins A at a stable level of IgG (Smolianinov et al 1997).

Apoptosis induction

Baicalein, baicalin and wogonin have been shown to induce apoptosis, disrupt the mitochondria and inhibit proliferation in various human hepatoma cell lines (Chang et al 2002, Chen et al 2000). The platelet-type 12-lipoxygenase (12-LOX) pathway is a critical regulator of prostate cancer progression and apoptosis by affecting various proteins regulating these processes. Baicalein inhibits 12-LOX and may be a potential therapeutic agent in the treatment of prostate cancer (Pidgeon et al 2002) as well as breast cancer (Tong et al 2002) and lung cancer (Leung et al 2007).

Antiproliferative

Baicalein, baicalin and wogonin have been shown to induce apoptosis and inhibit proliferation in various human hepatoma cell lines (Chang et al 2002).

Baicalin has been shown to inhibit the proliferation of prostate cancer cells in vitro. However, the response to baicalin differed among different cell lines (Chan et al 2000).

COX-2, which converts arachidonic acid to PGE_2, is highly expressed in head and neck squamous cell carcinoma (HNSCC). *S. baicalensis*, but not baicalein, suppressed proliferation, cell nuclear antigen expression and PGE_2 synthesis. A 66% reduction in tumour mass was observed in the mice with HNSCC. Baical selectively and effectively inhibits cancer cell growth in vitro and in vivo and can be an effective chemotherapeutic agent for HNSCC (Zhang et al 2003).

In a study designed to determine the ability of baical skullcap to inhibit various human cancer cells in vitro, *S. baicalensis* demonstrated a significant dose-dependent, growth inhibition on squamous cell carcinoma, breast cancer, hepatocellular carcinoma, prostate carcinoma and colon cancer cell lines (Ye et al 2002). Prostate and breast cancer cells were particularly sensitive. Baical skullcap has also been shown to arrest mouse leukaemia cell proliferation in vivo (Ciesielska et al 2002, 2004). Inhibition of PGE_2 synthesis via suppression of COX-2 expression may be responsible for its anticancer activity (Ye et al 2002). Differences in the biological effects of baical compared with baicalein suggest synergistic effects among components in baical (Zhang et al 2003). Another study has shown complete inhibition of acute lymphatic leukaemia, myeloma and lymphoma cell lines in vitro (Kumagai et al 2007). Baicalein, baicalin and wogonin have been shown to reduce proliferation of human bladder cancer cell lines in a dose-dependent manner, but baicalin exhibited the greatest antiproliferative activity. In an in vivo study baical skullcap extract had a significant inhibition of tumour growth ($P < 0.05$) (Ikemoto et al 2000).

Baical skullcap significantly inhibited prostate-specific antigen production and reduced PGE_2 synthesis via direct inhibition of COX-2 activity in vitro (Ye et al 2007). The extract also reduced cyclin D1, resulting in a G1 phase arrest, and inhibited cyclin-dependent kinase 1 (cdk1) expression and kinase activity leading to a G2/M cell cycle arrest. An animal study reported a 50% reduction in tumour volume after 7 weeks (Ye et al 2007). Another study found that baicalein, wogonin, neobaicalein and skullcap-flavone inhibited prostate cancer cell proliferation in vitro (Bonham et al 2005). Additionally, the in vivo phase of the study found that baicalein (20 mg/kg/day) reduced the growth of prostate cancer xenografts in mice by 55% after 2 weeks.

Wogonin inhibited PMA-induced COX-2 protein and mRNA levels in human lung epithelial cancer cells (Chen et al 2008). It appears that this was due to activator protein 1 (AP1) inhibition.

Adjunct to chemotherapy

In experiments with murine and rat transplantable tumours, baical skullcap extract treatment improved cyclophosphamide and 5-fluorouracil-induced myelotoxicity and decreased tumour cell viability

(Razina et al 1987). Wogonin has also demonstrated the ability to hasten etoposide-induced apoptotic cell death (Lee et al 2007). Another in vitro study found that wogonin increased apoptosis and induced cell cycle arrest at the G2/M phase (Himeji et al 2007).

Prevention of metastases

The advancement of Pliss' lymphosarcoma in rats is associated with disorders of platelet-mediated haemostasis, presenting with either lowered or increased aggregation activity of platelets. Extract of baical was shown to produce a normalising effect on platelet-mediated haemostasis whatever the pattern of alteration. This activity is thought to be important for antitumour and, particularly, metastasis-preventing effects (Razina et al 1989).

Experiments in mice inoculated with metastasising Lewis lung carcinoma showed that the antitumour and antimetastatic effects of cyclophosphamide are potentiated by baical, rose root (*Rhodiola rosea*), licorice (*Glycyrrhiza glabra*), and their principal acting components, baicalin, paratyrosol and glycyrrhizin (Razina et al 2000).

Chemoprevention

Baicalein prevents chemically-induced DNA damage in a cell culture model (Chan et al 2002).

Anti-angiogenesis

Baicalein and baicalin have demonstrated anticancer activity against several cancers in vitro. The flavonoids have also been shown to be potent inhibitors of angiogenesis in vitro and in vivo. Baicalein was found to be more potent than baicalin (Liu et al 2003).

Cytochrome Inhibition

Baical flavonoids inhibit hepatic cytochromes CYP1A2 and CYP3A2 in vitro and in vivo (Kim et al 2002, de Boer et al 2005).

CLINICAL USE

Baical skullcap is an ingredient in the very popular traditional Chinese/Japanese formulation, Minor Bupleurum Combination, also known as Xiao Chai Hu Tang (Chinese) and Sho-saiko-to (Japanese). Minor Bupleurum Combination has been used in China for about 3000 years for the treatment of pyretic diseases.

Minor Bupleurum Combination (Sho-saiko-to) is now a prescription drug approved by the Ministry of Health and Welfare of Japan and widely used in the treatment of chronic viral liver diseases. Since 1999, Sho-saiko-to has been administered to 1.5 million patients with chronic liver diseases, because it can significantly suppress cancer development in the liver (Yamashiki et al 1999). Sho-saiko-to is also used for the treatment of bronchial asthma in Japan (Nakajima et al 2001). As such, many studies have been conducted with the herbal combination making it difficult to determine the role of baical skullcap as a stand-alone treatment.

Minor Bupleurum Combination (Sho-saiko-to, Xiao Chai Hu Tang)

- *Bupleurum falcatum* (bupleurum)
- *Scutellaria baicalensis* (baical skullcap)
- *Pinellia ternata* (pinellia)
- Panax ginseng (Korean ginseng)
- *Zizyphus jujuba* (zizyphus)
- *Glycyrrhiza uralensis* (Chinese licorice)
- *Zingiber officinale* (ginger)

Respiratory infection

Sixty patients with respiratory infection (mainly nosocomial pneumonia) were treated either by injection of baical compound or piperacillin sodium (IV). The total efficacy was evaluated after treatment for 1 week.

- Total effective treatment rates were 73.3% for baical compared with 76.7% in the antibiotic treatment group.
- Body temperature was decreased similarly and symptoms disappeared or were relieved in 11.67 ± 6.75 days with the herb and 11.53 ± 7.30 days with the antibiotic.
- In the piperacillin sodium group, fungal infections occurred in 4 of 30 patients, but there were none in the baical treatment group (Lu 1990).

Bone marrow stimulation during chemotherapy

Haemopoiesis was studied in 88 patients with lung cancer during combination treatment with chemotherapy and a *S. baicalensis* extract. Administration of the plant preparation was associated with haemopoiesis stimulation, intensification of bone marrow erythrocytopoiesis and granulocytopoiesis, and increased numbers of circulating precursors of erythroid and granulomonocytic colony-forming units (Goldberg et al 1997).

Epilepsy (in combination with other herbs)

Saiko-keishi-to, a spray-dried decoction of bupleurum (cinnamon, peony, ginger, licorice, ginseng, pinellia, zizyphus and baical) was administered to 24 people with epilepsy who had frequent uncontrollable seizures (3–5 seizures per day in the most severe case and 5 seizures per month in the mildest case) of various types, despite treatment with pharmaceutical anticonvulsants. Of them, 6 were well controlled with Saiko-keishi-to whereas 13 experienced improvement and 3 showed no effect. No patients experienced worsening of their condition. Two patients dropped out during treatment (Narita et al 1982).

Chronic active hepatitis (in combination with other herbs)

In a double-blind, multicentre clinical study of 222 patients with chronic active hepatitis, Sho-saiko-to was found to significantly decrease AST and ALT values compared with placebo. The difference between the treatment and placebo groups in the mean value was significant after 12 weeks. In patients with chronic active hepatitis type B (HB), a tendency towards a decrease of HB e antigen and an increase of

anti-HB e antibodies was also observed. No remarkable side effects were noticed (Hirayama et al 1989).

Liver fibrosis (in combination with other herbs)

Minor Bupleurum Combination (Sho-saiko-to) has been shown to play a chemopreventive role in the development of hepatocellular carcinoma in cirrhotic patients in a prospective study, and several studies have demonstrated the preventive and therapeutic effects of Sho-saiko-to on experimental hepatic fibrosis (Shimizu 2000). Sho-saiko-to has been shown to inhibit the activation of hepatic stellate cells, the major collagen-producing cells. Sho-saiko-to has a potent antifibrotic effect by inhibiting oxidative stress in hepatocytes and hepatic stellate cells. It is proposed that the active components are baicalin and baicalein, because they both have chemical structures very similar to silybinin, the active compound in *Silybum marianum* (St Mary's thistle), which exhibits antifibrotic activities.

OTHER USES

Because of its wide range of pharmacological effects, baical skullcap is used for many different indications. Although controlled trials are not yet available to determine its effectiveness, evidence from in vitro and animal studies provides a theoretical basis for the following uses:

- chronic inflammatory conditions such as asthma, arthritis and allergies (anti-allergic and anti-inflammatory effects)
- hepatitis (as a hepatoprotective agent)
- common infections such as the common cold (antimicrobial and immunostimulant effects)
- nausea and vomiting (anti-emetic effect)
- mild hypertension (hypotensive activity demonstrated in several animal models).

In practice, baical skullcap is used in combination with other herbs for these conditions.

DOSAGE RANGE

- Dried herb: 6–15 g/day (Bensky & Gamble 1986).
- Liquid extract (1:2): 30–60 mL/week or 4.5–8.5 mL/day in divided doses.

ADVERSE REACTIONS

There have been several case reports of Sho-saiko-to-induced interstitial pneumonia (Liu et al 2002). One case of Sho-saiko-to-induced pneumonia in a patient with autoimmune hepatitis was reported (Katou et al 1999); however, direct toxicity is very low.

Toxicity studies of three different traditional Chinese/Japanese formulations containing baical suggest a very low acute or subchronic toxicity for the herbs in them. The studies found no herb-related abnormalities such as changes in body weight or food consumption, abnormalities on ophthalmological and haematological examination, urinalysis and gross pathological examination, changes in organ weights or optical microscopic examination (Iijima et al 1995, Kanitani et al 1995, Kobayashi et al 1995, Minematsu et al 1992, 1995). The acute lethal activity of wogonin is low, with an LD_{50} of 3.9 g/kg (Kwok et al 2002).

SIGNIFICANT INTERACTIONS

There are reports of baical flavonoids interacting with P450 enzymes. Baical flavonoids inhibit hepatic CYP1A2 (Kim et al 2002) and CYP2E1 expression (Jang et al 2003). Theoretically, inhibition of CYP1A2 and CYP2E1 may affect certain medical drugs metabolised by these P450 enzymes. There are, however, no clinical reports of such herb–drug interactions.

Sho-saiko-to during interferon therapy

Sho-saiko-to, as well as interferon, is used for the treatment of chronic hepatitis. There have been reports of acute pneumonitis due to a possible interferon–herb interaction. Pneumonitis, also called extrinsic allergic alveolitis, is a complex syndrome caused by sensitisation to an allergen. The mechanism of the Sho-saiko-to–interferon interaction seems to be due to an allergic–immunological mechanism rather than direct toxicity (Ishizaki et al 1996) — contraindicated.

Cyclosporin

A decoction of *S. baicalensis* has been reported to significantly decrease plasma levels of cyclosporin in rats. The co-administration of these two substances should be avoided until further research is available (Lai et al 2004).

Warfarin/anticoagulants

Increased risk of bleeding is theoretically possible — use with caution.

CONTRAINDICATIONS AND PRECAUTIONS

Baical skullcap and the formulation Sho-saiko-to (Minor Bupleurum Combination, Xiao Chai Hu Tang) are contraindicated during interferon therapy. Baical is contraindicated in cold conditions in TCM.

PREGNANCY USE

Baical is used in TCM for restless fetus (threatened abortion) and toxaemia of pregnancy. A recent animal study found that baical skullcap combined with *Atractylodes macrocephala* had an anti-abortive effect through inhibition of maternal–fetal interface immunity. The herbs prevented lipopolysaccharide-induced abortion by reducing natural killer cells and interleukin 2 activity (Zhong et al 2002). Although this is encouraging, safety in pregnancy is still unknown.

PATIENTS' FAQs

What can this herb do for me?

Baical skullcap may be useful as an adjunctive therapy during cancer treatment to reduce nausea and immune suppression. Baical skullcap may also be beneficial in the treatment of vascular disorders, allergies, liver disease and infections, hypertension and arthritis; however, effectiveness is largely unknown.

When will it start to work?

For acute allergic and infectious conditions, the beneficial effects of baical skullcap should be noticeable within a few days. For chronic diseases, long-term use is recommended.

Are there any safety issues?

Baical skullcap is a safe and non-toxic herb, which is used in both acute and chronic conditions. It should only be used during pregnancy on the recommendation of a healthcare practitioner. Baical and the formulation Sho-saiko-to (Minor Bupleurum Combination known as Xiao Chai Hu Tang in Mandarin) are contraindicated during interferon therapy.

PRACTICE POINTS/PATIENT COUNSELLING

- Baical skullcap is a traditional Chinese herb used to treat fever, cough with thick yellow sputum, thirst and irritability, nausea, jaundice and diarrhoea.
- Baical skullcap extract, many of its constituents, and as part of herbal combination treatments, has been studied in many different experimental models. However, few clinical trials have been conducted using baical as a stand-alone treatment.
- It is used to treat chronic inflammatory conditions such as asthma, arthritis and allergy, because of its anti-inflammatory and anti-allergic effects.
- It is used as a hepatoprotective agent in the treatment of hepatitis.
- Because of its antimicrobial and immunostimulant effects, baical is used to treat infections such as the common cold and bronchitis.
- Anti-emetic effects suggest a role in nausea and vomiting.
- Hypotensive activity demonstrated in various animal models provides a basis for its use in hypertension.
- In practice, it is combined with other herbal medicines for a more targeted approach.

Beta-carotene

BACKGROUND AND RELEVANT PHARMACOKINETICS

Carotenoids

The carotenoids are a family of bright yellow, orange and red compounds found in fruit, vegetables and some animal products such as salmon, lobster and egg yolk. Carotenoids can be divided into the provitamin A group, such as beta-carotene, and xanthophylls such as lutein, zeaxanthin and lycopene, which are important fat-soluble antioxidants. Of the 600 or so carotenoids known to exist in nature, approximately 20 are found in humans. In plants, carotenoids play a vital role in photosynthesis and participate in the energy-transfer process, as well as protecting plants from oxidative damage. The red, orange and yellow colours of these compounds is due to their preferential absorption of blue light, which is the most energetic and hence the most biologically damaging part of the visible spectrum.

In animals, carotenoids have many functions. In addition to providing direct photoprotection via absorption of blue light, carotenoids act as powerful fat-soluble antioxidants linked to oxidation prevention. They also play a role in cellular communication, including stimulation of gap-junction communication which is important for cancer prevention, by regulating cell growth, differentiation, apoptosis and angiogenesis. Carotenoids may also be involved in detoxification of carcinogens, DNA repair and immunosurveillance. These properties are believed to contribute to their antioxidant, immune-enhancing, anticarcinogenic and photoprotective activity.

Beta-carotene was the first of the carotenoids to be discovered, being initially isolated from carrots. The bioavailability of beta-carotene is dependent on its source. In raw foods such as carrots it forms part of a protein-polysaccharide matrix, and absorption is only about 20% of absorption from supplemental forms. Although beta-carotene is lipid soluble, its absorption requires only a limited amount of fat (Roodenburg et al 2000); however, there is a wide individual variation in serum response to beta-carotene administration (Bowen et al 1993, Pryor et al 2000).

Although it has been suggested that different carotenoids compete for absorption, this was not confirmed by a postprandial study (Tyssandier et al 2002). Beta-carotene is absorbed in the intestine and released into the lymphatic circulation within chylomicrons. It is then taken up by hepatocytes and released into the blood, and transported predominantly within LDLs. It is distributed to adipose tissue and the skin and excreted in the faeces (Micromedex 2003). The time to reach peak concentration is up to 4–6 weeks with oral dosing (Mathews-Roth 1990a).

Animal feeding studies suggest that a natural algae-derived beta-carotene isomer mixture is more readily absorbed than synthetic all-*trans* beta-carotene, and that this higher bioavailability can be enhanced by increasing dietary lipid levels (Mokady & Ben-Amotz 1991). Natural algal beta-carotene has also been shown to have higher accumulation in rat liver than synthetic all-*trans* beta-carotene (Ben-Amotz et al 1989, Takenaka et al 1993) with at least a 10-fold higher accumulation having been observed in chick and rat liver (Ben-Amotz et al 1989).

Animal studies suggest that there is some bioconversion within the body between different stereoisomers of beta-carotene (Ben-Amotz et al 2005). Further studies in humans suggest that, regardless of the isomer mix, there is preferential absorption or transport of the all-*trans* isomer in comparison with the 9-*cis* isomer, with plasma levels of the all-*trans* isomer being around 10 times that of the 9-*cis* form (Gaziano et al 1995b, Jensen 1987, Morinobu et al 1994, Stahl & Sies 1993, Tamai et al 1993).

It is suggested that *Helicobacter pylori* infection may impair the protective role of alpha-tocopherol and beta-carotene in the stomach, because infected people have been found to have reduced beta-carotene concentrations in gastric juice, and the presence of gastric atrophy and intestinal metaplasia is associated with reduced mucosal alpha-tocopherol and beta-carotene concentrations (Zhang et al 2000).

Chemical components

Beta-carotene comes in natural and synthetic forms. The natural form is derived mainly from algal sources and consists of roughly equal amount of 9-*cis* and all-*trans* isomers, with small amounts of the 13-*cis* isomer. Synthetic beta-carotene is primarily composed of the all-*trans* isomer, with small residues of the 13-*cis* isomer (PDRHealth 2005). Although all-*trans* beta-carotene is converted into vitamin A, which plays an essential role in vision, growth, reproduction, immune function and maintenance of the skin and mucous membranes (see Vitamin A monograph), the 9-*cis* isomer is not converted into vitamin A but does act as a powerful antioxidant (Ben-Amotz & Levy 1996).

Food sources

Carrots are the major contributors of beta-carotene in the diet, but it is also found in rockmelon, broccoli and spinach. Carotenoids have emerged as the best single tissue marker for a diet rich in fruits and vegetables, and measurements of plasma and tissue carotenoids have an important role in defining the optimal diets for humans (Handelman 2001).

Natural beta-carotene for use in supplements is generally obtained from palm oil or the micromarine algae (phytoplankton) *Dunaliella salina* (also known as *D. bardawil*), which is the richest natural source of beta-carotene. Whole dried *D. salina* is also available in a supplemental form that contains between 1% and 2% beta-carotene. The typical Western diet is estimated to provide approximately 2–4 mg/day of beta-carotene (Pryor et al 2000).

Deficiency signs and symptoms

Beta-carotene is considered a conditionally essential nutrient and becomes an essential nutrient when the dietary intake of retinol (vitamin A) is inadequate.

Low serum beta-carotene levels have been associated with male gender, younger age, lower non-HDL-cholesterol, greater ethanol consumption and higher BMI (Brady et al 1996), insulin resistance (Arnlöv et al 2009), increased lipoprotein density and the presence of inflammation (Kritchevsky 1999), high C-reactive protein (Erlinger et al 2001, Wang et al 2008), high blood glucose (Abahusain et al 1999), hypertension (Coudray et al 1997), exposure to environmental tobacco smoke (Farchi et al 2001), as well as all measures of obesity (Wallstrom et al 2001), including obesity in children (Strauss 1999).

Low serum beta-carotene and/or low beta-carotene intake has also been associated with a number of clinical conditions, such as breast cancer (Hacisevki et al 2003), non-melanoma and melanoma skin cancer (Gollnick & Siebenwirth 2002), rheumatoid arthritis (Kacsur et al 2002), Alzheimer's dementia (Jimenez-Jimenez et al 1999), age-related macular degeneration (Cooper et al 1999a), metabolic syndrome (Revett 2008, Sugiura et al 2008), poor glycaemic control and type 2 diabetes (Abahusain et al 1999, Arnlöv et al 2009, Coudray et al 1997). It has been further shown that the inverse association between serum carotenoid and metabolic syndrome is more evident in current smokers (Revett 2008; Sugiura et al 2008).

Low serum beta-carotene has been independently associated with an increased all-cause mortality risk in older men. Apparently, a synergistic effect occurs between low beta-carotene and high inflammation burden in predicting higher mortality rates (Hu et al 2004). In another study of 668 hospitalised patients aged 70 years or over and 104 healthy controls, the diseased elderly people had reduced plasma levels of retinol, beta-carotene and alpha-tocopherol (Tebi et al 2000). It is unclear whether these observed low levels of beta-carotene seen in disease states are a cause or a result of disease processes.

MAIN ACTIONS

Pro-vitamin A

Beta-carotene is converted to retinoic acid (vitamin A — see Vitamin A monograph) by an enzyme found in the intestinal mucosa and liver, with 2 μg of all-*trans* carotene being equal to 1 μg of all-*trans* retinol (vitamin A) or 3.33 IU (PDRHealth 2005). This conversion is regulated by vitamin A status and may be enhanced by alpha-tocopherol (Wang & Krinsky 1998). Zinc may also be important for bioconversion, as indicated by a double-blind, placebo-controlled trial of 170 pregnant women that found that supplementation zinc improved the postpartum vitamin A status of both mothers and infants (Dijkhuizen et al 2004).

Immunomodulation

The mechanisms by which beta-carotene influences immune function are not well understood, and both direct and indirect effects on immune function, via its pro-vitamin A activity, have been demonstrated (Watson et al 1991). Beta-carotene directly influences immune function by reducing oxidative damage to cell membranes and their receptors, by influencing the activity of redox-sensitive transcription factors and the production of cytokines and prostaglandins, and by enhancing cell-to-cell communication (Hughes 2001).

These actions are influenced by several factors, such as dose and timing of supplementation, age and health status of the individual. A double-blind, placebo-controlled, randomised crossover study in 25 healthy adult-male non-smokers found that 15 mg/day of beta-carotene enhanced cell-mediated immune responses, with significant increases in the percentages of monocytes expressing the major histocompatibility complex class II molecule HLA-DR and adhesion molecules, as well as increased ex vivo tumour necrosis factor alpha (TNF-alpha) secretion by blood monocytes (Hughes et al 1997). Beta-carotene has also been shown to increase plasma levels of TNF-alpha in patients given 30 mg/day for the treatment of oral leucoplakia (Prabhala et al 1993).

In controlled trials, supplementation with 30 mg beta-carotene was shown to protect against UV-induced photosuppression of immune function in young men (Fuller et al 1992), as well as in older men, with serum beta-carotene levels being significantly associated with maintenance of the delayed-type hypersensitivity response (Herraiz et al 1998). Another controlled trial found that 60 mg/day beta-carotene for 44 weeks increased the CD4–CD8 ratio after 9 months without affecting NK cells, virgin T cells, memory T cells or cytotoxic T cells in healthy male non-smokers; supplementation with 60 mg/day beta-carotene for 4 weeks was shown to significantly increase lymphocyte counts and $CD4^+$ in a pilot study of seven patients with AIDS (Murata et al 1994).

Natural killer-cell activity was also found to increase in older adults in a dose-finding study in which 30 mg/day beta-carotene for 2 months significantly increased in a dose-dependent manner the percentage of lymphoid cells with surface markers for T-helper and NK cells, and cells with IL-2 and transferrin receptors (Watson et al 1991). In a further study of 59 men participating in the Physicians Health Study, 10–12 years of supplementation with 50 mg beta-carotene on alternate days was found to increase NK cell activity without increasing the percentage of NK cells, IL-2 production or receptor expression in elderly but not middle-aged men (Santos et al 1996).

Although beta-carotene supplementation has been shown to enhance NK cell responses, there are a number of randomised controlled trials (RCTs) that suggest that it does not influence other aspects of immune activity in healthy individuals. In separate RCTs, supplementation with 90 mg beta-carotene for 3 weeks or 50 mg on alternate days for more than 10 years was not found to influence T-cell-mediated immunity of healthy elderly people (Santos et al 1997), and supplementation with 30 mg beta-carotene was not found to affect the T-lymphocyte proliferative response to phytohaemagglutinin in healthy lactating and non-lactating women (Gossage et al 2000). Another study found that supplementation with 8.2 mg/day of beta-carotene for 12 weeks did not influence several markers of T-cell-mediated immunity in well-nourished, healthy elderly individuals (Corridan et al 2001).

Antioxidant

Beta-carotene has consistently demonstrated antioxidant activity in vitro, although the mechanism of action is poorly understood. At low partial pressures of oxygen, such as those found in most tissues under physiological conditions, it exhibits good radical-trapping antioxidant behaviour; this capacity is lost at high oxygen pressures in vitro with autocatalytic, pro-oxidant effects observed (Burton & Ingold 1984).

Beta-carotene has been shown to quench singlet oxygen, scavenge peroxyl radicals and inhibit lipid peroxidation in vitro; however, there is ongoing debate about its ability to act as an antioxidant in vivo, with some evidence suggesting this varies from system to system for reasons that are poorly understood (Pryor et al 2000).

Beta-carotene acts synergistically with other antioxidants, such as vitamins E and C, or other dietary components as part of the antioxidant network (see Vitamin E monograph). A combination of beta-carotene and alpha-tocopherol has been shown to inhibit lipid peroxidation significantly more than the sum of the individual inhibitions in a membrane model (Palozza & Krinsky 1992), and a synergistic effect has also been demonstrated in vitro and in vivo with vitamins E and C (Bohm et al 1997, 1998a).

In vivo studies

A number of studies have demonstrated that beta-carotene has antioxidant activity in vivo. Supplementation with 180 mg of beta-carotene for 2 weeks was found to increase the beta-carotene content of LDL and significantly reduce plasma lipid peroxidation and LDL susceptibility to oxidation, as analysed by malondialdehyde generation (Levy et al 1996). Similarly, lipid peroxidation as measured by breath pentane output was found to be significantly reduced in healthy subjects by 4 weeks of daily supplementation with 120 mg of beta-carotene (Gottlieb et al 1993). In a case-controlled trial involving 20 patients with long-standing type 1 diabetes mellitus, as well as age- and sex-matched controls, supplementation with 60 mg/day of natural algae-derived beta-carotene for 3 weeks was found to significantly reduce malondialdehyde and lipid peroxide production and the increased susceptibility towards LDL oxidation seen in the diabetic subjects (Levy et al 2000). Beta-carotene supplementation was also found to significantly reduce serum lipid peroxidation in a dose-dependent manner in a number of double-blind, placebo-controlled trials (Greul et al 2002, Lee et al 2000). Beta-carotene supplementation has also been demonstrated to significantly reduce lipid peroxidation of erythrocytes membranes in people with beta-thalassaemia (Mahjoub et al 2007).

These results contrast with those from a number of studies that failed to demonstrate any in vivo antioxidant activity. A study of 79 healthy volunteers found that normal concentrations of carotenoids in plasma and tissues did not correlate with total antioxidant capacity of the plasma or breath pentane measurements (Borel et al 1998). In other studies

supplementation was seen to increase LDL beta-carotene without changing LDL susceptibility to oxidation (Princen et al 1992, Reaven et al 1993).

It is possible that beta-carotene is more likely to demonstrate antioxidant activity in conditions of increased oxidative stress. This is suggested by the results of a randomised, double-blind controlled trial that involved 42 non-smokers and 28 smokers who received either 20 mg of beta-carotene or a placebo; this trial showed that beta-carotene reduced lipid peroxidation as indicated by breath pentane output in smokers, but not in non-smokers (Allard et al 1994). This is further supported by a study of whole-body irradiation in rats that found that supplementation with natural algae-derived beta-carotene protected against the reduction in growth rate and the selective decline in 9-*cis* beta-carotene and retinol seen in irradiated animals, as well as partially reversing the effect of irradiation when given after the irradiation (Ben-Amotz et al 1996). Algae-derived beta-carotene was also found to protect against CNS oxygen toxicity in rats, as indicated by a significant increase in the latent period preceding oxygen seizures in supplemented animals (Bitterman et al 1994).

Isomer difference

Individual isomers and isomer mixtures demonstrate different antioxidant properties in vivo. The 9-*cis* isomer, which is present in greater amounts in natural beta-carotene, exhibits higher antioxidant potency than the all-*trans* isomer in vitro (Levin & Mokady 1994). Natural beta-carotene, such as that obtained from algal sources, also exhibits greater antioxidant activity than synthetic beta-carotene in vivo (Takenaka et al 1993).

In humans, supplementation with natural algal beta-carotene containing a 50:50 mix of all-*trans* and 9-*cis* isomers has been shown to be a more effective lipophilic antioxidant than all-*trans* beta-carotene (Ben-Amotz & Levy 1996). Human supplementation with natural algal and synthetic beta-carotene has also been shown to produce similar reductions in LDL oxidation, despite the fact that synthetic beta-carotene produced double the rise in LDL beta-carotene content (Levy et al 1995).

These studies contrasted with in vitro studies that suggest that 9-*cis* beta-carotene and all-*trans* beta-carotene have equal antioxidant activities (Liu et al 2000), and that synthetic beta-carotene is twice as effective as algal beta-carotene in inhibiting LDL lipid peroxidation following LDL incubation with copper ions (Lavy et al 1993).

Photoprotection

Beta-carotene, together with other carotenoids, is present in all photosynthetic organisms where it serves an important photoprotective function, either by dissipating excess excitation energy as heat or by scavenging reactive oxygen species and suppressing lipid peroxidation (Penuelas & Munne-Bosch 2005). Studies in bacteria, animals and humans have demonstrated that carotenoids can prevent or lessen photosensitivity by endogenous and exogenous photosensitisers (Mathews-Roth 1993). High doses of beta-carotene (from 180 mg/day up to 300 mg/day) have been used to treat the photosensitivity associated with erythropoietic protoporphyria (Mathews-Roth 1987). There is also consistent evidence from animal and human studies that beta-carotene has photoprotective effects.

Beta-carotene is present at the target sites of light-induced damage in the dermis, epidermis and stratum corneum, with levels varying in skin areas with higher concentration in the forehead and palms (Alaluf et al 2002). Skin levels are related to the levels found in the plasma (Sies & Stahl 2004). Beta-carotene and other endogenous antioxidants are reduced in both skin and blood by UV exposure (Gollnick et al 1996).

Although it is presumed that beta-carotene exerts a light-protective function by quenching excited species such as singlet oxygen and free radicals (Mathews-Roth 1987), there are a number of other ways that beta-carotene may contribute to photoprotection (i.e. protection against the absorption of UV light). These include the protection of target molecules through its antioxidant activity, enhancement of the repair of UV damage, modulation of enzyme activity and gene expression, enhancement of cell-to-cell communication and suppression of cellular responses and inflammation (Sies & Stahl 2004). It is also suggested that the UVA protection provided by beta-carotene is due to the siting of beta-carotene deep inside membranes in proximity to the UVA chromophores that initiate the cell damage (Bohm et al 1998b).

As a strong natural pigment, beta-carotene produces a yellow-orange colouration in the skin that adds to the red colouration from haemoglobin and the brown colouration from melanin to create the normal human skin colour (Alaluf et al 2002). Beta-carotene acts as a blue light filter by absorbing light in the range of 360–550 nanometers (Pathak 1982), with the *cis* isomers having been found to exhibit an additional absorption maximum in the UV range (Sies & Stahl 2004), thus suggesting a possible advantage for natural beta-carotene over synthetic all-*trans* beta-carotene in providing photoprotection.

As with titanium dioxide, the beta-carotene in the skin takes the form of finely dispersed particles that can increase the natural pigment action. This was observed in a human trial involving 20 subjects that found that supplementation with 50 mg of natural algal beta-carotene for 6 weeks increased the reflection capacity of the skin 2.3-fold, irrespective of the wavelength (Heinrich et al 1998). A study on whole albino hairless mouse skin and epidermis, however, suggests that although beta-carotene did impart a visible change in skin colour its absorbance was insufficient to impart significant photoprotection, which indicates that its photoprotective action is mediated through processes in addition to blue light absorption (Sayre & Black 1992).

In a controlled study injection of phytoene, the colourless triene precursor of beta-carotene was found to significantly reduce radiation-induced erythema in guinea pigs (Mathews-Roth & Pathak 1975); however, a further study on albino hairless mice found that 10 g/kg feed of beta-carotene and

200 mg/kg feed of 13-*cis* retinoic acid for 12 weeks did not prevent UVB-induced dermal damage (Kligman & Mathews-Roth 1990).

An in vitro study on human keratinocytes suggests that beta-carotene dose-dependently suppressed UVA-induction of matrix metalloproteases through quenching of singlet oxygen and that this action was not enhanced by vitamin E (Wertz et al 2004). Further studies suggest that beta-carotene also interferes with UVA-induced gene expression by multiple pathways, including inhibition of UVA-induced extracellular matrix degradation, enhanced UVA induction of tanning-associated protease-activated receptor-2, promotion of keratinocyte differentiation and synergistic induction of cell cycle arrest and apoptosis (Wertz et al 2005).

Beta-carotene has also been observed to have synergistic effects with other antioxidants in protecting cultured human fibroblasts from UVA, although only additive effects were observed for UVB (Bohm et al 1998b). The interaction between different antioxidants and/or other as yet unidentified phytochemicals has been used to explain the finding that UV carcinogenesis was enhanced with a beta-carotene-supplemented semi-defined diet in mice (Black 2004, Black & Gerguis 2003, Black et al 2000).

Enhanced intercellular communication

In addition to its antioxidant activity, beta-carotene enhances gap junction intercellular communication by upregulation of the gap junction protein connexin 43. This action may be important in its control of tumour growth (Yeh & Hu 2003) and is likely to be independent of its ability to quench singlet molecular oxygen (Stahl et al 1997).

Animal studies have indicated that a beta-carotene dose of 50 mg/kg/day for 5 days inhibits, whereas a lower dose (5 mg/kg/day) increases gap junction intercellular communication in rat liver. Further in vitro studies suggest that the observed inhibition is due, at least in part, to oxidised beta-carotene (Yeh & Hu 2003).

Anticarcinogenic activity

Observational epidemiological studies have consistently shown a relationship between dietary beta-carotene intake and low risk of various cancers (Cooper et al 1999b, Pryor et al 2000). In animal studies beta-carotene has been found to be chemoprotective, with inhibition of spontaneous mammary tumours (Fujii et al 1993, Nagasawa et al 1991), as well as prevention of skin carcinoma formation (Ponnamperuma et al 2000), UV-induced carcinogenesis in mice (Epstein 1977, Mathews-Roth 1982) and oral cancer in laboratory and animal models (Garewal 1995). Studies in ferrets suggest that the beta-carotene molecule becomes unstable in smoke-exposed lungs and that when given with alpha-tocopherol and ascorbic acid to stabilise the beta-carotene molecule, there is a protective effect against smoke-induced lung squamous metaplasia (Russell 2002).

A review of carotenoid research by the International Agency for Research on Cancer suggests there is sufficient evidence that beta-carotene has cancer-preventive activity in experimental animals, based on models of skin carcinogenesis in mice and buccal pouch carcinogenesis in hamsters (Vainio & Rautalahti 1998), despite a review suggesting that beta-carotene does not protect against lung cancer in animals (De Luca & Ross 1996).

Whether beta-carotene has anticancer properties in humans is unclear. It has been suggested any such effects could be mediated through multiple mechanisms that may include: antioxidant activity preventing oxidative damage to DNA and inhibition of lipid peroxidation; stimulation of gap junction communication; effects on cell transformation and differentiation; inhibition of cell proliferation and oncogene expression; effects on immune function; and inhibition of endogenous formation of carcinogens (Cooper et al 1999a). Additional mechanisms may include the metabolic conversion of beta-carotene to retinoids, which may in turn modulate the gene expression of factors linked to differentiation and cell proliferation. The modulation of enzymes that metabolise xenobiotics and inhibition of endogenous cholesterol synthesis by modulation of HMG-CoA reductase expression may also lead to a possible inhibition of cell proliferation and malignant transformation (PDRHealth 2005).

None of these mechanisms has been conclusively found to contribute to the prevention of cancer in vivo, and there is ongoing debate about the role of beta-carotene in cancer prevention (Cooper et al 1999a, Patrick 2000). This debate has been further fuelled by the findings of two large intervention studies: the Alpha-Tocopherol Beta-Carotene (ATBC) Cancer Prevention Study (the 'Finnish study': Heinonen et al 1994) and the Carotene and Retinol Efficacy Trial (CARET: Omenn et al 1996b), which found a significantly increased risk of lung cancer in high-risk individuals supplemented with synthetic beta-carotene (see *Clinical use* for more details).

The mixed findings from beta-carotene intervention trials have produced much controversy in the scientific literature and although it has been suggested that there is no known biologically plausible explanation for the findings, a number of hypotheses have been put forward (Bendich 2004). It has been suggested that the dose, duration of study and/or choice of synthetic all-*trans*-beta-carotene may have been inappropriate in the intervention trials (Cooper et al 1999b) and that supplementation with monotherapy using synthetic beta-carotene may have inhibited the absorption of other carotenoids (Woodall et al 1996). It is also suggested that, although beta-carotene may be effective in the prevention of lung cancer before or during the phases of initiation and early promotion of cancer, the intervention studies that involved heavy smokers and asbestos workers probably included individuals in whom these processes were already initiated (Bendich 2004).

Additional possible explanations for the observed increase in lung cancer risk with beta-carotene supplementation include possible pro-oxidant activity of beta-carotene or its oxidative metabolites in the high-oxygen environment of smokers' lungs, with oxidised beta-carotene metabolites inducing

carcinogen-bioactivating enzymes, facilitating the binding of metabolites to DNA, enhancing retinoic acid metabolism by P450 enzyme induction and acting as pro-oxidants, causing damage to DNA (Russell 2002) as well as inhibition of retinoid signalling (Wang et al 1999). It is further suggested that the beta-carotene molecule may become unstable due to the presence of a lower level of antioxidants, such as ascorbic acid, in smokers than in non-smokers (Bohm et al 1997), together with the presence of significant oxidative stress in smokers who consume high amounts of alcohol (PDR Health 2005).

It has further been suggested that beta-carotene may increase lung cancer risk in smokers because of its ability to improve lung function. Thus smokers supplemented with beta-carotene may have increased lung capacity, resulting in deeper breathing of carcinogens and other oxidants. It is also suggested that beta-carotene may improve smokers' immune responses and thus reduce the number of days they suffer from upper respiratory tract infections, which enables them to smoke more (Bendich 2004).

The suggestion that beta-carotene may have pro-oxidant effects is supported by an in vitro study showing that although cell viability and DNA integrity were not affected by beta-carotene, they were significantly and dose-dependently decreased by oxidised beta-carotene (Yeh & Hu 2001). There was a dose-dependent increase of beta-carotene cleavage products, together with increasing genotoxicity in vitro when beta-carotene was supplemented during oxidative stress induced by hypoxia/reoxygenation (Alija et al 2004, 2005). Carotenoid cleavage products have also been found to impair mitochondrial function and increase oxidative stress in vitro (Siems et al 2002, 2005), as well as produce a booster effect on phase I carcinogen-bioactivating enzymes in the rat lung (Paolini et al 1999). Beta-carotene has also been shown to be degraded by stimulated polymorphonuclear leukocytes in vitro, producing highly reactive and potentially toxic cleavage products (Sommerburg et al 2003). These pro-oxidant effects have not been conclusively demonstrated in vivo, and beta-carotene at a dose of 50 mg/day for several years was not found to have pro-oxidant effects in either smokers or non-smokers, as measured by urinary excretion of F2-isoprostanes (Mayne et al 2004).

Cardiovascular protection

There are a number of ways in which beta-carotene may act to protect against cardiovascular disease. Free-radical scavenging may prevent cellular transformations leading to atherosclerosis, and protection of LDL oxidation may further act to protect against atheroma formation (Halliwell 1993). Other mechanisms proposed for the possible favourable effect of antioxidants include an increase of HDL cholesterol and the preservation of endothelial functions (Tavani & La Vecchia 1999). Patients with acute myocardial infarction (AMI) have also been shown to have reduced plasma antioxidant vitamins and enhanced lipid peroxidation upon thrombolysis, suggesting that antioxidants may reduce free-radical generation processes in reperfusion injury in AMI (Levy et al 1998).

In an animal study, atherosclerosis was inhibited in rabbits fed a high-cholesterol diet supplemented with all-*trans* beta-carotene. In that study all-*trans* beta-carotene was undetectable in LDL, although tissue levels of retinyl palmitate were increased, suggesting that any anti-atherogenic effect is separate from the resistance of LDL to oxidation and that metabolites of beta-carotene may inhibit atherosclerosis in hypercholesterolaemic rabbits, possibly via stereospecific interactions with retinoic acid receptors in the artery wall (Shaish et al 1995). A randomised, placebo-controlled trial in 149 male smokers taking 20 mg/day of beta-carotene for 14 weeks, however, found no influence on haemostatic measures, suggesting that it is unlikely that cardiovascular protection from beta-carotene is via an effect on haemostasis (Van Poppel et al 1995).

OTHER ACTIONS

An animal study found that rats supplemented with beta-carotene-rich algae had improved reproduction and body growth, with a markedly lower stillbirth rate, a higher litter size or rearing rate, and enhanced body growth in male offspring (Nagasawa et al 1989).

CLINICAL USE

Vitamin A deficiency

In a series of large, double-blind, cluster-randomised, placebo-controlled field trials involving as many as 44,000 Nepalese women, weekly supplementation with 42 mg of *trans*-beta-carotene was found to reduce the prevalence of selected illness symptoms such as loose stools, night blindness and symptoms of high fever during late pregnancy, at the time of birth and during 6 months post-partum (Christian et al 2000b). Beta-carotene was further found to reduce maternal, but not infant, mortality among smokers and non-smokers by approximately 50%, with a protective effect becoming evident after 18 months of supplementation (Christian et al 2004, West et al 1999). Beta-carotene supplementation has also been found to reduce the five-fold increased risk of infection-related mortality in women who were night-blind because of vitamin A deficiency (Christian et al 2000a). In a randomised controlled trial of children in rural China it was found that beta-carotene supplementation had a similar effect on correcting childhood vitamin A deficiency to retinol supplementation, with reduced morbidity and increased weight. The authors concluded that, considering the health risk of vitamin A supplementation and the easier acquisition and antioxidant value of dietary beta-carotene, dietary beta-carotene supplementation should be recommended for addressing vitamin A deficiency in this population (Lin et al 2009).

These studies contrast with one that found an association between self-reports of poor night vision and beta-carotene consumption in women involved in the Blue Mountain Eye Study, in which the authors concluded that perceived poor

night vision caused an increase in carrot consumption in women (Smith et al 1999).

Cancer prevention

There are at least 35 observational epidemiological studies, including prospective cohort and case-controlled studies, involving smoking and non-smoking men and women from diverse regions of the world, which have found a positive association between dietary or serum beta-carotene levels and reduced risk of cancer (Cooper et al 1999a). This association, however, does not necessarily imply a causal link, because it may be an association between beta-carotene ingestion and other dietary or lifestyle factors (Peto et al 1981). Beta-carotene intake is linked to a variety of healthy dietary and lifestyle factors, as well as being highly correlated with the intake of many other protective dietary phytochemicals and nutrients (Cooper et al 1999a). Furthermore, these results have not always been consistent with a 6-year study of 137,001 European men, which found no link between plasma carotenoids and prostate cancer risk (Key et al 2007), and with a pooled analysis of 11 cohort studies suggesting no link with colorectal cancer risk (Männistö et al 2007). Similarly a pooled analysis of 10 cohort studies involving 521,911 women found no association between dietary carotenoids and the risk of ovarian cancer (Koushik et al 2006).

While the protective effect of dietary carotenoids on cancer risk is still being debated, findings of two large intervention trials have reported an increased lung cancer risk with synthetic beta-carotene supplementation (Heinonen et al 1994, Omenn et al 1996a).

The Alpha-Tocopherol Beta-Carotene (ATBC) Cancer Prevention Study, also known as the Finnish study, was the first large intervention trial to test the hypothesis that beta-carotene reduces the risk of lung cancer. This double-blind, placebo-controlled primary-prevention trial involved 29,133 male smokers, 50–69 years of age, who were randomised to receive daily supplementation with alpha-tocopherol (50 mg/day) alone, synthetic (all-*trans*) beta-carotene (20 mg/day) alone, or both. After a follow-up period of 5–8 years, the results suggested that there was an unexpected 18% increase in the incidence of lung cancer with an associated 8% higher mortality among those who received beta-carotene (Heinonen et al 1994). Subgroup analysis revealed that the increased risk with beta-carotene supplementation was only greater for those who smoked at least 20 cigarettes per day, with the risk of those who smoked 5–19 cigarettes/day being no greater than that of the placebo group. An increased risk was also observed for those who consumed more than 11 g/day alcohol compared with those with a lower alcohol intake (Albanes et al 1996). Further analysis found no effect of beta-carotene supplementation on the risk of pancreatic cancer (Rautalahti et al 1999), colorectal cancer (Albanes et al 2000), urothelial or renal cell cancer (Virtamo et al 2000), or gastric cancer (Malila et al 2002).

The Carotene and Retinol Efficacy Trial (CARET) tested the effect of synthetic, all-*trans* beta-carotene (30 mg) and retinyl palmitate (25,000 IU) on the incidence of lung cancer, other cancers and death in 18,314 participants who were at high risk of lung cancer because of a history of heavy smoking or asbestos exposure. CARET was stopped ahead of schedule in January 1996 because participants who were randomly assigned to receive the active intervention were unexpectedly found to have a 28% increase in incidence of lung cancer, a 17% increase in incidence of death and a higher rate of cardiovascular disease mortality compared with participants in the placebo group (Omenn et al 1996b). Further analysis revealed results similar to the ATBC study, with the increased risk of lung cancer being greatest for heavy smokers and those with the highest alcohol intake, while former smokers were found to have a similar risk to that of those taking placebo (Omenn et al 1996b).

The finding of an increased risk of lung cancer in smokers taking beta-carotene in the ATBC and CARET studies is consistent with a number of other studies. A prospective cohort study of 59,910 French women found that self-reported supplemental use of beta-carotene was directly associated with double the risk of cancers among smokers, yet dietary beta-carotene intake was associated with less than half the risk of tobacco-related cancers among non-smokers in a statistically significant dose-dependent relationship (Touvier et al 2005). Similarly, the results of a case-control study of 362 adenoma cases and 427 polyp-free controls suggest a protective effect for colon cancer with beta-carotene in non-smokers and an adverse effect in smokers (Senesse et al 2005). Alcohol intake and cigarette smoking were also observed to modify the effect of beta-carotene supplementation on the risk of colorectal adenoma recurrence in another double-blind, placebo-controlled clinical trial involving 864 patients randomised to receive either beta-carotene (25 mg), vitamin C (1000 mg) or vitamin E (400 mg), beta-carotene with vitamins C and E, or a placebo; after 4 years this trial found no evidence that supplementation reduced the incidence of adenomas (Greenberg et al 1994). Subgroup analysis from this study, however, found that beta-carotene supplementation was associated with a marked decrease in the risk of one or more recurrent adenomas among subjects who neither smoked cigarettes nor drank alcohol, but conferred a modest increase in the risk of recurrence among those who either smoked or drank alcohol and doubled the risk for those who both smoked and drank (Baron et al 2003).

The results of these studies are contrasted with those from the Physicians' Health Study, which found that beta-carotene supplementation had no effect on cancer risk in smokers or non-smokers. This RCT of 50 mg of synthetic beta-carotene given on alternate days involved 22,071 US male physicians, 11% of whom were smokers. After more than 12 years of follow-up, no overall effect on cancer incidence was evident with beta-carotene supplementation (Hennekens et al 1996) and no benefit or harm was observed for lung, prostate or colon cancer (Cook et al 2000), or for squamous cell

carcinoma (Frieling et al 2000). Subgroup analysis of this study population revealed that total cancer was modestly reduced with supplementation among those aged more than 70 years, and total cancers and colon cancer was reduced in those who drank alcohol daily (Cook et al 2000). Total cancers and prostate cancer were also reduced in those in the highest BMI quartile (Cook et al 2000) and those with low baseline beta-carotene levels (Cook et al 1999), while those with high baseline levels had a non-significant increased risk of prostate cancer with beta-carotene supplementation (Cook et al 1999).

Similar to the results of the Physicians' Health Study the results of the Women's Health Study, which involved 39,876 women supplemented with 50 mg of beta-carotene on alternate days for 2 years, found no benefit or harm from beta-carotene supplementation on the incidence of cancer or cardiovascular disease in apparently healthy women, and no benefit or harm observed for the 13% of women who were smokers at baseline (Lee et al 1999).

In contrast to these results, a RCT performed on a poorly nourished population found a lower cancer incidence with beta-carotene supplementation. This study involved 29,584 adults aged between 40 and 69 years from Linxian County, China, which has one of the world's highest rates of oesophageal/gastric cardia cancer and a persistently low intake of several micronutrients. In this study people were randomised to receive retinol and zinc, riboflavin and niacin, vitamin C and molybdenum, or beta-carotene, vitamin E and selenium, at doses that ranged from one- to two-fold the US RDI for a period of 6 years. Results revealed a significantly lower total mortality among those receiving supplementation with beta-carotene, vitamin E and selenium, mainly attributable to lower cancer rates, especially stomach cancer (Blot et al 1993).

Possible reasons for the mixed results

The mixed results from the beta-carotene intervention studies have created significant debate. The results of a review of carotenoid research by the International Agency for Research on Cancer suggest there is a lack of cancer-preventive activity for beta-carotene when it is used as a supplement at high doses (Vainio & Rautalahti 1998). This is supported by a more recent study that examined the relationship between dietary beta-carotene and lung cancer, using pooled data from seven cohort studies that involved 399,765 participants and 3155 lung cancer cases. This study found that dietary beta-carotene intake was not associated with increased or decreased lung cancer risk in those who had never smoked, past or current smokers (Männistö et al 2004). Similarly a recent systematic review and meta-analysis of six randomised clinical trials examining the efficacy of beta-carotene supplements and 25 prospective observational studies assessing the associations between carotenoids and lung cancer suggests that beta-carotene supplementation is not associated with a significant altered risk of developing lung cancer (Gallicchio et al 2008).

The mixed results from beta-carotene intervention studies may also be a reflection of a difference between natural and synthetic beta-carotene, as the negative intervention studies have all used synthetic rather than natural beta-carotene. These studies, however, do provide consistent evidence for a link between dietary and serum beta-carotene levels and reduced cancer risk. Even in the studies that found an adverse effect of beta-carotene supplementation, study participants with the highest intake and serum concentrations of beta-carotene at baseline developed fewer subsequent lung cancers, regardless of their intervention assignment (Albanes 1999, Holick et al 2002). Therefore, although monotherapy with synthetic beta-carotene is no longer generally recommended, there continues to be a consistent call for an increased consumption of beta-carotene-containing foods to assist in the prevention of cancer (Mayne 1996, Pryor et al 2000).

Oral leucoplakia

Beta-carotene consumption has been found to be inversely associated with precancerous lesions of the oral cavity in tobacco users (Gupta et al 1999), and it is suggested that there is a significant role for antioxidant nutrients in preventing oral cancer (Garewal & Schantz 1995). This is supported by the findings of multiple clinical trials in which beta-carotene and vitamin E have been shown to produce regression of oral leucoplakia, a premalignant lesion for oral cancer (Garewal 1994, Wright et al 2007).

In a more recent, double-blind RCT involving 160 people, 360 mg/week of beta-carotene for 12 months was found to induce regression in oral precancerous lesions, with half of the responders relapsing after ceasing supplementation. Similarly, another multicentre, double-blind, placebo-controlled trial found improvement in dysplasia with 60 mg/day of beta-carotene for 6 months (Garewal et al 1999).

These studies are contrasted with a subgroup analysis involving 409 white male cigarette smokers from the ATBC Study, which suggested that beta-carotene supplementation does not play an essential role in preventing oral mucosal changes in smokers (Liede et al 1998).

Cardiovascular disease

Epidemiological studies support the idea that a diet rich in high-carotenoid-containing foods is associated with a reduced risk of heart disease (Kritchevsky 1999). A review of observational and intervention studies on beta-carotene and the risk of coronary heart disease found that seven cohort studies (Gaziano et al 1995a, Gey et al 1993, Knekt et al 1994, Manson et al 1991, Morris et al 1994, Rimm et al 1993, Street et al 1994) reported relative risks between 0.27 and 0.78 for high serum beta-carotene levels or high dietary intake; the review found that this was supported by case-control studies (Bobak et al 1998, Bolton-Smith et al 1992, Kardinaal et al 1993, Torun et al 1994, Tavani et al 1997) that reported odds ratios between 0.37 and 0.71, with a possible stronger protection for current smokers (Tavani & La Vecchia 1999). These results contrast with those of four more recent cohort studies (Knekt et al 1994, Kushi et al 1996, Pandey et al 1995, Todd et al 1995) and five large RCTs

(Hennekens et al 1996, Lee et al 1999, Redlich et al 1999, Vlot et al 1995) that have not reported any significant prevention of cardiovascular disease with beta-carotene supplementation.

The final results of the Physicians' Health Study (see *Cancer prevention* above) indicated that beta-carotene supplementation exerted no significant benefit or harm on cancer or cardiovascular disease during more than 12 years of treatment (Hennekens et al 1996). Similarly, the results of the Women's Health Study, which involved 39,876 women aged 45 years or older, found that beta-carotene supplementation of 50 mg on alternate days did not influence cardiovascular disease after 2 years of supplementation and 2 years of further follow-up. Subgroup analysis revealed that beta-carotene supplementation had an apparent benefit on subsequent vascular events among 333 men with prior angina or revascularisation (Christen et al 2000).

In contrast, analysis of the data from the ATBC cancer prevention study, which involved 23,144 male smokers, found that beta-carotene supplementation slightly increased the risk of angina (Rapola et al 1996) and intracerebral haemorrhage, while having no overall effect on the risk of stroke (Leppala et al 2000a, 2000b), abdominal aortic aneurysm (Tornwall et al 2001), or symptoms and progression of intermittent claudication (Tornwall et al 1999). Beta-carotene, however, was found to decrease the risk of cerebral infarction modestly among a subgroup with greater alcohol consumption (Leppala et al 2000a, 2000b). In a 6-year post-intervention follow-up study, beta-carotene was found to increase the risk of first-ever myocardial infarction, while continuing to have no overall effect on the incidence of stroke (Tornwall et al 2004). An analysis of 52 men from the CARET study concluded that there was no significant effect on total, HDL or LDL cholesterol levels that could account for the increase risk of cardiovascular disease observed in this study (Redlich et al 1999).

A pooled analysis of four randomised trials of beta-carotene therapy ranging from 20 mg to 50 mg involving 90,054 patients found beta-carotene supplementation to be associated with a significant increase in all-cause mortality and cardiovascular death in patients at risk of coronary disease, with the increased risk being strongest in smokers. A further meta-analysis of eight randomised trials involving 138,113 patients found that supplementation with 15–50 mg of beta-carotene was associated with a small but significant increase in all-cause mortality and a slight increase in cardiovascular death (Vivekananthan et al 2003).

The apparent discrepancy between the findings of observational and intervention studies may be due to several factors, including the length and nature of the intervention (Tavani & La Vecchia 1999). For example, the intervention trials involved supplementation with synthetic beta-carotene in isolation or with other single nutrients, whereas the observational studies involved the consumption of beta-carotene-rich foods containing a range of additional antioxidant vitamins, phytonutrients and micronutrients.

Photoprotection

Excessive exposure to solar radiation, especially UVA (320–400 nm) and UVB (290–320 nm), may induce UV-carcinogenesis and erythema in the skin (Lee et al 2000). There have been a number of controlled clinical trials that have demonstrated that supplementation with beta-carotene alone, or in combination with other antioxidants, can reduce UV-induced erythema (Gollnick et al 1996, Heinrich et al 1998, Heinrich et al 2003, Lee et al 2000, Mathews-Roth et al 1972, Sies & Stahl 2004, Stahl et al 2000). These studies suggest that at least 8–10 weeks of supplementation are required before protection against erythema becomes evident and that doses of at least 24 mg/day of beta-carotene are required (Sies & Stahl 2004).

In uncontrolled studies, a protective effect against UV-induced erythema was observed after supplementation with 180 mg of beta-carotene for 10 weeks (Mathews-Roth et al 1972) and with 50 mg for 6 weeks (Heinrich et al 1998). These results are supported by more rigorous studies that have shown photoprotective activity with smaller doses of beta-carotene. An RCT involving supplementation with 30 mg of natural beta-carotene for 8 weeks, with the dose increasing to 60 mg for a further 8 weeks and then to 90 mg for another 8 weeks, found a dose-dependent reduction in UVA- and UVB-induced erythema (Lee et al 2000). In another RCT, supplementation for 12 weeks with 24 mg/day of natural beta-carotene or a natural carotenoid mix supplying similar amounts of beta-carotene, lutein and lycopene also significantly reduced UV-induced erythema (Heinrich et al 2003). Similarly, a randomised trial found that supplementation with 25 mg of natural algal beta-carotene for 12 weeks significantly reduced UV-induced erythema, with the effect enhanced by the addition of alpha-tocopherol (Stahl et al 2000). Yet another trial suggests that the photoprotective action of beta-carotene enhances the action of topical sunscreens. In this randomised, placebo-controlled, double-blind study of 20 healthy young females, 30 mg/day beta-carotene for 10 weeks reduced UV-induced erythema and protected against UV-induced drop in serum beta-carotene levels and UV-induced reduction in Langerhans cells; beta-carotene combined with topical sunscreens was more effective than sunscreen cream alone (Gollnick et al 1996). A protective effect against photo-immunosuppression was demonstrated in another study in which 30 mg/day of beta-carotene for 4 weeks protected against UV-induced suppression of delayed-type hypersensitivity in young men (Fuller et al 1992).

It has been suggested that the duration of supplementation may be more important than the dose, as the studies that have not demonstrated significant reduction in UV-induced erythema have all involved supplementation of relatively short duration (Lee et al 2000). No photoprotective effects were observed with supplementation of 90 mg beta-carotene for 3 weeks (Garmyn et al 1995), 150 mg/day for 4 weeks (Wolf et al 1988) or 15 mg/day for 8 weeks (McArdle et al 2004).

It has also been suggested that a combination of antioxidants may be more effective than the sum of the separate components because the skin's antioxidant defence system appears to involve an intricate connection between individual antioxidants (Steenvoorden & Beijersbergen van Henegouwen 1997). This is supported by a randomised, double-blind, placebo-controlled study that found that short-term (2-week) supplementation with an anti-oxidative combination containing beta-carotene and lycopene, as well as vitamins C and E, selenium and proanthocyanidins, significantly decreases the UV-induced expression of matrix metallo-proteinases, with a non-statistically significant trend towards reduced minimal erythema dose (Greul et al 2002).

Although beta-carotene supplementation may provide some degree of protection against sunburn, the effect is modest and there is still some debate about its use for routine photoprotection (Biesalski & Obermueller-Jevic 2001, Fuchs 1998). However, beta-carotene is likely to be clinically useful in providing photoprotection for people with specific photosensitivity. High doses (180 mg/day, up to 300 mg/day) have been shown to reduce photosensitivity in people with the genetic condition erythropoietic protoporphyria in a number of case series (Mathews-Roth et al 1970, Mathews Roth et al 1974, Thomsen et al 1979), and the results of a double-blind RCT suggest that beta-carotene may be useful in conjunction with canthaxanthin in preventing polymorphous light eruptions (Suhonen & Plosila 1981).

The ability of beta-carotene to protect against UV-induced erythema and photosensitivity does not appear to extend to protecting against non-melanotic skin cancer. In a randomised placebo-controlled trial involving 1805 subjects with recent non-melanotic skin cancer, daily supplementation with 50 mg beta-carotene for 5 years had no effect on the incidence of new or recurring non-melanotic skin cancers, with similar results for those with low-baseline beta-carotene levels and smokers (Greenberg et al 1990). Similarly, in another randomised, placebo-controlled trial of 1621 adults aged between 25 and 74 years, daily supplementation with 30 mg beta-carotene did not reduce the development of solar keratoses over the 3-year study period (Darlington et al 2003, Green et al 1999). These results are supported by an analysis of data from the Physicians' Health Study that found that 12 years of beta-carotene supplementation had no effect on the incidence of non-melanotic skin cancer (Frieling et al 2000); a subgroup analysis from this study also that found no effect on non-melanotic skin cancer in men with low-baseline plasma beta-carotene levels (Schaumberg et al 2004). In a further randomised, placebo-controlled study of 62 patients with numerous atypical naevi, 25 mg of beta-carotene given twice daily for 36 months resulted in a non-significant reduction in newly developed naevi, with a significant reduction observed for the lower arm and feet, but not for ten other body sites (Bayerl et al 2003).

Oxidative stress

There are a number of human studies that suggest that supplementation with beta-carotene can reduce the oxidative stress associated with different pathological conditions or stressors such as intense exercise or radiation. Supplementation with beta-carotene (30 mg/day) and vitamin E (500 mg/day) for 90 days has been found to enhance the antioxidant enzyme activity of superoxide dismutase and catalase in the neutrophils of sportsmen (Tauler et al 2002). Similarly, in a study of 13 professional basketball players, 35 days of antioxidant supplementation with 600 mg alpha-tocopherol, 1000 mg ascorbic acid and 32 mg beta-carotene led to a significant decrease in plasma lipid peroxides, with a significant decrease of lactate dehydrogenase serum activity and a non-significant increase in the anabolic/catabolic balance being observed during a 24-hour recuperation time after exercise (Schroder et al 2001).

The results of an Israeli study of 709 children exposed to radiation from the Chernobyl accident suggest that natural algae-derived beta-carotene may act as an in vivo lipophilic antioxidant or radioprotector. This study found that exposed children had increased susceptibility to lipid oxidation and that supplementation with 40 mg of natural 9-*cis* and all-*trans* equal isomer mixture beta-carotene twice daily for a period of 3 months reduced plasma markers of lipid oxidation (Ben-Amotz et al 1998).

A double-blind study has also found that beta-carotene supplementation reduced the severity, but not the incidence, of post-endoscopy pancreatitis, which is thought to be mediated by oxidative stress (Lavy et al 2004). A further small, controlled trial involving 15 patients with rheumatoid arthritis found that 3 weeks of supplementation with natural beta-carotene resulted in a significant increase in plasma antioxidants, but did not change indicators of disease (Kacsur et al 2002).

There is also evidence that beta-carotene may protect against the oxidative stress caused by chemotherapy and radiotherapy. A study on conditioning therapy found antioxidant protection after supplementation with 45 mg beta-carotene, 825 mg alpha-tocopherol and 450 mg ascorbic acid daily for 3 weeks preceding bone marrow transplantation. The conditioning therapy, which consists of high-dose chemotherapy and total body irradiation, has acute and delayed toxic effects that are considered to be due to peroxidation processes and exhaustion of antioxidants. Supplementation, however, was found to increase serum antioxidant levels and reduce the post-conditioning rise in plasma lipid hydroperoxides in patients receiving the conditioning therapy before transplantation (Clemens et al 1997). A higher then usual dietary intake of beta-carotene has also been found to reduce the occurrence of severe adverse effects of radiation therapy and decrease local cancer recurrence in people with head and neck cancer (Meyer et al 2007).

Contrasting with the above studies are two small studies that showed no change in oxidative stress in healthy subjects after beta-carotene supplementation. Normal concentrations of carotenoids in plasma and tissues were not correlated with clinical

markers of antioxidant and oxidative stress in a study of 79 healthy volunteers (Borel et al 1998), and a placebo-controlled, single-blind study found that daily supplementation with 15 mg of beta-carotene for 3 months did not significantly improve biomarkers of oxidative stress in healthy males (Hininger et al 2001).

Immune function

Beta-carotene supplementation of 15 mg/day has been shown to significantly reduce IgE and respiratory rate and improve recovery of pneumonia among children aged 6–36 months (Mohamed et al 2008). In a study of 652 non-institutionalised elderly people, the incidence of acute respiratory infections was reduced for those with the highest plasma levels, suggesting that beta-carotene may improve the immune response and result in decreased risk of infectious diseases (van der Horst-Graat et al 2004).

In contrast to these findings, analyses of male smokers who participated in the ATBC study found that supplementation with synthetic beta-carotene had no overall effect on the risk of hospital-treated pneumonia or the incidence of the common cold (Hemila et al 2002, 2004), but instead increased the risk of colds in subjects carrying out heavy exercise at leisure but not at work (Hemila et al 2003).

Asthma and chronic obstructive pulmonary disease

Studies have shown increased oxidative stress in patients with chronic airflow limitation (Ochs-Balcom et al 2005) and accumulating evidence suggests that dietary antioxidant vitamins are positively associated with lung function (Schunemann et al 2001), with serum beta-carotene levels being associated with improved forced expiratory volume in the first second (FEV_1) (Grievink et al 2000). Thus it has been suggested that antioxidant protection is important for protecting the lungs against high oxygen levels and that oxidative stress may contribute to respiratory pathology such as asthma (Rahman et al 2006, Wood et al 2003). This is supported by the finding of a significant association between serum vitamin C, vitamin E, beta-cryptoxanthin, lutein/zeaxanthin, beta-carotene, and retinol with FEV_1 (Schunemann et al 2001), together with a study involving a subset from the CARET study of 816 asbestos-exposed men with a high rate of current and former cigarette smoking, which found that serum beta-carotene was associated with a significant improvement in forced expiratory volume in one second (FEV_1) and forced vital capacity (FVC) (Chuwers et al 1997).

Studies on the correlation between serum beta-carotene levels and asthma, however, have produced mixed results. A recent meta-analysis of 10 studies on the incidence of dietary antioxidant intake and the risk of asthma found no positive association between intakes of beta-carotene or vitamin E and asthma risk (Gao et al 2008). One small study of 15 asthmatic subjects and 16 healthy controls found that despite similar dietary intake, whole blood levels of total carotenoids — including beta-carotene, lycopene, lutein, beta-cryptoxanthin and alpha-carotene — were significantly lower in the asthmatics, with no differences in plasma or sputum carotenoid levels (Wood et al 2005). Another small study found that beta-carotene, alpha-tocopherol and ascorbic acid were significantly lower in asthmatics at remission compared to controls, and that beta-carotene was significantly lower and lipid peroxidation products significantly higher during attacks than in periods of remission (Kalayci et al 2000). A further small study found that increased dietary consumption of beta-carotene was associated with better quality of life (Moreira et al 2004).

These results are supported by an analysis of 7505 youths (4–16 years) from the Third National Health and Nutrition Examination Survey, which found that increased serum beta-carotene was associated with reduced asthma prevalence (Rubin et al 2004). Another analysis involving 4093 children from the same study, 9.7% of whom reported a diagnosis of asthma, found that asthma diagnosis was associated with lower levels of serum beta-carotene, vitamin C, alpha-carotene and beta-cryptoxanthin (Harik-Khan et al 2004).

In contrast to these findings, a much larger study involving 771 people with self-reported asthma, 352 people with former asthma and 15,418 people without asthma found that asthma status was not significantly associated with serum antioxidant concentrations (Ford et al 2004). Similarly, in a study of 15 mild asthmatics and 15 age- and sex-matched controls, oxidative stress was found to be increased in the asthmatics, with no difference in plasma dietary antioxidant vitamins (Wood et al 2000).

Although the role of antioxidant vitamins in prevention and/or treatment of asthma remains to be determined (Kalayci et al 2000), the results of one intervention study suggest that there may be a role for beta-carotene in exercise-induced asthma. This randomised, double-blind, placebo-controlled trial involved 38 subjects with proven exercise-induced asthma and found that supplementation with 64 mg/day of natural algal beta-carotene for 1 week protected against post-exercise reduction in FEV_1 (Neuman et al 1999).

Cystic fibrosis

Cystic fibrosis (CF) is characterised by exocrine pancreatic insufficiency and reduced absorption of fat-soluble vitamins, as well as by chronic lung inflammation and an associated increased oxygen free-radical generation. Patients with CF have been found to have lower levels of beta-carotene, and it has been suggested that they would benefit from beta-carotene supplementation (Cobanoglu et al 2002, Walkowiak et al 2004). This suggestion is supported by a study of 52 patients with CF, which found a statistically significant correlation between serum beta-carotene and the clinical course of the disease as indicated by faecal elastase-1 and FEV_1 (Walkowiak et al 2004), together with a study showing that the plasma levels of beta-carotene and vitamin E increased and the plasma levels of TNF-alpha and malondialdehyde decreased after 6 months of beta-carotene supplementation (Cobanoglu et al

2002). This is further supported by a RCT of 24 CF patients who were supplemented with up to 50 mg/day beta-carotene for 12 weeks and 10 mg/day beta-carotene for a further 12 weeks; a significant decrease in oxidative stress, correction of total antioxidative capacity and improved pulmonary response to treatment were found in the supplemented group (Rust et al 2000).

Cataracts

Although a high intake of foods containing beta-carotene has been associated with the prevention of cataracts, the role of supplementation is uncertain. An assessment of dietary beta-carotene intake in a subgroup of 472 non-diabetic female participants aged 53–73 years in the Nurses' Health Study found that the odds of posterior subcapsular cataracts were 72% lower in those with the highest intakes of beta-carotene who had never smoked, whereas beta-carotene intake and cataract risk were not associated in current or past smokers (Taylor et al 2002). In contrast to this finding, intervention studies have shown that beta-carotene may help prevent cataracts in smokers (Christen et al 2003, 2004). Two years of beta-carotene treatment was found to have no significant beneficial or harmful effect on the development of cataract in a randomised, double-masked, placebo-controlled trial of 39,876 female health professionals aged 45 years or older who participated in the Women's Health Study, although a subgroup analysis suggests a possible beneficial effect in smokers (Christen et al 2004). Similarly, the Physicians' Study (see above) found that 12 years of supplementation did not reduce the overall incidence of cataracts or cataract extraction; however, in a subgroup of smokers the risk of cataract was reduced by approximately 25% (Christen et al 2003).

In two randomised, double-masked trials that involved 5390 nutritionally deprived subjects in Linxian, China, supplementation with selenium, alpha-tocopherol and beta-carotene for 5–6 years was found to significantly reduce the prevalence of nuclear, but not cortical, cataracts in older subjects (Sperduto et al 1993). This contrasts with the finding that 500 mg of vitamin C, 400 IU of vitamin E and 15 mg of beta-carotene had no apparent effect on the 7-year risk of development or progression of age-related lens opacities or visual acuity loss in a relatively well-nourished older adult cohort of 4629 people, aged from 55 to 80 years, who participated in the Age-Related Eye Disease (ARED) study (Kassoff et al 2001).

Age-related macula degeneration

Although beta-carotene and other nutrients may have been found to be beneficial for preventing age-related macula degeneration (ARMD), the carotenoids lutein and zeaxanthin appear to provide the most protection (see monograph *Lutein and zeaxanthin*).

A high intake of beta-carotene-containing foods has been associated with the prevention of ARMD, and observational and experimental data suggest that carotenoid supplements may delay progression of both ARMD and vision loss. This is supported by the findings from the ARED study, in which an 11-centre, double-masked clinical trial involving 3640 participants with ARMD found that supplementation with vitamin C 500 mg, vitamin E 400 IU, beta-carotene 15 mg and zinc 80 mg for 6 years significantly reduced the development of advanced ARMD and moderate visual acuity loss (Kassoff et al 2001). This result contrasts with findings from the Physicians' Study (see above), which found no beneficial or harmful effects of beta-carotene supplementation on the incidence of ARMD (Christen et al 2007).

Erythropoietic protoporphyria and photosensitivity

Studies in bacteria, animals and humans have demonstrated that carotenoid pigments can prevent or lessen photosensitivity to endogenous photosensitisers, such as chlorophyll or porphyrins, as well as to exogenous photosensitisers (Mathews-Roth 1993). High doses of beta-carotene (between 180 and 300 mg/day) have been used to effectively prevent or lessen photosensitivity in most patients with erythropoietic protoporphyria and in some patients with other photosensitivity diseases such as solar urticaria, hydroa aestivale, porphyria cutanea tarda and actinic reticuloid (Mathews-Roth 1986, 1987, Mathews-Roth et al 1977).

Cognitive function

A study of cognitive function in high-functioning older people found that beta-carotene may offer protection from cognitive decline in people with a greater genetic susceptibility, as evidenced by the presence of the apolipoprotein E4 allele (Hu et al 2006). There is also evidence to suggest that long-term supplementation with beta-carotene may provide cognitive benefits, whereas short-term supplementation does not. A study examining cognitive function in 5956 participants older than 65 years in the Physicians' Health Study found significant higher cognitive function in the beta-carotene group when 4052 continuing participants who had been receiving either beta-carotene supplementation or a placebo for an average of 18 years were examined, but no difference was found between the beta-carotene and placebo groups in 1904 newly recruited subjects after 1 year of intervention (Grodstein et al 2007).

DOSAGE RANGE

Consumption of the recommended five or more servings of fruits and vegetables per day provides 3–6 mg of beta-carotene. Supplemental intake of beta-carotene ranges from 3 to 30 mg/day, although medicinal doses to treat erythropoietic protoporphyria or prevent a reaction to sun in patients with polymorphous light eruption range from 30 to 300 mg/day (PDRHealth 2005). The dose required to provide photoprotection is greater than 24 mg/day for more than 2 months (Sies & Stahl 2004).

To enhance absorption, supplementation should be taken with meals.

TOXICITY

Beta-carotene is readily converted into vitamin A when required by the body and is considered to be non-toxic, even when given in doses as high as 300 mg/day (Mathews-Roth 1990b, 1993).

A review of the literature on adverse effects of carotenoids on human and animal development suggests that beta-carotene does not have any genotoxic affects (Mathews-Roth 1988), and a toxicity study performed on rats suggests a no-observed-adverse-effect-level (NOAEL) is at a dietary level of at least 5%, or more than 3000 mg/kg/day (Nabae et al 2005). Beta-carotene overdose is not reported in the literature.

ADVERSE REACTIONS

At doses greater than 30 mg/day, beta-carotene may cause an orange-yellow colouration of the skin (carotenodermia), which is usually seen first as yellowness of the palms and soles. This condition is harmless and reversible when intake ceases (Micozzi et al 1988). Carotenodermia is distinguished from jaundice by the absence of yellowed ocular sclerae. For some people, this skin colouration is actually considered desirable (Mathews-Roth 1990a) and is utilised in tanning tablets to produce a natural-looking skin tan (DerMarderosian & Beutler 2002).

At present it is unclear if there is a true link between increased lung cancer risk and long-term beta-carotene supplementation in smokers, because supplementation studies with synthetic beta-carotene have produced mixed results: two studies demonstrated an increased lung cancer risk in heavy smokers or those with high asbestos exposure (Group 1994, Heinonen et al 1994, Omenn et al 1996a), while other studies found either no effect (Hennekens et al 1996, Lee et al 1999) or a protective effect (Blot et al 1993).

The association between increased lung cancer risk and beta-carotene has not been found with natural beta-carotene, and there is no suggestion that heavy smokers should reduce their intake of beta-carotene-rich foods. A review suggests that there is no evidence at present that consuming small amounts of supplemental beta-carotene in a multivitamin tablet at amounts that exist in foods (< 6 mg) is unwise for any population (Pryor et al 2000).

SIGNIFICANT INTERACTIONS

Drugs reducing fat absorption

Drugs that reduce fat absorption, such as cholestyramine, colestipol and orlistat, may also reduce absorption of beta-carotene (PDRHealth 2005). This can be avoided by spacing the administration of these substances by at least 2 hours. Plant sterols have been found to reduce beta-carotene bioavailability by approximately 50% in normocholesterolaemic men (Richelle et al 2004).

Fibrates

There may be a positive interaction between fibrate and natural beta-carotene, which has been found to significantly increase HDL cholesterol levels in fibrate-treated mice and humans (Shaish et al 2006).

Valproate

Epileptic patients who gain weight with valproate therapy have been found to have reduced plasma concentrations of beta-carotene and other fat-soluble antioxidant vitamins; this is reversible after valproate withdrawal (Verrotti et al 2004).

CONTRAINDICATIONS AND PRECAUTIONS

Heavy smokers should be advised not to take synthetic beta-carotene supplements for long periods of time.

PREGNANCY USE

Beta-carotene crosses the placenta. Adequate and well-controlled studies in humans have not been documented. No problems with pregnancy have been documented in women taking up to 30 mg beta-carotene daily (Micromedex 2003). As vitamin A is vital for the development of the fetus and the newborn baby, it has been recommended that pregnant women increase their vitamin A intake by 40% and breastfeeding women by 90%. It is further suggested that increasing dietary beta-carotene is an effective way for women to maintain their vitamin A levels (Strobel et al 2007).

PRACTICE POINTS/PATIENT COUNSELLING

- Beta-carotene is an antioxidant found in carrots, other vegetables and fruits, as well as in seaweed and algae. Together with other carotenoids, it is an effective marker for a diet rich in fruits and vegetables.
- Beta-carotene is fat soluble and should be consumed with meals.
- Although beta-carotene is converted into vitamin A in the body, unlike vitamin A it is considered non-toxic even in large doses.
- When supplementing with beta-carotene, it is preferable to use supplements containing natural beta-carotene from the algae *Dunaliella salina* or palm oil, rather than synthetic beta-carotene.
- Beta-carotene is a powerful pigment that contributes to the normal yellow component of skin, and increased beta-carotene intake may protect from the effects of excessive exposure to sunlight and the symptoms of sunburn.
- Consumption of beta-carotene-rich food is associated with reduced risk of cancers, heart disease and eye disease; however, these benefits have not been found in large studies that have used synthetic beta-carotene, with two studies finding an increase in lung cancer in heavy smokers and asbestos workers taking large doses of synthetic beta-carotene.

PATIENTS' FAQs

What will this supplement do for me?

Beta-carotene supplementation will ensure you maintain adequate vitamin A levels. It may possibly assist in preventing cancer and cardiovascular disease, help maintain a healthy immune system, prevent sunburn and photoageing of the skin, assist with asthma, and deal with oxidative stress.

When will it start to work?

It may take up to 2–3 months to see a benefit with UV protection, whereas other benefits may be observable only over many years.

Are there any safety issues?

Beta-carotene is considered non-toxic. Large doses may cause a yellowing of the skin, but this is harmless and reversible.

Bilberry

HISTORICAL NOTE Bilberries have been used as a food for many centuries and are valued for their taste and high nutritional content. They are still commonly used to make jams, pies, syrups and beverages. Medicinally, the berries have been used internally to treat diarrhoea and haemorrhoids and externally for inflammation of the mouth and mucous membranes as they have significant astringent activity. According to folklore, World War II British Royal Air Force pilots noticed that their night vision seemed to improve after consuming bilberries or bilberry preserves, sparking a renewed interest in the medicinal properties of the fruits.

COMMON NAME
Bilberry

OTHER NAMES
Baies de myrtille, blaubeeren, dwarf bilberry, European bilberry, European blueberries, huckleberry, hurtleberry, heidelbeeren, petit myrte, whortleberry, wine berry

BOTANICAL NAME/FAMILY
Vaccinium myrtillus (family Ericaceae)

PLANT PARTS USED
Dried ripe fruit or fresh fruit (berries)

CHEMICAL COMPONENTS
The fruit contains catechin tannins (up to 10%), invert sugar, fruit acids, flavonol glycosides including astragalin, hyperoside, isoquercitrin and quercitrin, phenolic acids, pectins, triterpenes, and polyphenols such as anthocyanosides. The volatile oil includes methyl salicylate, farnesol, vanillin, myristicin and citronellol. Bilberry also contains vitamin C and chromium, which are suspected of playing a role in its pharmacological activities.

Some of the anthocyanosides are responsible for the deep blue pigment of the fruit (Kahkonen et al 2001). As the fruit ripens, the anthocyanoside content increases. Some commercially available extracts are standardised to anthocyanoside content. Recent research indicates that the anthocyanidin content is particularly high in the pulp of the fruit, however, all parts of the fruit are potential sources of phenolic compounds (Riihinen et al 2008). Anthocyanin concentration in the fresh fruit is approximately 0.1–0.5%, while concentrated bilberry extracts are usually standardised to 25% anthocyanins (Ichiyanagi et al 2004, Zhang et al 2004).

Clinical note — Tannins
Tannins are polyphenolic compounds that have an affinity for proteins. They also complex with alkaloids and therefore should not be mixed with alkaloid-containing herbs.

Anthocyanosides are condensed tannins. When they come into contact with mucous membranes they have an astringent action, making the mucosa less permeable. This activity has been used therapeutically in a variety of ways.

Taken internally, herbs with a high tannin content such as bilberry have been used to treat diarrhoea; applied externally, a styptic action occurs that reduces blood loss.

MAIN ACTIONS
The pharmacological actions of bilberry have not been significantly investigated in clinical studies, so information is generally derived from in vitro and animal studies or based on known information about key constituents found within the herb. Most of the research undertaken to understand the pharmacology of the herb has focused on the anthocyanoside content.

Antioxidant
Anthocyanosides are the main phenolic constituents in bilberry and have well established antioxidant activity (Kahkonen et al 2001, Roy et al 2002). This activity is believed to be primarily due to their chemical structure (Mozaffarieh et al 2008, Yao et al 2007). Anthocyanosides have exhibited superoxide radical scavenging properties and cytoprotective activity against oxidative damage in animal models (Valentova et al 2007).

Reduces ischaemic reperfusion injury
Bilberry anthocyanosides have been shown to improve ischaemic damage, preserve capillary perfusion, inhibit increased permeability of reperfusion and save arteriolar tone in an animal model of ischaemic reperfusion injury (Bertuglia et al 1995).

Ophthalmic conditions
Bilberry's significant antioxidant activity is believed to be responsible for much of its activity in the eye, in particular, prevention of cataract.

Anti-inflammatory and anti-oedema activity
Biochemical and histochemical data show that the anthocyanins decrease vascular permeability and alter capillary wall dynamics by increasing the

Clinical note — Cataract
Growing evidence suggests that senile cataract development may in part be linked to the endogenous generation of free radical molecules, such as superoxide derived from oxygen and light in the aqueous humour and lens (Varma & Richards 1988, Varma et al 1982, 1994). As such, substances with significant antioxidant activity such as anthocyanins, vitamin C and vitamin E have been investigated as potential prophylactic treatments.

endothelium barrier effect via stabilising membrane phospholipids and increasing synthesis of the mucopolysaccharides in the connective ground substance, thus restoring the altered pericapillary sheath (Mian et al 1977).

These effects have been demonstrated in animal models for both oral administration and topical application of bilberry anthocyanins (1% alcohol solution) and were seen to be stronger and longer lasting than those of rutin (Lietti et al 1976).

Astringent

The astringent properties of bilberry are well established and attributed to its significant tannin content.

Improves visual function

Epidemiological investigations have indicated that moderate consumption of anthocyanin-containing herbs such as bilberry extract is associated with an improvement of visual function (Hou 2003). Several animal studies suggest a positive effect on dark adaptation (Canter & Ernst 2004). More specifically, bilberry enhances regeneration of rhodopsin in the retina, which is essential for optimal functioning of the rods and therefore light adaptation and night vision (Blumenthal et al 2000). Other possible mechanisms of action in the eye include accelerated modulation of retinal enzyme activity and improved microcirculation (Canter & Ernst 2004).

Jang et al 2005 demonstrated that two anthocyanins from bilberry were potent antioxidants that suppressed photo-oxidative processes initiated in retinal pigment epithelial (RPE) cells by A2E, which is associated with ageing and some inherited forms of retinal degeneration (Kim et al 2008).

Gastroprotective activity

In vitro results have found that a specific anthocyanin found in bilberry causes an increase in the efficiency of the gastric mucosal barrier (Cristoni et al 1989). When administered orally in an animal model it retarded the development of gastric ulcers induced by stress, NSAIDs, ethanol, reserpine and histamine (Magistretti et al 1988).

Hypoglycaemic activity

A dried hydroalcoholic extract of bilberry leaf administered orally to streptozotocin-diabetic rats for 4 days decreased plasma glucose levels by 26% (Cignarella et al 1996).

Reduces triglyceride levels

A dried hydroalcoholic extract of bilberry leaf administered orally to streptozotocin-diabetic rats for 4 days decreased plasma triglyceride levels by 39% (Cignarelli et al 1996).

Neuroprotective

Anthocyanoside content is beneficial in reversing the course of neurodegeneration in animals by affecting calcium homoeostasis and improving motor performance (Kolosova et al 2006, Landfield et al 1994).

Anticarcinogenic activity

Preliminary research has found that components of the hexane/chloroform fraction of bilberry exhibit anticarcinogenic activity (Bomser et al 1996). More recently, antiangiogenic activity has also been identified (Roy et al 2002) as well as anticarcinogenic activity via inhibition of the nuclear factor-kappa B activation pathway (Aggarwal et al 2006). One animal study demonstrated significant reduction in colon cancer in animals fed an anthocyanidin mixture derived from bilberry (Cooke et al 2006).

OTHER ACTIONS

Bilberry extract inhibits platelet aggregation according to ex vivo tests (Pulliero et al 1989).

CLINICAL USE

Bilberry extracts are popular in Europe and have been investigated in numerous clinical trials, primarily in non-English speaking European countries. As a result, many research papers have been published in other languages. To provide a more complete description of the evidence available, secondary sources have been used when necessary.

Non-specific acute diarrhoea

The considerable astringent activity of bilberry provides a theoretical basis for its use in non-specific acute diarrhoea. Commission E approved crude fruit preparations for this indication (Blumenthal et al 2000).

Mild inflammation of the mouth and throat

The considerable astringent, anti-inflammatory and anti-oedema activity of bilberry provides a theoretical basis for its use as a topical application in these indications. Commission E approved this indication (Blumenthal et al 2000).

Haemorrhoids, varicose veins, venous insufficiency

The considerable astringent, anti-inflammatory and anti-oedema activity of bilberry provides a theoretical basis for its use in these conditions. Several human case series and a single-blind trial report significant improvements in lower extremity discomfort and oedema related to chronic venous insufficiency; however, further research is required to confirm these findings (Ulbricht & Basch 2005).

Pregnancy

A bilberry product (Myrtocyan®) was taken at a dose of 320 mg daily in the last trimester by women aged 24–37 years with pregnancy-induced lower extremity oedema and found to significantly improve symptoms of burning and itching, heaviness, pain, diurnal and nocturnal leg cramps, oedema and capillary fragility (Ghiringhelli et al 1978 and reported in Blumenthal 2003).

Ophthalmic conditions

Bilberry preparations have been used to improve poor night vision, light adaptation and photophobia, myopia and to prevent or retard diabetic retinopathy, macular degeneration and cataracts.

Primarily the collagen-enhancing and antioxidant activities of bilberry provide a theoretical basis for these indications.

Visual acuity and light adaptation

A systematic review of 12 placebo-controlled trials (5 RCTs and 7 placebo-controlled non-randomised trials) concluded that the anthocyanosides from *Vaccinium myrtillus* were not effective for improving night vision; however, the authors point out that the potential therapeutic role of these constituents should not yet be dismissed because confounding factors and supportive auxiliary evidence exists (Canter & Ernst 2004). Four of the RCTs showed no positive effects for *V. myrtillus* anthocyanosides on outcome measures relevant to vision in reduced light whereas the fifth RCT and all seven non-randomised trials reported positive effects on outcome measures relevant to night vision. Seventeen other studies were located by Canter and Ernst but not included in the analysis because they did not contain a placebo group. Sixteen of those studies produced positive results on measures relevant to night vision in either healthy subjects or patients with a range of visual disorders and only one was negative.

The authors point out several confounding factors, in particular the wide range of doses, possible geographical variations in extract composition, choice of subject (generally healthy) and methods used to obtain and interpret electroretinograms, which varied between older and newer studies. For example, two of the negative RCTs tested the lowest dose levels of any of the trials: 36 mg daily for acute treatment and ≤ 48 mg for short-term treatment.

A significant improvement in visual performance has been demonstrated for bilberry extract in people with retinitis pigmentosa and haemeralopia (inability to see distinctly in bright light), suggesting that effects may be more pronounced in cases of impaired visual acuity (Gloria & Peria 1966, Junemann 1967).

Glaucoma

In one small study of eight patients, a single oral dose of 200 mg bilberry anthocyanosides was shown to improve glaucoma, as assessed by electroretinography (Caselli 1985).

Retinopathy

In Europe, bilberry anthocyanoside extracts are recognised as highly effective in preventing or treating diabetic retinopathy, with clinical research supporting its use (Lietti et al 1976, Orsucci et al 1983, Perossini et al 1987, Scharrer & Ober 1981).

One double-blind study involving 40 patients with diabetic and/or hypertensive retinopathy showed that a dose of bilberry extract (Tegens™) equivalent to 160 mg anthocyanosides taken twice daily for 1 month significantly improved ophthalmoscopic parameters and angiographic parameters (Perossini et al 1987). Another study of 31 subjects with different forms of retinopathy (diabetic retinopathy, retinitis pigmentosa, macular degeneration or haemorrhage due to anticoagulant use) found that treatment with bilberry extract (Difrarel 100™) reduced vascular permeability and the tendency to haemorrhage in all patients (Scharrer & Ober 1981). A small open study by Orsucci et al of 10 subjects with diabetic retinopathy found that 6 months of treatment with bilberry extract (Tegens™) equivalent to 240 mg anthocyanosides daily resulted in reduction or disappearance of haemorrhages and improvement in the retinal picture (Orsucci et al 1983 and reported in Blumenthal 2003).

Myopia

Uncontrolled trials report a beneficial effect of the extract on patients with myopia (Canter & Ernst 2004).

Additional studies using purified anthocyanoside oligomers highlight significant improvements in subjective symptoms and objective contrast sensitivity in myopia patients with poor night vision (Lee et al 2005). However, as specificity of source is not provided, this information can only be used in conjunction with the additional supportive evidence listed above.

Cataract

In practice, bilberry has been recommended to delay cataract progression. A case series of 50 elderly subjects with early-stage cataract found that a combination of anthocyanosides extracted from bilberry and vitamin E slowed progression of lens opacities by 97% (Ulbricht & Basch 2005). Placebo-controlled trials are now required to confirm these results.

OTHER USES

Traditionally, bilberry has been used to treat dysentery, diabetes, gastrointestinal inflammatory conditions, vaginal discharges, haemorrhoids, and to stop lactation. Externally, bilberry preparations have been used to treat wounds, ulcers and skin infections. More recently, other uses include treatment for bleeding gums, nose bleeds, spider veins, capillary fragility, peptic ulcers, Raynaud's syndrome and venous insufficiency (such as claudication).

Additionally, a double-blind placebo-controlled study confirmed that bilberry improves peripheral vascular disorders by improving subjective symptoms after 30 days' treatment (Mills & Bone 2000).

DOSAGE RANGE

Internal

- Fluid extract (1:1) standardised to provide 60–120 mg daily of anthocyanins: 6–12 mL/day taken in three divided doses.
- Oral dose forms: bilberry extracts providing 240–480 mg of anthocyanins daily.
- Decoction of dried herb: 5–10 g of crushed, dried fruit in 150 mL of cold water, which is then boiled for up to 10 minutes and strained while hot. For symptomatic treatment of diarrhoea, drink the cold decoction several times daily.
- Gargle: a 10% decoction of the above preparation.
- Fresh berries: 165–345 g daily.

External
- 5–10 g crushed dried fruit in 150 mL of cold water, brought to the boil for 10 minutes then strained while hot to make a decoction for local application.

TOXICITY
Rats administered high doses of up to 400 mg/kg showed no adverse effects (Murray 1995).

ADVERSE REACTIONS
No adverse effects were reported in a systematic review of 12 placebo-controlled trials of *V. myrtillus* anthocyanosides (Canter & Ernst 2004). According to the same authors, a post-marketing surveillance study of 2295 people identified that 4% experienced side-effects related to the skin, nervous system or gastrointestinal tract.

SIGNIFICANT INTERACTIONS
Controlled studies are not available, therefore interactions are theoretical and based on evidence of pharmacological activity with uncertain clinical significance.

Anticoagulant and antiplatelet drugs
A theoretical risk exists that high doses (>170 mg anthocyanidins) may increase bleeding risk, however, this remains uncertain as there is inadequate clinical evidence (Stargrove et al 2008).

Iron
Reduced absorption is theoretically possible if taken at the same time because of the tannin content of the herb — separate doses by 2 hours.

Hypoglycaemic agents
Additive effects are theoretically possible with leaf preparations — observe patient.

CONTRAINDICATIONS AND PRECAUTIONS
High doses (>170 mg anthocyanidins) should be used with caution by people with haemorrhagic disorders.

PREGNANCY USE
A study investigating bilberry extract for pregnancy-induced lower extremity oedema reported no adverse effects (Ulbricht & Basch 2005) — likely to be safe when berry is consumed in dietary amounts.

PATIENTS' FAQs
What will this herb do for me?
Bilberry is used to relieve the symptoms of mild diarrhoea and improve poor night vision, sensitivity to glare, photophobia, peptic ulcers, varicose veins, venous insufficiency and haemorrhoids when taken internally. It is also used as a mouthwash, gargle or paint for mild inflammation of the mouth or throat, such as gingivitis or pharyngitis.

When will it start to work?
This depends on the indication. Improvements in night vision, photophobia and glare sensitivity have been reported within 2–4 weeks of use in some people whereas preventive effects are likely to require long-term use. In peripheral vascular diseases, 30 days' treatment may be required before effects are noticed.

Are there any safety issues?
Considered a safe herb overall, bilberry can theoretically reduce blood glucose levels in people with diabetes and so should be used carefully in these patients. At very high doses it may interact with warfarin and antiplatelet drugs.

PRACTICE POINTS/PATIENT COUNSELLING
- Bilberry has antioxidant, anti-inflammatory and astringent actions and has considerable polyphenol content.
- Bilberry extract is a popular treatment in Europe for preventing and treating retinopathy. It is also used to treat several other ophthalmic conditions such as poor night vision, poor light adaptation, and sensitivity to glare, photophobia, glaucoma, myopia and cataract.
- Some research also suggests that it is useful in venous insufficiency, peripheral vascular disorders (such as Raynaud's syndrome) and capillary fragility.
- Approved by Commission E for the treatment of non-specific, acute diarrhoea and mild inflammatory conditions of the mouth and throat.
- Preliminary evidence suggests it may reduce serum glucose levels and triglycerides in diabetes and prevent peptic ulcer formation due to NSAIDs or stress; however, clinical research is still required to confirm these effects.
- In vitro investigation has identified anticarcinogenic activity.

Bitter melon

HISTORICAL NOTE Bitter melon is used as a traditional medicine wherever it is found. It has a long history of use in Asia, Africa and Latin America and has been widely acclaimed as an important remedy for diabetes mellitus since ancient times. The term *momordica* means 'to bite' and refers to the jagged edges of the leaf, which appear as if bitten. Bitter melon has been used to treat fevers, viral infections and as an emmenagogue in reproductive health. It has also been used to treat gastrointestinal complaints, worms, constipation, headaches, skin conditions and diabetes. The fruit is used topically for wound healing. The plant has also been used in traditional ceremonies and considered a powerful charm, which is worn as a necklace, wrist or ankle bracelet or crown (Beloin et al 2005). The ritual ceremonial importance of the plant is accompanied by its considerable reputation as a medicinal plant for the treatment of disease.

OTHER NAMES

African cucumber, balsam pear, bitter gourd, kakara, karela, ku gua, sushavi, wild cucumber

BOTANICAL NAME/FAMILY

Momordica charantia (family Curcubitaceae)

PLANT PARTS USED

Fruit, leaves

CHEMICAL COMPONENTS

It contains several biologically active constituents that include glycosides (e.g. momordicins I and II), steroidal saponins (e.g. charantins), alkaloids, fixed oils and proteins (e.g. MAP 30: Momordica anti-HIV protein; molecular weight, 30 kD). The immature fruits are a good source of vitamin C and also provide vitamin A, phosphorus, and iron (Grover & Yadav 2004).

MAIN ACTIONS

Bitter melon has been the subject of countless studies and has demonstrated significant pharmacological activity in a variety of experimental models.

Antidiabetic

The antidiabetic potential of bitter melon is well established in normal, streptozocin- or alloxan-induced diabetic animals and in genetic models of diabetes (Ahmed et al 2004, Bailey et al 1985, Chaturvedi 2005, Day et al 1990, Harinantenaina et al 2006, Jayasooriya et al 2000, Kar et al 2003, Miura et al 2001, 2004, Ojewole et al 2006, Reyes et al 2006, Sarkar et al 1996, Shetty et al 2005, Shibib et al 1993). All parts of the plant (fruit pulp, seeds, leaves and whole plant) have shown activity.

A systematic study comparing the hypoglycaemic activity of three extracts in vivo found that the methanolic extract of dried whole fruits and seeds reduced blood glucose by 49% at the end of the first week, which became 39% by week 5; the aqueous extract of fresh, unripe, whole fruits reduced fasting blood glucose by 50%, which was consistent until the study ended, and the chloroform extract of dried whole fruits and seeds showed almost no hypoglycaemic activity (Virdi et al 2003).

These observations have special significance when one considers that the whole bitter gourd is cooked in water and consumed in many cultures, particularly in India.

The hypoglycaemic activity is attributed to a mixture of steroidal saponins known as charantins, insulin-like peptides and alkaloids that are concentrated in the fruit (Grover & Yadav 2004), whereas several different fractions of *Momordica charantia* extract may make different contributions to its cell repairing activity and its ability to stimulate insulin secretion (Xiang et al 2007).

At least eight clinical studies of different designs have investigated the hypoglycaemic activity of bitter gourd preparations producing mostly positive results. Of note, most studies are small and statistical analyses are poorly described. Large-scale clinical trials are required before clinical significance can be confirmed.

Based on studies with animal models, it appears that *Momordica charantia* increases the renewal of beta-cells in the pancreas, or may permit the recovery of partially destroyed beta-cells (Ahmed et al 1998, Fernandes et al 2007, Singh & Gupta 2007, Xiang et al 2007), and stimulates pancreatic insulin secretion (Fernandes et al 2007, Welihinda et al 1982). It also improves peripheral glucose uptake (Fernandes et al 2007, Welihinda & Karunanayake 1986), improves insulin sensitivity and insulin signaling (Sridhar et al 2008). A study with streptozocin-induced diabetic animals found that bitter melon juice normalises the structural abnormalities of peripheral nerves, regulates glucose uptake into the jejunum membrane brush border vesicles and stimulates glucose uptake into skeletal muscle cells (Ahmed et al 2004). A recent study of streptozocin-induced diabetic animals further reveals a beneficial role for bitter gourd in controlling glycoconjugate- and heparan sulfate-related kidney complications in diabetes thus prolonging late complications of diabetes (Kumar et al 2008).

Lipid-lowering

Lipid-lowering activity has been reported in studies of normal and diabetic animals for the fruit extract, flavonoids extracted from bitter melon or a methanolic fraction of the plant (Ahmed et al 2001, Anila & Vijayalakshmi 2000, Chaturvedi 2005, Chaturvedi et al 2004, Senanayake et al 2004, Singh et al 1989). Typically, decreases in triglyceride and LDL levels and increases in HDL levels are seen.

In contrast, karela oil increased total lipid levels and phospholipid concentrations in heart and brain as compared with linseed, according to an in vivo study (Dhar & Bhattacharyya 1998).

Antiviral

Several constituents found in bitter melon (e.g. alpha- and beta-momorcharin, lectin and MAP 30) have demonstrated in vitro antiviral activity against Epstein-Barr, HSV-1, HIV, coxsackievirus B3 and polio viruses (Beloin et al 2005, Bourinbaiar & Lee-Huang 1996, Foa-Tomasi et al 1982, Grover & Yadav 2004, Sun et al 2001).

A study using a lyophilised extract of *Momordica charantia* against HSV-1 suggests that the presence of light may be important for antiviral activity (Beloin et al 2005). The active antiviral constituents are not the main bitter principles momordicins I and II, as these have not shown activity against HSV-1 (Beloin et al 2005). One constituent referred to as MAP 30 has received special attention, as it exhibits potent inhibition of HIV-1 and HSV (Schreiber et al 1999).

Antibacterial

Broad-spectrum antibacterial activity has been demonstrated for the leaf extracts (aqueous, ethanol and methanol) (Grover & Yadav 2004). In vitro antimicrobial activity occurred against *Escherichia coli*, *Salmonella paratyphi*, *Shigella dysenterae* and *Streptomyces griseus* (Grover & Yadav 2004, Ogata et al 1991, Omoregbe et al 1996). In a phase II study, the leaf extracts inhibited the growth of *Mycobacterium tuberculosis* in vitro, using the BACTEC 460 susceptibility test method (Frame et al 1998).

Tests with an extract of the entire plant demonstrated antiprotozoal activity against *Entamoeba histolytica* (Grover & Yadav 2004) and a fruit extract exhibited activity against *Helicobacter pylori* (Yesilada et al 1999).

Anti-inflammatory

Bitter gourd extract has been found to suppress lipopolysaccharide (LPS)-induced TNF-alpha production in vitro and, more recently, the butanol-soluble fraction was also found to strongly suppress LPS-induced TNF-alpha production (Kobori et al 2008).

Anthelmintic

The anthelmintic activity of the leaves of *Momordica charantia* against *Caenorhabditis elegans* was identified and described as high in one study (Beloin et al 2005).

Triterpene glycosides of bitter melon (momordicins I and II) were found to be very active nematicides. A preparation of *M. charantia* exhibited stronger anthelmintic activity in vitro than piperazine hexahydrate against *Ascaridia galli* (Lal et al 1976).

Abortifacient

Experimental studies with mice have demonstrated that bitter melon can induce abortions (Chan et al 1984, 1985, Tam et al 1984). According to an in vivo study, the glycoproteins alpha- and beta-momorcharin isolated from the seeds are effective in inducing early and midterm abortions (Chan et al 1986) and the momorcharins were teratogenic in cultured mouse embryos (Chan et al 1986).

OTHER ACTIONS

Anticancer

Various preliminary studies (in vitro and in vivo) with crude bitter melon extract and its various constituents (e.g. MAP 30, momordin I, alpha-momorcharin) have shown anticancer activity (Basch et al 2003).

Analgesic

An in vivo study identified a dose-dependent analgesic effect for a methanolic extract of bitter melon seeds (Biswas et al 1991). The dose that produced a 50% response was 5 mg/kg SC. Analgesic activity was rapid and short lived. The opiate pathway was not involved, as naloxone pretreatment did not modify the analgesic response.

Wound healing

Momordica charantia Linn. fruit powder, in the form of an ointment (10% w/w dried powder in simple ointment base), was evaluated for wound-healing potential in an excision, incision and dead space wound model in rats (Prasad et al 2006). The Momordica ointment produced a statistically significant response ($P < 0.01$), in terms of wound-contracting ability, wound closure time, period of epithelisation, tensile strength of the wound and regeneration of tissues at wound site when compared with the control group. These results were comparable to those of the reference drug used, which was povidone iodine ointment.

CLINICAL USE

Although bitter melon and several of its constituents have been investigated in many experimental studies, few clinical studies have been conducted.

Diabetes

Bitter melon has shown promising effects in prevention as well as delay in progression of diabetic complications (e.g. nephropathy, neuropathy, cataract and insulin resistance) in experimental animals (Grover & Yadav 2004).

Various bitter melon preparations, such as bitter melon fruit juice, dried fruit, seeds and tea have been investigated for hypoglycaemic activity. Some preparations have demonstrated hypoglycaemic activity in clinical studies and experimental models; however, sample sizes are consistently small and statistical analyses are vaguely described (Dans et al 2007).

Most recently, a randomised, double-blind trial was conducted by Dans et al at the outpatient clinic of the Philippines General Hospital (Dans et al 2007). The study involved 40 patients who were either newly diagnosed with type 2 diabetes or had poorly controlled type 2 diabetes. Patients were randomised to receive either *M. charantia* capsules (two capsules three times daily) after meals or placebo as an adjunct to their preexisting medication. HbA_{1c} in both the bitter gourd treatment group and the control group showed a statistically insignificant rise with a mean change of −0.28% and −0.50%, respectively. The mean difference of 0.217 (95% CI: −0.40 to 0.84) was in favour of bitter gourd but did not reach statistical significance ($P = 0.483$). The authors concluded that the study was underpowered and suggested that a larger study with greater numbers is required to better measure any significant changes. The study identified gastrointestinal complaints as the most commonly reported adverse event, in particular abdominal discomfort or pain and diarrhoea.

Cancer

Controlled studies are not available to determine the clinical significance of the encouraging experimental findings.

According to an intriguing case report from the 1970s, a patient with gallbladder carcinoma who was given an estimated survival of 2 years after surgery survived a further 10 years, possibly because of drinking bitter melon tea daily. The signs and symptoms of disease reappeared after consumption of the tea ceased for 4 months because of lack of availability and the patient subsequently died (West et al 1971).

HIV

Nine case reports of people with HIV taking bitter melon, sometimes in combination with other herbal medicines, suggest that it may normalise the CD4/CD8 ratio; however, further investigation is required (Zhang & Khanyile 1992).

OTHER USES

Traditionally, bitter melon has been used as a treatment for a variety of conditions such as diabetes, gastrointestinal complaints, worms, constipation, headaches, skin conditions, viral infections and as an emmenagogue in reproductive health. Experimental studies support its use in some of these indications; however, controlled studies are still required to determine its role in practice.

DOSAGE RANGE

General guide

- Juice: 50–100 mL/day.

According to clinical studies

- Diabetes: aqueous extract of bitter melon fruit juice containing 100 g of fruit in 100 mL of extract taken daily.

ADVERSE REACTIONS

Gastrointestinal symptoms are the most common adverse effects seen. Clinically, this occurs

as epigastric discomfort, pain and diarrhoea which ceases once treatment is stopped.

There are two case reports of bitter melon tea inducing hypoglycaemic coma and convulsions in children (Basch et al 2003). Headaches have been reported with ingestion of the seeds (Ulbricht & Basch 2005).

SIGNIFICANT INTERACTIONS

Controlled studies are not available; therefore, interactions are based on evidence of activity and are largely theoretical and speculative.

Hypoglycaemic agents

Theoretically an additive effect is possible, resulting in increased hypoglycaemic effects — caution. Possible beneficial interaction when used under professional supervision.

CONTRAINDICATIONS AND PRECAUTIONS

Avoid bitter melon seed or the outer rind due to the presence of toxic lectins and avoid use of bitter melon in people with glucose-6-phosphate dehydrogenase deficiency (Ulbricht & Basch 2005).

When low doses of bitter melon extract were ingested for up to 2 months in experimental models, no signs of nephrotoxicity, hepatotoxicity or adverse effects on food intake, growth organ weights and haematological parameters were observed. However, toxicity and even death in laboratory animals have been reported when extracts in high doses were administered intravenously or intraperitoneally (Kusamran et al 1998).

PREGNANCY USE

Based on experimental studies in animal models and traditional use, bitter melon is contraindicated in pregnancy until safety is established.

PATIENTS' FAQs

What will this herb do for me?

According to preliminary research, bitter melon may lower blood glucose levels and aid in the management of diabetes.

When will it start to work?

This is difficult to predict. Diabetics should monitor their blood glucose readings when taking bitter melon.

Are there any safety issues?

Bitter melon is contraindicated in pregnancy and people with glucose-6-phosphate dehydrogenase deficiency. The seeds and outer rind should be avoided because they contain toxic lectins. Diabetic patients should monitor their blood glucose when taking bitter melon to prevent hypoglycaemia.

PRACTICE POINTS/PATIENT COUNSELLING

- Bitter melon is used as a traditional remedy for diabetes mellitus. Evidence from experimental studies and case reports support moderate hypoglycaemic activity; however, large-scale clinical trials are needed before clinical significance can be clarified.
- Traditionally, bitter melon has also been used as a treatment for gastrointestinal complaints, worms, constipation, headaches, skin conditions, viral infections and as an emmenagogue.
- According to experimental studies, bitter melon and/or its various constituents exert lipid-lowering, antibacterial, anthelmintic, abortifacient, antineoplastic and analgesic activities.
- Bitter melon is contraindicated in pregnancy and people with glucose-6-phosphate dehydrogenase deficiency.
- Avoid bitter melon seed or the outer rind, which have toxic lectins.

Black cohosh

HISTORICAL NOTE Native Americans first used black cohosh many centuries ago, mainly as a treatment for female reproductive problems, including pain during childbirth, uterine colic and dysmenorrhoea, and also for fatigue, snakebite and arthritis. It was widely adopted by European settlers, eventually becoming a very popular treatment in Europe for gynaecological conditions.

COMMON NAME
Black cohosh

OTHER NAMES
Baneberry, black snakeroot, bugbane, rattle-root, rattle-top, rattleweed, squawroot, traubensilberkerze, wanzenkraut

BOTANICAL NAME/FAMILY
Cimicifuga racemosa now known as *Actaea racemosa* Linnaeus (family Ranunculaceae)

PLANT PARTS USED
Rhizome and root

CHEMICAL COMPONENTS

Black cohosh contains various triterpene glycosides, including cimicifugoside and actein, 27-deoxyactein, *N*-methylcytosine and other quinolizidine alkaloids, phenolic acids, isoferulic and salicylic acids, resins, fatty acids and tannins.

Until recently, the isoflavone, formononetin, was believed to be a pharmacologically important constituent of the herb; however, recent testing of numerous samples has failed to detect it in any sample, including the commercial products Remifemin (Schaper & Brummer GmbH & Co. KG, Salzgitter, Germany) and CimiPure (Kennelly et al 2002).

MAIN ACTIONS

Hormone modulation

The hormonal effects of black cohosh are believed to be the result of complex synergistic actions of several components, particularly the triterpene glycosides. It appears unlikely that black cohosh exerts oestrogenic activity, as although oestrogenic activity has been detected in some tests (Duker et al 1991, Kruse et al 1999, Liu et al 2001), it has not been observed in others (Beck et al 2003, Einer-Jensen et al 1996, Zierau et al 2002). Additionally, the herb has demonstrated anti-oestrogenic activity (Zierau et al 2002).

It has been shown that black cohosh decreases local oestrogen formation in normal human breast tissue in vitro. This may contribute to the lack of hormonal effects of black cohosh in breast tissue observed in previous studies (Stute et al 2007). Preclinical studies to determine how black cohosh works have yielded conflicting results, but several hypotheses have been proposed. It acts either (1) as a selective oestrogen receptor modulator (SERM), (2) through serotonergic pathways, (3) as an antioxidant, or (4) on inflammatory pathways (Ruhlen et al 2008). One study suggests that black cohosh works as a SERM, augmented by central nervous effects (Viereck et al 2005). Results from studies found that it has SERM activity with a lower potency but comparable efficacy to that of 17 beta-oestradiol (Bolle et al 2007). It has no action in the uterus, but beneficial effects in the hypothalamo-pituitary unit and in bone (Seidlova-Wuttke et al 2003). This has been confirmed in a double-blind, randomised, multicentre study (Wuttke et al 2003). In that study, the standardised black cohosh extract BNO 1055 was equipotent with conjugated oestrogens in reducing menopausal symptoms, had beneficial effects on bone metabolism and significantly increased vaginal superficial cells; however, it did not exert uterotrophic activity.

Overall, it is generally agreed that black cohosh reduces LH secretion. This has been confirmed in a human study and is believed to be the result of at least three different active constituents acting synergistically (Duker et al 1991).

Anti-inflammatory

Animal studies have identified some anti-inflammatory activity (Hirabayashi et al 1995).

> ***Clinical note — Selective oestrogen receptor modulators (SERMs)***
>
> These are compounds that, in contrast to pure oestrogen agonists or antagonists, have a mixed and selective pattern of oestrogen agonist–antagonist activity, which largely depends on the tissue targeted. The therapeutic aim of using these substances is to produce oestrogenic actions in those tissues in which it would be beneficial (e.g. bone, brain, liver) and have either no activity or antagonistic activity in tissues, such as breast and endometrium, where oestrogenic actions (like cellular proliferation) might be deleterious. They are a relatively new class of pharmacologically active agents and are being used by women who cannot tolerate pharmaceutical HRT or are unwilling to use it. The most actively studied SERMs are tamoxifen and raloxifen (Hernandez & Pluchino 2003).

Serotonergic

In vitro tests identified compounds in a black cohosh methanol extract that were capable of strong binding to the 5-HT(1A), 5-HT(1D), and 5-HT(7) receptor subtypes (Burdette et al 2003). Further investigation by these authors found that the components functioned as a partial agonist of the 5-HT(7) receptor.

Dopaminergic

It is suggested that the effects of *A. racemosa* may be due to dopaminergic activity, because black cohosh extract BNO 1055 displayed dopaminergic activity with a D(2)-receptor assay (Jarry et al 2003). Considering that dopaminergic drugs reduce some symptoms (e.g. hot flushes) associated with menopause, this theory is feasible; however, further studies are required to explain why black cohosh is devoid of the typical side effects associated with dopaminergic drugs (Borrelli & Ernst 2002).

OTHER ACTIONS

A dose-dependent antihypertensive effect was identified for a triterpene found in black cohosh (actein) in animal tests. The clinical significance of this finding for humans using black cohosh root is unknown (Genazzani & Sorrentino 1962).

Black cohosh is traditionally thought to act as a tonic and nervous system restorative medicine and exert antispasmodic and anti-inflammatory activity.

No effect on CYP3A was detected in a recent human study (Gurley et al 2006a).

CLINICAL USE

Menopausal symptoms

Most clinical research on black cohosh is on its ability to treat menopausal symptoms. Most trials test the commercial preparation of black cohosh known as Remifemin, which is standardised to contain triterpene glycosides (0.8–1.2 mg/tablet), but recently there has been some investigation of BNO 1055, an aqueous ethanolic extract (58% vol/vol), sold as

Klimadynon and Menofem (Bionorica AG, Neumarkt, Germany). Overall, results from clinical studies have been positive but not always consistent making it difficult to reach a definitive conclusion about efficacy. This is likely due to variations in test dose, extraction method, constituent levels present, plant type, and co-administration of other herbs or methodological issues such as variations in outcome measures and small sample size.

A review of eight clinical trials published in 1998 found that black cohosh (Remifemin) is a safe and effective alternative to HRT for menopausal patients in whom HRT is contraindicated (Lieberman 1998). Symptoms responding to treatment with black cohosh included hot flushes, vaginal thinning and drying, night sweats, sleep disturbances, anxiety and depression. Since then there have been a number of clinical trials showing positive benefit for reduction of hot flushes in menopausal women using black cohosh. A pilot study demonstrated that BNO 1055 is able to reduce oestrogen deficiency symptoms to the same degree as conjugated oestrogens (Wuttke et al 2006b). A randomised, double-blind, controlled 3-month study to investigate the efficacy–safety balance of black cohosh (Remifemin) in comparison with tibolone in 244 symptomatic menopausal Chinese women gave remarkable results. The efficacy of both treatments was similar and statistically significant. The safety for both groups was also good. However, the tolerability profile was greatly in favour of the herbal treatment with a significantly lower incidence of adverse events (Bai et al 2007). In a large study of changes in subjective symptoms of menopause in 2016 Hungarian women black cohosh was found to be effective in the alleviation of menopausal symptoms, especially reduction of hot flushes (Vermes et al 2005). In another prospective study, hot flushes and night sweats decreased to a greater extent in women taking black cohosh compared with fluoxetine (Oktem et al 2007). Black cohosh had a significant effect in women with menopausal disorders of moderate intensity decreasing scores on the Menopause Rating Scale by 48% compared with 14% for placebo according to a randomised, placebo-controlled, double-blind study (Frei-Kleiner et al 2005). Another double-blind, randomised, multicentre study compared the effects of BNO 1055 (40 mg/d) to conjugated oestrogens (0.6 mg/d) and placebo on climacteric complaints, bone metabolism and endometrium (Wuttke et al 2003). The study involved 62 postmenopausal women who took their allocated treatment for 3 months. BNO 1055 proved to be equipotent to conjugated oestrogens and superior to a placebo in reducing climacteric symptoms, and both active treatments produced beneficial effects on bone metabolism. Vaginal superficial cells increased with both active treatments; however, BNO 1055 had no effect on endometrial thickness, which was significantly increased by conjugated oestrogens.

Two RCTs found stronger effects of black cohosh in perimenopausal than in postmenopausal women (Frei-Kleiner et al 2005, Osmers et al 2005). Preclinical studies have suggested that a combination of oestrogen and black cohosh is more effective than oestrogen alone. Therefore, the efficacy of black cohosh could be enhanced by the presence of endogenous oestradiol that still occurs in perimenopausal women.

There have been a couple of notable exceptions to these positive findings. A large randomised controlled study (n = 351) of herbal alternatives for menopause, the HALT study, which tested black cohosh, a multibotanical (including 200 mg of black cohosh), a multibotanical plus soy diet counselling, oestrogen ± progesterone, and placebo found that there were no statistically significant differences in the average adjusted change in vasomotor symptoms per day or in vasomotor symptom intensity between the herbal interventions and placebo at 3, 6 or 12 months (Newton et al 2006). The HALT study also showed that black cohosh had no demonstrable effects on lipids, fibrinogen, glucose and insulin (Spangler et al 2007). A smaller double-blind, randomised, crossover clinical trial also failed to provide any evidence that black cohosh reduced hot flushes beyond placebo treatment (Pockaj et al 2006).

Given the number of clinical trials and the conflicting evidence on efficacy of black cohosh in alleviating menopausal symptoms, there have been a number of systematic reviews of the evidence. One systematic review, including randomised, controlled trials, open trials and comparison group studies, found that the evidence to date suggests that black cohosh is safe and effective for reducing menopausal symptoms, primarily hot flushes and possibly mood disorders (Geller & Studee 2005). Later reviews by the same research team showed that black cohosh significantly reduced depression and anxiety in all studies reviewed (Geller & Studee 2007). Another more recent systematic review identified seven randomised controlled trials of black cohosh and concluded that it may be beneficial in the treatment of menopausal vasomotor symptoms in some women (Cheema et al 2007).

An update of a previous systematic review evaluated the clinical evidence for or against the efficacy of black cohosh in alleviating menopausal symptoms. Seventy-two clinical trials were identified but only six of these, with a total of 1163 peri and postmenopausal women, met the inclusion criteria. With one exception, the results for each of these trials were positive; yet, the authors concluded that the efficacy of black cohosh in reducing menopause symptoms is currently not supported by full conclusive evidence, citing small sample size as a limitation in establishing statistical significance (Borrelli & Ernst 2008). Similarly, a recent review of 16 eligible studies suggested that there were methodological flaws in many studies making a definitive conclusion difficult. Methodological issues included: lack of uniformity of the drug preparation used, variable outcome measures and lack of a placebo group (Palacio et al 2009). Clearly, further investigation is required to clarify the most effective preparation and method of use for black cohosh in the treatment of menopausal symptoms.

Weight gain

Rat models demonstrate that BNO 1055 black cohosh extract decreases enhanced pituitary LH secretion, attenuates body weight gain and intra-abdominal fat accumulation, lowers fasting plasma insulin and has no effects on uterine mass. The effects on plasma lipids are complex and are characterised by an increase of LDL cholesterol and decrease of triglyceride levels, which is in contrast to the effects of oestrogen (Rachon et al 2008). There has been no investigation of these effects in human trials.

Osteoporosis prevention

Black cohosh demonstrates osteoprotective effects comparable to oestrogen, although through a different mechanism of increasing osteoblast activity (Wuttke et al 2006a), mediated via an oestrogen receptor-dependent mechanism (Chan et al 2008). A recent experimental study has shown that a triterpenoid glycoside isolated from black cohosh (25-acetyl-cimigenol xylopyranoside) both blocks the osteoclastogenesis enhanced by cytokines in vitro and attenuates TNF-alpha-induced bone loss in vivo (Qiu et al 2007). These results demonstrate that black cohosh can offer effective prevention of postmenopausal bone loss.

Breast cancer protection

A number of in vitro studies on black cohosh show that it is cytotoxic to human breast cancer cells and inhibits the conversion of oestrone sulphate to active oestradiol in breast cancer cells (Rice et al 2007), and suppresses tumour cell invasion without affecting cell viability (Hostanska et al 2007). One in vitro study found that black cohosh enhances the action of some chemotherapy agents, most notably tamoxifen (Al-Akoum et al 2007). The triterpene glycoside, actein, induced a stress response and apoptosis in human breast cancer cells (Einbond et al 2006, 2007, 2008). A recent in vitro study suggests that a herbal combination, Avlimil (which includes black cohosh, licorice, red raspberry, red clover and kudzu), exhibits both stimulatory and inhibitory effects on the growth of oestrogen-dependent breast tumour (MCF-7) cells. This casts doubt on the safety of Avlimil for women with oestrogen-dependent breast cancer (Ju et al 2008).

A randomised study (Hernandez & Pluchino 2003) was also performed with 136 young premenopausal breast cancer survivors experiencing hot flushes as a result of tamoxifen therapy. When BNO 1055 (Menofem/Klimadynon, corresponding to 20 mg of herbal drug) was used together with tamoxifen for 12 months, the number and severity of hot flushes were reduced, with almost 50% of subjects becoming free of hot flushes, and severe hot flushes were reported by only 24% compared with 74% for those using tamoxifen alone.

In contrast, a previous double-blind, placebo-controlled study (n = 85) failed to detect significant improvements with black cohosh for hot flush frequency or severity when used by patients with breast cancer for 2 months and who were also taking tamoxifen (Jacobson et al 2001). Unfortunately, the authors of that study did not specify which black cohosh product was being used or the dosage, making a comparison with the previous study difficult.

Herbal combination studies

A number of studies have been conducted investigating the combination of black cohosh and St John's wort for the treatment of symptoms of menopause with mood symptoms. One double-blind, randomised study of 301 women found that 16 weeks of herbal treatment produced a significant 50% reduction in the Menopause Rating Scale score compared with 20% with placebo and a significant 42% reduction in the Hamilton Depression Rating Scale compared with only 13% in the placebo group (Uebelhack et al 2006). Another large-scale (n = 6141), prospective, controlled open-label observational study supports the effectiveness and tolerability of black cohosh combined with St John's wort for alleviating menopausal mood symptoms (Briese et al 2007). In another double-blind, randomised, placebo-controlled, multicentre study, 89 peri or postmenopausal women experiencing menopause symptoms were treated with a combination of St John's wort and black cohosh extract (Gynoplus) or a matched placebo. Hot flushes were significantly lower and HDL levels increased in the Gynoplus group (Chung et al 2007).

A combination of soy isoflavones, black cohosh and nutritional supplements failed to have a significant effect on menopausal symptoms in a 12-week randomised, placebo-controlled, double-blind study of 124 women (Verhoeven et al 2005).

Commission E has approved the use of this herb as a treatment for menopausal symptoms (Blumenthal et al 2000). Similarly, the World Health Organization (WHO) recognises its use for the 'treatment of climacteric symptoms such as hot flushes, profuse sweating, sleeping disorders and nervous irritability'. The North American Menopause Society recommends black cohosh, in conjunction with lifestyle approaches, as a treatment option for women with mild menopause-related symptoms (North American Menopause Society 2004). In herbal practice generally, menopausal symptoms are usually addressed using a combination of herbs, supplements and dietary and lifestyle advice.

Premenstrual syndrome and dysmenorrhoea

Commission E has approved the use of black cohosh as a treatment in these conditions (Blumenthal et al 2000). Randomised clinical studies are still required to confirm efficacy in these conditions.

Menstrual migraine

An RCT of 49 women with menstrual migraines tested placebo against a herbal combination consisting of 60 mg soy isoflavones, 100 mg dong quai and 50 mg black cohosh, with each component standardised to its primary alkaloid (Burke et al 2002). Over the course of the study, the average frequency of menstrually associated migraine episodes was significantly reduced in the active treatment group.

OTHER USES

Prostate cancer

Two in vitro studies suggest that black cohosh may have theoretical usefulness in the treatment of prostate cancer (Hostanska et al 2005, Jarry et al 2005, Seidlova-Wuttke et al 2006). Further research may demonstrate that black cohosh can effectively prevent and treat prostate cancer.

Black cohosh has been used traditionally to treat a variety of other female reproductive disorders, inflammatory disorders, especially menopausal arthritis and diarrhoea. It has also been used to promote menstruation. The British Herbal Pharmacopoeia states it is indicated in ovarian dysfunction and ovarian insufficiency.

SAFETY

Four hundred postmenopausal women with symptoms related to oestrogen deficiency were enrolled into a prospective, open-label, multinational, multicentre study to investigate endometrial safety and the tolerability and efficacy of the black cohosh extract, BNO 1055. Low dose treatment (40 mg) for 52 weeks showed no case of hyperplasia or more serious adverse endometrial outcome occurred (Raus et al 2006). This finding is supported by the HALT study (Reed et al 2008).

A population-based case-control study consisting of 949 breast cancer cases and 1524 controls was used to evaluate the relationship between phytoestrogens and breast cancer risk. Use of black cohosh was found to have a significant breast cancer protective effect. This association was similar among women who reported use of either black cohosh or Remifemin (Rebbeck et al 2007). Another smaller trial demonstrated that Remifemin does not cause adverse effects on breast tissue. A total of 65 healthy, naturally postmenopausal women completed a trial with 40 mg black cohosh daily. Mammograms were performed, and breast cells were collected by percutaneous fine needle aspiration biopsies at baseline and after 6 months (Hirschberg et al 2007). A systematic review was conducted about the safety and efficacy of black cohosh in patients with cancer. There is laboratory evidence of antiproliferative properties but no confirmation from clinical studies for a protective role in cancer prevention. Black cohosh appears to be safe in breast cancer patients (Walji et al 2007).

A pharmacoepidemiologic, observational, retrospective cohort study examined breast cancer patients to investigate the influence of Remifemin on recurrence-free survival after breast cancer, including oestrogen-dependent tumours. Remifemin was not found to be associated with an increase in the risk of recurrence but was associated with prolonged disease-free survival. After 2 years following initial diagnosis, 14% of the control group had developed a recurrence, while the Remifemin group reached this proportion after 6.5 years, demonstrating a protractive effect of black cohosh on the rate of recurrence of breast cancer for women with a history of breast cancer who had used Remifemin, compared to women who had not (Zepelin et al 2007).

DOSAGE RANGE

- Decoction or powdered root: 0.3–2 g three times daily.
- Tincture (1:10): 2–4 mL three times daily.
- Fluid extract (1:1) (g/mL): 0.3–2 mL three times daily.

Many practitioners have used black cohosh long term without safety concerns; however, Commission E does not recommend more than 6 months' continuous use.

TOXICITY

Overdose has produced nausea and vomiting, vertigo and visual disturbances.

Idiosyncratic hepatic reactions

Rare, spontaneous hepatotoxicity has been reported in 42 case reports world-wide with treatment by *Cimicifugae racemosae rhizoma* (Levitsky et al 2005, Lynch et al 2006, Nisbet & O'Connor 2007, Teschke & Schwarzenboeck 2009, Whiting et al 2002). As a result, several safety reviews have been conducted to evaluate the available data and determine what risk exists with the use of this herb. A safety review of black cohosh products was recently conducted by the Dietary Supplement Information Expert Committee of the US Pharmacopeia's Council of Experts. All the reports of liver damage were assigned possible causality, and none were probable or certain causality. The clinical pharmacokinetic and animal toxicological information did not reveal unfavourable information about black cohosh. The Expert Committee determined that in USA black cohosh products should be labelled to include a cautionary statement, a change from their decision of 2002, which required no such statement (Mahady et al 2008).

Assessment of the 42 cases by European Medicines Agency (EMEA) has shown a possible or probable causality in only four out of 42 patients. A diagnostic algorithm has been applied in the four patients with suspected BC hepatotoxicity using several methods to allow objective assessment, scoring and scaling of the probability in each case. Due to incomplete data, the case of one patient was not assessable. For the remaining three patients, quantitative evaluation showed no causality for BC in any patient regarding the observed severe liver disease (Teschke & Schwarzenboeck 2009).

In Australia in February 2006, the TGA announced that based on the appraisal of case reports, a causal association between black cohosh and serious hepatitis exists; however, the incidence is very low considering its widespread use. As a result, products available in Australia containing black cohosh have to carry label warnings informing consumers of the risk. The conclusion made by the TGA is considered controversial by some experts because numerous confounding factors were present in many of the case reports, such as the use of multiple ingredient preparations, concurrent use of at least one pharmaceutical medicine and the presence of other medical conditions.

A recent study evaluated the effects of black cohosh extract on liver morphology and on levels

of various hepatic function indices in an experimental model finding that at high doses, well above the recommended dosage, black cohosh appears quite safe (Mazzanti et al 2008).

ADVERSE REACTIONS

Although large doses are reported to produce, headache, tremors or giddiness in some people, gastrointestinal disturbances and rashes are the most common adverse effects, according to data from clinical studies and spontaneous reporting programs (Huntley & Ernst 2003). A few serious adverse events, including hepatic and circulatory conditions, have been reported, but without a clear causality relationship (see above). Two cases of cutaneous vasculitis were tenuously linked to supplementation with black cohosh (Ingraffea et al 2007), although no analysis was undertaken to determine specifically what ingredients the supplement contained. One case of pseudolymphoma was linked to Remifemin, which the patient had taken for 1 year. Six months after initial administration of Remifemin skin lesions appeared which continuously increased. Withdrawal of Remifemin resulted in regression and complete remission of the lesions within 12 weeks (Meyer et al 2007). In another case, a woman with severe asthenia and very high blood levels of creatine phosphokinase and lactate dehydrogenase showed a progressive normalisation of biochemical parameters and improvement of myopathy after discontinuing a dietary supplement derived from black cohosh (product not specified). A causative role for black cohosh was hypothesised because of the temporal relationship between use of herbal product and asthenia and the absence of other identified causative factors. Rechallenge with the suspected agent was inadvisable for ethical reasons because of the risk of a serious relapse (Minciullo et al 2006). Both these adverse events are likely to be the result of idiosyncratic reaction to black cohosh.

Despite these reports, the adverse effects of black cohosh tend to be rare, mild and reversible.

SIGNIFICANT INTERACTIONS

A human trial examined the use of a black cohosh (40 mg daily) supplement for 14 days to test phytochemical-mediated modulation of P-glycoprotein (P-gp) and other drug transporters thought to underlie many herb–drug interactions. No statistically significant effects on digoxin pharmacokinetics were observed following supplementation with black cohosh indicating no effect on P-gp (Gurley et al 2006b).

Cisplatin

Black cohosh decreased the cytotoxicity of cisplatin in an experimental breast cancer model — whilst the clinical significance of this finding is unknown, it is recommended that patients taking cisplatin should avoid black cohosh until safety can be confirmed.

Doxorubicin

Black cohosh increased the cytotoxicity of doxorubicin in an experimental breast cancer model — whilst the clinical significance of this finding is unknown, it is recommended patients taking doxorubicin avoid black cohosh until safety can be confirmed.

Docetaxel

A trial used mouse breast cancer cell line to test whether black cohosh altered the response of cancer cells to radiation and to four drugs commonly used in cancer therapy. The black cohosh extracts increased the cytotoxicity of doxorubicin and docetaxel and decreased the cytotoxicity of cisplatin, but did not alter the effects of radiation or 4-hydroperoxycyclophosphamide (4-HC), an analogue of cyclophosphamide which is active in cell culture. This evidence may be applicable to humans so it is advisable that patients undergoing cancer therapy should be made aware that use of black cohosh could alter their response to the agents commonly used to treat breast cancer (Rockwell et al 2005).

CONTRAINDICATIONS AND PRECAUTIONS

There is some controversy over the use of black cohosh in women with a history of breast cancer. Results from a 2002 study testing the safety of black cohosh in an in vitro model for oestrogen-dependent breast tumours found that the herbal extract significantly inhibited tumour cell proliferation, oestrogen-induced proliferation and enhanced the antiproliferative effects of tamoxifen (Bodinet & Freudenstein 2002). This finding is supported in a more recent in vitro study which showed black cohosh having a cytotoxic effect on both oestrogen-sensitive and oestrogen-insensitive breast cancer cells and a synergism with tamoxifen for inhibition of cancerous cell growth (Al-Akoum et al 2007). The synergistic action of black cohosh and tamoxifen needs to be taken into account and evidence that oestrogenic action may not be clinically relevant. Despite this positive preliminary evidence, no clinical studies are available to help establish safety in women with a history of breast cancer. As a result, it is suggested that black cohosh only be used under professional supervision in people with oestrogen-dependent tumours.

PREGNANCY USE

Although it has been used to assist in childbirth, black cohosh is not traditionally recommended in pregnancy, particularly during the first trimester although it has been used in the final weeks of pregnancy to aid in delivery. Safety in lactation remains to be confirmed; however, it is usually avoided because of its hormonal effects (Dugoua et al 2006).

PATIENTS' FAQs

What will this herb do for me?

Black cohosh may be an effective treatment for menopausal symptoms in most women, especially those with mild to moderate symptoms. It may also be useful in the treatment of premenstrual syndrome and prevention of period cramping.

When will it start to work?

Studies suggest that benefits are seen within 4–12 weeks for the treatment of menopausal symptoms.

Are there any safety issues?

Black cohosh should only be used under professional supervision by people undergoing chemotherapy, receiving treatment for oestrogen-dependent tumours or during pregnancy.

PRACTICE POINTS/PATIENT COUNSELLING

- In general, clinical trials support the use of black cohosh for menopausal symptoms; however, not all studies have yielded consistent results and further research is indicated to provide definitive proof.
- It appears that 4–12 weeks' continuous treatment are required for adequate menopausal symptom relief.
- Black cohosh is also used in the treatment of premenstrual syndrome and dysmenorrhoea and is Commission E-approved for these uses; however, controlled studies are not available to confirm its efficacy.
- There is some evidence suggesting that black cohosh exerts selective oestrogen receptor modulator activity, serotonergic activity and possibly dopaminergic activity.
- Black cohosh should be used only under professional supervision by people with oestrogen-dependent tumours or during pregnancy.
- Black cohosh is well tolerated; however, rare case reports of idiosyncratic hepatic reactions have been described.

Brahmi

HISTORICAL NOTE Brahmi is the Sanskrit name for the herb *Bacopa monniera* and has been used in Ayurvedic medicine as a nerve tonic since time immemorial. Under this system, *B. monniera* is classified under 'Medhya rasayana', that is, medicinal plants rejuvenating intellect and memory and has been used in India for almost 3000 years. The ancient classical Ayurvedic treatises recommend it for the promotion of memory, intelligence and general performance. Over time, it has earned a reputation as an important brain tonic (Williamson 2002).

COMMON NAME
Brahmi

OTHER NAMES
Bacopa, herb of grace, herpestis herb, Indian pennywort, jalanimba, jalnaveri, sambrani chettu, thymeleave gratiola, keenmind, Nira-Brahmi, Sambrani Chettu

Centella asiatica (gotu kola) and *Merremia gangetica* have also been referred to by the name brahmi, but most authorities associate brahmi with *Bacopa monniera*. The name Brahmi is derived from the word 'Brama', the mythical 'creator' in the Hindu pantheon. Because the brain is the centre for creative activity, any compound that improves the brain health is called Brahmi (Russo & Borrelli 2005).

BOTANICAL NAME/FAMILY
Bacopa monniera (family Scrophulariaceae)

PLANT PARTS USED
Dried whole plant or herb, mainly leaves and stems (aerial parts)

CHEMICAL COMPONENTS
Dammarene-type saponins (bacosides (A, B, C) and bacosaponines (D, E, F), based on the bacogenins A1–A5, are considered the most important) and alkaloids (brahmine, herpestine), flavonoids (luteolin-7-glucoside, glucuronyl-7-apigenin and glucuronyl-7-luteolin), phytosterols (Chakravarty et al 2003) and luteolin, phenylethanoid glycosides, monnierasides I–III and plantainoside B have been isolated (Adams et al 2007).

Standardised extract BacoMind™ has been shown to contain bacoside A_3, bacopaside I, bacopaside II, jujubogenin isomer of bacopasaponin C, bacosine, luteolin, apigenin and β-sitosterol D glucoside (Dutta et al 2008).

MAIN ACTIONS
The mechanism of action of brahmi has not been significantly investigated in clinical studies, so results from in vitro and animal tests provide most of the mechanistic evidence. Some studies have investigated the effects of an Ayurvedic herbal combination known as brahmi rasayan, which consists of 10 parts bacopa, 2 parts cloves, 1 part cardamom, 1 part *Piper longum* and 40 parts sucrose.

Antioxidant
Brahmi has potent antioxidant activity, which appears to be a result of both direct free-radical scavenging activity and increasing the activity of endogenous antioxidant systems (Bhattacharya et al 2000, Tripathi et al 1996). Administration of bacoside A reduced the effects of cigarette smoke in an animal model by increasing lactate dehydrogenase and its isoenzymes (Anbarasi et al 2005a). Bacoside A has also been shown to reduce creatine kinase in brain and cardiac tissue (Anbarasi et al 2005b), and prevent expression of hsp70 and neuronal apoptosis (Anbarasi et al 2006) thus preventing smoke-induced damage. An extract of brahmi provided protection against DNA damage in both animal cells (Russo et al 2003a) and human cells (Russo et al 2003b) in vitro. Dose-related increases in superoxide dismutase, catalase and glutathione peroxidase activities in several important regions of the brain has been demonstrated in animal models (Bhattacharya et al 2000) and it has been shown to induce the activity of superoxide dismutase and catalase in the liver (Kar et al 2002). Additionally, brahmi enhances antioxidant activity to protect against reactive oxygen species (ROS)-induced damage in diabetic rats (Kapoor et al 2009).

Neuroprotective
Bacopa has demonstrated neuroprotective activity in a number of animal models, chiefly mediated by an antioxidant mechanism. In one study, bacopa significantly protected lipids and proteins from oxidative stress-induced damage caused by aluminium. The protective antioxidant effect was described as similar to L-deprenyl (Jyoti et al 2007).

In another experiment, bacopa improved memory functions in hypobaric conditions which induce hypoxia, most likely due to neuroprotective activity, antioxidant and mitochondria stabilising effects (Hota et al 2009).

Administration of bacoside A prevented the structural and functional impairment of mitochondria upon exposure to cigarette smoke in vivo (Anbarasi et al 2005c). From the results, it was suggested that chronic cigarette smoke exposure induces damage to the mitochondria and that bacoside A protects the brain from this damage by maintaining the structural and functional integrity of the mitochondrial membrane.

In an Alzheimer's dementia model, bacopa extract significantly reduced beta-amyloid levels when administered prior to beta-amyloid deposition (Dhanasekaran et al 2004). The neuroprotective effect was specific for beta amyloid-induced cell death but not glutamate-induced excitotoxicity (Limpeanchob et al 2008). Bacopa extracts contain polyphenols and sulfhydryl compounds that

demonstrate dose-dependent antioxidant activity, which reduces divalent metals, decreases the formation of lipid peroxides and inhibits lipoxygenase activity (Dhanasekaran et al 2007).

Cognitive or nootropic effects

Evidence shows that the effects on the cholinergic system include the modulation of acetylcholine release, choline acetylase activity and muscarinic cholinergic receptor binding (Das et al 2002). Cholinergic effects in combination with antioxidant and mitochondrial stabilisation effects are suggested as the mechanisms responsible for cognitive activation. Results from a double-blind, placebo-controlled trial using brahmi (300 mg/d) support this view, as one of the major effects seen was on speed of early information processing, a function predominantly modulated by the cholinergic system (Stough et al 2001). More recently, *Bacopa monniera* (120 mg/kg oral) significantly reversed diazepam-induced (1.75 mg/kg i.p.) amnesia in an animal study (Saraf et al 2008) thereby confirming previous reports of cholinergic activity (Dhanasekaran et al 2007). The saponins bacoside A and B are considered to be the most important active constituents responsible for enhancing cognitive function (Russo et al 2005, Singh & Dhawan 1982).

Antidepressant activity

A rodent model of depression found that an extract of brahmi produced significant antidepressant activity comparable to that of imipramine after 5 days of oral administration (Sairam et al 2002).

Antiulcer effects

Significant antiulcer activity for the fresh juice from the whole plant of *Bacopa monniera* has been demonstrated in an animal model of aspirin-induced gastric ulceration (Rao et al 2000). The study found that brahmi had a beneficial influence on the natural mucosal defensive factors, such as enhanced mucin secretion, mucosal glycoprotein production and decreased cell shedding, thereby reducing ulceration (Rao et al 2000). A follow-up in vivo study in various gastric ulcer models further confirmed brahmi's ability to increase the body's natural defence factors and showed that *B. monniera* is effective for both the prophylaxis and treatment of gastric ulcers (Sairam et al 2001). In addition, brahmi was shown to reduce lipid peroxidation. An in vitro study demonstrated that *B. monniera* significantly inhibited *Helicobacter pylori*, and the effect was comparable to that of bismuth subcitrate, a known *H. pylori* growth inhibitor (Goel et al 2003).

Anti-inflammatory effects

Several different mechanisms are responsible for the observed anti-inflammatory activity of brahmi. Inhibition of COX-2, 5-LOX and 15-LOX and down regulation of TNF-alpha was demonstrated in one study testing a methanolic extract of *B. monniera*. The activity was found for both EtOAc and bacoside fractions (Viji & Helen 2008). Channa et al (2006) also identified anti-inflammatory activity but reported that this was mediated by PGE_2 inhibition, inhibition of histamine, serotonin and bradykinin release (Channa et al 2006).

The anti-inflammatory activity of bacopa was found to be comparable to indomethacin without causing an associated gastric irritation (Jain et al 1994). Several constituents are thought to be responsible for the anti-inflammatory action, chiefly the triterpene, betulinic acid, saponins and flavonoids.

OTHER ACTIONS

Adaptogen

A standardised extract of *B. monniera* possesses adaptogenic effects in an animal model, which were found to be comparable to *Panax quinquefolium* (Rai et al 2003). The neuropharmacological adaptogenic activity of brahmi was identified by significant normalisation of stress-induced changes in plasma corticosterone, and monoamine levels and dopamine in cortex and hippocampus regions of the brain (Sheikh et al 2007).

Antinociceptive activity

Brahmi rasayan (an Ayurvedic herbal combination containing brahmi) has demonstrated antinociceptive activity in animal experiments (Shukia et al 1987). An interaction with the GABA-ergic system is believed to be involved. Although encouraging, it is not certain to what extent brahmi was responsible for these results.

Mast cell stabilisation

The methanolic fraction of brahmi exhibits potent mast cell stabilising activity in vitro, which was found to be comparable to that of disodium cromoglycate (Samiulla et al 2001).

Increased thyroid hormone levels

Results from animal experiments have found that brahmi increases T_4 concentrations by 41% without enhancing hepatic lipid peroxidation (Kar et al 2002).

Antispasmodic effect on smooth muscle

A spasmolytic effect on smooth muscle has been demonstrated in vivo, and is predominantly due to inhibition of calcium influx into the cell (Dar & Channa 1999). Bronchodilatory effects have also been demonstrated, most likely due to the same mechanism (Channa et al 2003).

Anticlastogenic effect

An in vitro study identified significant anticlastogenic effects of the standardised extract of BacoMind™ on human lymphocytes due to the herb's antioxidant activity (Dutta et al 2008).

Hepatoprotective

Bacoside A was hepatoprotective against D-galactosamine-induced liver injury in rat studies. Researchers found that bacoside A reduced ALT, AST, ALP, γ-GT, LDH and 5'ND enzyme levels and restored the decreased levels of vitamins C and E reduced by D-galactosamine in both liver and plasma (Sumathi & Nongbri 2008).

Clinical note — Scientific investigation of Ayurvedic medicines in India

Modern-day interest in many Ayurvedic herbs, such as brahmi, really started in 1951 when the then Prime Minister of India set up the Central Drug Research centre in Lucknow. The goal of this initiative was to encourage scientists to investigate many of the traditional Ayurvedic herbs in a scientific way, and to determine their potential as contemporary drugs or as potential sources for newer drugs.

CLINICAL USE

Brahmi has been subject to many in vitro and animal studies, which indicate that the herb and several of its key constituents have significant pharmacological activity. Increasingly, clinical studies are being published; however, there is much that remains untested, so information derived from preliminary scientific evidence and traditional evidence is still used as a basis for some clinical applications.

Improving cognitive function — learning, memory, intelligence

In Ayurvedic medicine, bacopa is used to improve cognitive function and increase intelligence. Over time, it has developed an excellent reputation, prompting scientific researchers to investigate the activity of bacopa more closely.

To date, results from animal studies and human trials are encouraging and generally positive; however, more high-quality studies are required. Oral administration of brahmi extract (40 mg/kg) for at least 3 days produced positive effects on learning skills, memory and reaction times compared with controls in one learning model (Singh & Dhawan 1982). Another study found that bacopa extract significantly reversed the cognitive impairment induced by the antiepileptic drug phenytoin, without affecting its anticonvulsant activity (Vohora et al 2000). More recent animal studies have shown that bacopa attenuates hyoscine-induced dementia and significantly inhibits acetylcholinesterase activity in vitro (Das et al 2002). Studies indicate that bacosides A and B present in the ethanolic extract are responsible for the cognition facilitating effects (Russo 2005).

Clinical studies have generally produced encouraging results. A double-blind, placebo-controlled trial using a dose of 300 mg bacopa over 12 weeks in 46 healthy volunteers found that it significantly improved the speed of visual information processing, learning rate and memory consolidation and that it has a significant anxiolytic effect (Stough et al 2001). Another study of the same design tested brahmi in 76 adults over 3 months (Roodenrys et al 2002); significant improvements in a test for new information retention was observed, but there were no changes in the rate of learning.

In 2008, Calabrese et al demonstrated that whole plant standardised dry extract of *Bacopa monniera* (300 mg/day) safely enhanced cognitive performance in the aged in a double-blind, randomised, placebo-controlled study (Calabrese et al 2008). The trial involved 54 volunteers aged 65 years or older, without clinical signs of dementia, who received placebo or herbal treatment for 12 weeks. The group receiving active herbal treatment also experienced a reduction in anxiety whereas anxiety increased in the placebo group.

Results from other double-blind studies producing negative results indicate that cognitive effects require long-term use and are less likely to be seen in short-term or single-dose studies (Nathan et al 2001, 2004).

Anxiety

Bacopa has traditionally been used in Ayurvedic medicine to treat anxiety, and preliminary evidence is promising.

A placebo-controlled, randomised study of healthy subjects found that 300 mg of brahmi daily reduced the anxiety compared with placebo, an effect most pronounced after 12 weeks compared to 5 weeks of treatment (Stough et al 2001). Further randomised studies are warranted.

OTHER USES

In India, brahmi is traditionally recognised as a supportive treatment for mental illness and epilepsy. After clinical trials in human volunteers, a chemically standardised extract of BM has now been made available for prescription by the Central Drug Research Institute in India (Dhawan & Singh 1996). It has been shown to inhibit acetylcholinesterase (AChE) (Das et al 2002, Mukherjee et al 2007), so may have application in Alzheimer's dementia; however, clinical studies are unavailable to determine its efficacy.

Traditional uses

Bacopa has been traditionally used as a brain tonic and is commonly recommended to improve memory and heighten learning capacity. It is also used as a nerve tonic to treat anxiety, nervous exhaustion or debility and is prescribed to enhance rehabilitation after any injury causing nervous deficit, such as stroke. Other traditional uses include promoting longevity, and treating diarrhoea and asthma. It is used as an anti-inflammatory, analgesic, anxiolytic and antiepileptic agent with some support for these uses provided by in vitro and in vivo studies.

Irritable bowel syndrome

An Ayurvedic herbal combination consisting of *Aegle marmelos correa* and *Bacopa monniera* successfully treated 65% of patients with irritable bowel syndrome (IBS) under double-blind, randomised conditions (Yadav et al 1989). Herbal treatment was particularly useful in the diarrhoea-predominant form of IBS, compared with the placebo. Follow-up reviews 6 months after the trial found that relapse rates were the same among all test subjects. Although encouraging, it is not certain to what extent brahmi was responsible for these results.

DOSAGE RANGE

- Dried aerial parts of herb: 5–10 g/day.
- Fluid extract (1:2) or equivalent oral dose form: 5–13 mL/day in divided doses.
- Standardised extract 300–450 mg/day (Pravina et al 2007).

For children aged 6 years and older: 350 mg of dried plant extract in a syrup form was administered three times daily.

Standardised extract

BacoMind™ is an enriched phytochemical composition of *B. monniera*, and is standardised to the content of the following bioactive constituents:

- bacoside A_3 (> 5.0% w/w)
- bacopaside I (> 7.0% w/w)
- bacopaside II (> 5.5% w/w)
- jujubogenin isomer of bacopasaponin C (> 7.0% w/w)
- bacopasaponin C (> 4.5% w/w)
- bacosine (> 1.5% w/w)
- luteolin (> 0.2% w/w)
- apigenin (> 0.1% w/w)
- β-sitosterol-d-glucoside (> 0.3% w/w).

According to clinical studies

- Cognitive activator effects: 300 mg/day.

Positive results obtained in one controlled study have found that 5–12 weeks use is required before clinical effects are observed (Stough et al 2001).

TOXICITY

The LD_{50} data for an ethanolic extract of bacopa is 17 g/kg (oral) (Mills & Bone 2005).

Animal studies indicate that LD_{50} of standardised extract (BacoMind™) is 2400 mg/kg b.w. with no observed adverse effect limit (NOAEL) of 500 mg/kg b.w. after 90 days (Allan et al 2007).

ADVERSE REACTIONS

These may include minor gastrointestinal disturbances, nausea, palpitations, dry mouth, thirst and fatigue.

SIGNIFICANT INTERACTIONS

Controlled studies are not available, so interactions are based on evidence of activity and are largely theoretical and speculative.

Cholinergic drugs

Cholinergic activity has been identified for brahmi, therefore increased drug activity is theoretically possible — observe patient, although a beneficial interaction is possible under professional supervision.

CONTRAINDICATIONS AND PRECAUTIONS

Caution is advised in hyperthyroidism, as bacopa has been shown to significantly elevate T_4 levels in vivo. The clinical significance of this finding is unknown.

Brahmi may cause gastrointestinal symptoms in people with coeliac disease, fat malabsorption syndromes, vitamins A, D, E or K deficiency, dyspepsia or preexisting cholestasis due to the high saponins content of the herb (Mills & Bone 2005).

PRACTICE POINTS/PATIENT COUNSELLING

- Brahmi is an Ayurvedic herb that has been used for several thousand years as a brain tonic, to enhance intellect, treat psychiatric illness, epilepsy, insomnia and as a mild sedative.
- Evidence of cognitive activator activity from animal models of learning is positive.
  - Human studies have shown that brahmi has a significant effect on memory when used long-term; however, short-term use or single doses are unlikely to have an effect.
- Brahmi has potent antioxidant activity, which appears to be a result of both direct free radical scavenging activity and increasing endogenous antioxidant systems in the brain and liver.
- Anticholinesterase, antidepressant, antiulcer, antispasmodic, anti-inflammatory, antihistamine, neuroprotective and antinociceptive activities have been demonstrated in animal studies. Elevated T_4 levels have also been observed.
- Overall, large controlled studies are not available to determine the clinical significance of these effects, but existing evidence is promising.

PREGNANCY USE

Brahmi is recommended as a tonic for anxiety in pregnancy according to traditional Ayurvedic medicine; however, insufficient information is available to confirm safety during pregnancy.

PATIENTS' FAQs

What will this herb do for me?

Brahmi has a long history of use as a brain tonic. Results from scientific studies suggest that it may enhance memory and cognitive function and reduce anxiety with long-term use.

When will it start to work?

Studies suggest that 12 weeks' continual use is required for benefits on cognitive function to become apparent.

Are there any safety issues?

Information from traditional sources suggests that brahmi is well tolerated at the usual therapeutic doses, but scientific investigation has yet to establish whether drug interactions exist.

Calcium

BACKGROUND AND RELEVANT PHARMACOKINETICS

In the context of both biosphere and biology (plant and animal) calcium plays a leading role. Its abundance in the environment (e.g. limestone, marble, coral) is reflected, in part, by its abundance in the human body; however, calcium homeostasis reflects a balancing act between requirements for proper function and the organism's need to protect against excess cellular calcium levels and associated toxicity. This balance has ramifications not only for our own physiology but also in terms of levels and bioavailability of dietary calcium.

Calcium, found in the diet or supplements, exists in salt form, from which it must be released for absorption to occur. Adequate hydrochloric acid levels are required to solubilise the majority of these calcium ions, failing which, calcium salts entering the higher pH environment of the small intestine are more likely to precipitate and be rendered insoluble (Wahlqvist 2002). Low or moderate calcium intakes (≤ 400 mg/d) are absorbed via active transport mechanisms that are influenced by vitamin D. When intake is high, active transport mechanisms become saturated, leading to greater passive absorption. Although most absorption occurs in the small intestine, the large intestine may also be responsible for up to 4% of absorption and provides compensatory mechanisms for those individuals with compromised small intestine absorption (Groff & Gropper 2009).

Calcium's bioavailability from both food and supplements shows enormous variation, from 4% to 45% (Recker 1985) and is dramatically influenced by other foods present in the gastrointestinal tract. Phytates, oxalates, all types of fibres, unabsorbed dietary fatty acids and other divalent minerals all potentially compromise its absorption, while lactose (especially in children) and other sugars, as well as protein and the presence of vitamin D all enhance uptake (Groff & Gropper 2009). There is also evidence of up to 60% inter-individual variance in calcium uptake; the underlying mechanisms, although unclear, may be linked to vitamin D receptor (VDR) polymorphisms (Heaney & Weaver 2003). Consistent with this, our understanding of the magnitude of vitamin D's influence upon calcium absorption continues to broaden, including the life-stage-dependent bioavailability of this mineral. The age-associated decline in calcium absorption (children absorb ≈ 75% compared with ≤ 30% in adults) (Groff & Gropper 2009) has now been linked to vitamin D via reduced available calcitriol and decreased intestinal VDR levels, producing vitamin D resistance (Groff & Gropper 2009, Pattanaungkul et al 2000). Similarly, the decreasing bioavailability associated with (peri)menopause and the increased absorption evident early in pregnancy (Prentice 2003) are attributed largely to vitamin D-mediated effects. Calcium absorption, however, is described as being generally inefficient, with a substantial amount of calcium remaining unabsorbed in the lumen (Heaney & Weaver 2003).

Distribution results in 99% of absorbed calcium being deposited in bones. The remainder of the absorbed calcium is present in teeth and the intracellular or extracellular fluids. Calcium is excreted in faeces, sweat and urine. Calcium homeostasis is tightly regulated by the actions of parathyroid hormone (PTH), calcitonin and vitamin D. Together, these hormones determine the level of absorption, excretion or retention by the kidneys, and sequestering or mobilisation of stores through bone mineralisation and resorption.

FOOD SOURCES

Good dietary sources of calcium include dairy products, fortified soy products, fish with bones, especially salmon and sardines, tofu, broccoli, collard greens, mustard greens, bok choy, clams and black strap molasses.

DEFICIENCY SIGNS AND SYMPTOMS

While there is little information available about the prevalence of deficiency across the general Australian population, a Melbourne study of 1045 women aged 20–92 years in 2000 revealed that approximately 76% of women consumed calcium at levels less than the recommended daily intake (RDI) and an additional 14% demonstrated a grossly inadequate intake of less than 300 mg/day (Pasco et al 2000). These figures are similar to those obtained by larger studies in the United States (Groff & Gropper 2009). Calculating the prevalence of calcium deficiency is partly hampered by physiological preservation of 'non-osseous' calcium for critical roles in exchange for the 'expendable' reserves in bone and, therefore, the slow development of overt deficiency features. Consequently, calcium deficiency is insidious in its early stages and potentially irreversible in the latter, making preventative optimisation the only successful pathway in all patients perceived to be at an increased risk. In addition to this, long-term suboptimal calcium has been linked to an increased risk of a range of other morbidities, including preeclampsia and colorectal cancer.

Deficiency signs and symptoms include:

- tetany: muscle pain, spasms and paraesthesias
- rickets
- osteomalacia
- increased neuromuscular irritability
- altered heart rate
- ambulatory developmental delays in children
- osteoporosis and increased risk of fractures
- bone pain and deformity
- tooth discolouration and increased decay
- hypertension
- increased risk of preeclampsia
- increased risk of colon cancer (controversial).

There are many situations and conditions in which the risk of hypocalcaemia may be increased.

Primary deficiency

Primary deficiency occurs as a result of inadequate dietary intake, with greatest risk seen in populations with increased calcium requirements e.g. children, adolescents, pregnant and lactating women, postmenopausal women, particularly those taking hormone replacement therapy (HRT) (Wahlqvist 2002), people experiencing rapid weight loss or patients receiving total parenteral nutrition (TPN).

Secondary deficiency

Calcium absorption is impaired in achlorhydria (more common in the elderly), intestinal inflammation and any malabsorptive disorder accompanied by steatorrhoea (Wilson et al 1991). Increased faecal calcium loss occurs with higher intakes of fibre and in fat malabsorption, while renal excretion has been shown in

some studies to be increased in those patients ingesting a high protein diet (Kerstetter et al 1998).

Factors that compromise vitamin D status or activity will also affect calcium status (Pattanaungkul et al 2000, Prince et al 1997) e.g. oral and inhaled corticosteroids (Beers & Berkow 2003, Rossi et al 2005).

Other conditions that can predispose to hypocalcaemia include hypoparathyroidism (a deficiency or absence of PTH), idiopathic hypoparathyroidism (an uncommon condition in which the parathyroid glands are absent or atrophied), pseudohypoparathyroidism (characterised not by deficiency of PTH, but by target organ resistance to its action), magnesium depletion, renal tubular disease, renal failure, acute pancreatitis, hypoproteinaemia, septic shock or the use of certain medicines such as anticonvulsants (phenytoin, phenobarbitone) and rifampicin, and corticosteroids (Beers & Berkow 2003, Rossi et al 2005).

MAIN ACTIONS

Calcium is an essential mineral required for the proper functioning of numerous intracellular and extracellular processes, including muscle contraction, nerve conduction, beating of the heart, hormone release, blood coagulation, energy production and maintenance of immune function. It also plays a role in intracellular signalling and is involved in the regulation of many enzymes.

Bone and teeth mineralisation

Calcium is found in bone where it is mainly complexed with other ions in the form of hydroxyapatite crystals. Approximately 1% of calcium in bone can be freely exchanged into the extracellular fluid in order to buffer changes in calcium balance.

Muscle contraction

Ionised serum calcium helps to initiate both smooth and skeletal muscle contraction and in particular, the regulation of rhythmic contraction of the heart muscle in combination with sodium and potassium.

Blood clotting

Calcium is involved in several steps of the blood clotting cascade.

Altered membrane functions

Calcium fluxes across membranes, both within the cell and across the plasma membrane, and acts as a vehicle for the signal transduction necessary for neurotransmitter and hormone function. It also selectively alters cell wall permeability to regulate passage of fluids in and out of cells.

OTHER ACTIONS

Regulates various enzyme systems responsible for muscle contraction, fat digestion and protein metabolism.

CLINICAL USE

Many of the indications for calcium supplements are conditions thought to arise from a gross or marginal deficiency; however, some are based on the concept of 'beyond-repletion' calcium therapy.

Calcium deficiency

Traditionally, calcium supplementation has been used to treat deficiency or prevent deficiency in high-risk conditions or people with increased calcium requirements such as pregnant women. Acute severe hypocalcaemic states are treated initially with intravenous infusion of calcium salts. In chronic cases, oral calcium supplements and occasionally vitamin D supplements are used.

Rickets and osteomalacia

A deficiency of either calcium or vitamin D can produce these bone disorders. (See Vitamin D monograph for further information.)

Infants

The percentage and type of fats within an infant formula and their ability to bind calcium salts and increase excretion has been shown to influence the bone mineral content (BMC) of infants. One hundred 8-week-old infants given formulas considered to be more similar to breastmilk and less likely to form calcium soaps in the gut showed increased BMC after only 1 month's treatment compared with those infants on standard formula (Kennedy et al 1999).

Bone mineral density (BMD) and osteoporosis prophylaxis

Children and adolescents

A 2006 Cochrane review of 19 trials, including 2859 participants, found no effect of calcium supplementation on femoral neck or lumbar spine BMD (Winzenberg et al 2006). There was a small effect on total body BMC and upper limb BMD; however, only the effect in the upper limb persisted after supplementation ceased. The effect is approximately equivalent to a 1.7% greater increase in supplemented groups, which, at best, would reduce absolute fracture risk in children by 0.1–0.2% annually. Additionally, there was no evidence of effect modification by baseline calcium intake, sex, ethnicity, physical activity or pubertal stage. The findings of this review, however, are contradicted by a more recent meta-analysis of 21 RCTs (Huncharek et al 2008b), which, while confirming a lack of effect in individuals with (near)adequate calcium intake at baseline, demonstrated significantly increased BMC (35–49 g) in those with a preexisting deficiency with long-term treatment. Overt critics of the methodology applied in the Cochrane review, another group of researchers undertook an 18-month study of calcium-deficient adolescent girls (average age 12 years), increasing their mean daily intake by 555 mg in the treatment group, yielding significantly increased BMC and BMD and reduced bone turnover markers in the treatment group compared with a placebo (Lambert et al 2008).

Adolescents

Peak bone mass is one of the main determinants of osteoporotic fracture in humans and, therefore, there is significant research dedicated to determine the influence of calcium status on the 40–50% peak

bone mass accretion that occurs during adolescence. Overall, studies in adolescent girls have shown that calcium supplementation significantly improves bone mineral status. Numerous studies, including one by Stear et al in 2003 of 144 pubertal girls, have confirmed a synergistic relationship between mechanical load, through physical activity, calcium status and bone calcium accumulation; however, it is important to note that physical activity has a positive effect on BMD only at high calcium intakes, with no effect at calcium intakes of less than 1000 mg/day (Harkness & Bonny 2005).

Until recently, all clinical trials with calcium supplements in children and adolescents demonstrating a positive effect on bone mass were conducted over durations of 1–3 years. As such, it is uncertain whether supplementation and resultant increases in bone mass had a beneficial effect in the long-term. A 2005 placebo-controlled study addressed this issue by using calcium supplements (670 mg/d) over a 7-year period. The study of 354 pubertal girls reported significant increases in BMD during growth spurts in the supplemented group; however, these gains did not uniformly persist into late adolescence and only girls of tall stature received long-lasting benefits. Interestingly, the placebo group exhibited a 'catch-up' in bone mineral accretion subsequent to the pubertal growth spurt (Matkovic et al 2005). These results introduce two novel concepts: the first being that dietary calcium requirement for skeletal development may be size dependent and, secondly, the possibility that a calcium mineral deficit may be a transient feature of the pubertal growth spurt, with a 'catch-up' possible during bone consolidation. In spite of these findings, the temporary gains in BMD may be important in the prevention of fractures during adolescence (Matkovic et al 2005).

A second study introduces other issues regarding the impact of variable calcium status in adolescents. The RCT of 144 prepubertal girls used 850 mg/d of calcium over 1 year. After follow-up some 7 years later, in addition to positive effects on BMD outcomes, an inverse relationship became apparent between calcium supplementation and age of menarche. The authors speculate that higher calcium intake prior to menarche may favourably impact on long-term BMD through this dual mechanism (Chevalley et al 2005).

Postmenopausal women

Numerous studies have confirmed an important role for calcium in the prevention of osteoporosis in postmenopausal women. Clinical studies have assessed its efficacy as a sole agent against placebo, in comparison with steroid hormones, antiresorptive drugs and as part of combination therapy.

Long-term supplementation with calcium protects against bone loss according to a 2-year study involving 60 postmenopausal, non-osteoporotic women. The trial showed that in comparison with the 3% BMD loss evident in the placebo group, those consuming 1633 mg/day on average of supplemental calcium suffered no bone loss, as measured at the greater trochanter, and, in fact, their BMD improved at other sites tested (Storm et al 1998). A similar trend was demonstrated by Daniele et al (2004) in their study of 120 women, given only 500 mg of calcium and 200 IU of vitamin D per day over 30 months. In general, though, the efficacy of calcium supplements in postmenopausal women appears to be largely dependent upon the baseline calcium intake. Those with an initial poor intake tend to achieve significant improvements over placebo, with more modest or no effect evident in groups with higher intakes at baseline (Daniele et al 2004, Fardellone et al 1998).

Whether calcium supplements are sufficient as a stand-alone preventative measure against osteoporosis is still being investigated. The results of one study suggest that the effects of calcium on BMD may require additional supplementation with the trace minerals zinc, manganese and copper (Strause et al 1994). However, the most impressive results obtained to date are for the combination of high-dose calcium with antiresorptive drugs such as oestrogen or calcitonin. A review of these studies highlights the gain in bone mass that resulted from the addition of calcium in contrast to the halt in BMD depletion commonly observed with use of calcitonin alone (Nieves et al 1998).

Other studies of both male (n = 50) and female (n = 200) populations using a combination of fluoride, as monofluorophosphate, and calcium over a 3–4-year period, found this combination to be superior to calcium alone in the prevention of BMD loss. Increased lumbar spine BMD and reduced risk of fractures was evident in both trials using the two minerals (Reginster et al 1998, Ringe et al 1998).

Men

The overwhelming majority of calcium studies for bone health have been conducted in postmenopausal women and often their results have simply been extrapolated to produce clinical protocols for men regarding osteoporosis prevention and management. The few studies conducted in male populations, while not always unanimous, have shown no benefit at 600 mg/day, while yielding BMD improvements secondary to higher doses (1200 mg/day) comparable with postmenopausal women. Enhanced results in some studies may be attributable to the addition of vitamin D (Reid et al 2008).

The elderly

A number of large studies investigating the preventative effect of calcium alone or in combination with vitamin D have produced predominantly positive results in the elderly. Studies by Chapuy et al (1992, 1994, 2002), Dawson-Hughes et al (1997) and Larsen et al (2004) demonstrate a significant reduction in fracture risk (≤ 16%), while a recent meta-analysis of 29 RCTs conducted in 63,897 individuals of 50 years and above, over an average of 3.5 years, also concluded that calcium alone (≥ 1200 mg/day) or in combination with vitamin D (≥ 800 IU/day) reduced the risk of fracture by 12–24% and reduced bone loss by 0.54% at the hip and 1.19% at the spine (Tang et al 2007).

Greatest improvements were noted specifically in the elderly, institutionalised, underweight and calcium deficient. Adding to this, a recent Australian trial investigating 1200 mg/day of calcium administered alone or combination with 1000 IU vitamin D over 5 years in 120 women aged 70–80 years yielded beneficial effects on BMD and bone turnover markers for both treatment groups, with evidence of more sustained improvements in those also taking vitamin D (Zhu et al 2008). The RECORD Trial in 2005, a RCT of 5292 people aged 70 years or older who received either 1000 mg of calcium or 800 IU of vitamin D/day, alone or together, for 24–62 months, however, failed to yield positive findings (The RECORD Trial group 2005). The authors postulate that improved results in previous studies may be due to the increased age (> 80 years) of study volunteers and poorer vitamin D status at baseline; however, the results of the studies cited here contradict this supposition.

Glucocorticoid-induced osteoporosis

Approximately one in six people with asthma receiving inhaled and/or systemic glucocorticoids developed fractures over 5 years. The interaction with calcium plays a small role in this process, with glucocorticoids directly inhibiting vitamin D-mediated intestinal absorption of calcium. High vitamin D doses (50,000 IU twice weekly) in combination with 1.5 g calcium daily can overcome this interference (Wilson et al 1991), whereas a randomised study found that treatment with calcium alone or in combination with etidronate may not be effective. A study of 352 volunteers found that treatment for 5 years did not significantly reduce the fracture rate (Campbell et al 2004).

Supplementation during pregnancy and lactation

Evidence from 1997 found that approximately 40% of primiparous Australian women failed to meet the RDI for calcium. Considered a critical nutrient during pregnancy with at least a twofold increase in requirements observed, its metabolism during gestation significantly changes from as early as 12 weeks, with doubling of both absorption and excretion, followed by additional losses through lactation, which can account for reductions in maternal bone mineral content of 3–10% (Prentice 2003). While it is clear that general supplementation would be necessary in those women with poor preconception calcium levels, it is suggested that for healthy women the metabolic compensation evident in pregnancy should be sufficient to guarantee adequate fetal levels.

Prevention of hypertension and preeclampsia

Epidemiological evidence illustrates an inverse relationship between calcium status and the prevalence of preeclampsia (Frederick et al 2005, Lopez-Jaramillo et al 2001) and recent studies confirm abnormalities in markers of calcium metabolism and status in preeclamptic populations compared to controls, including low urinary and serum calcium levels (Ingec et al 2006, Sukonpan & Phupong 2005). Trials that included a 1996 meta-analysis of studies involving calcium and hypertension in pregnancy have shown a substantial mean reduction in both systolic blood pressure (SBP) and diastolic blood pressure (DBP), which was also confirmed by more recent reviews (Atallah et al 2002, Bucher et al 1996).

Positive correlations demonstrated in original smaller trials between calcium supplementation and reduced prevalence of preeclampsia, involving over 400 women, were put into question when the Calcium for Prevention of Pre-eclampsia study (CPEP), the largest trial to date, found no effect on the incidence or severity of the condition (Levine et al 1997). However, the CPEP study, involving over 4000 healthy nulliparous women, was not a replication of the existing trials. While the original studies used populations with a low calcium intake to ascertain the connection between correction of this deficiency and prevalence of preeclampsia, the CPEP represented a 'pharmacological intervention in women with a normal calcium intake' (Lopez-Jaramillo et al 2001). A large study conducted by the WHO in eight countries of 8325 low-calcium-consuming women (< 600 mg/day), also failed to demonstrate a preventative effect for high-dose calcium; however, supplementation did reduce the severity of preeclampsia, in addition to reducing maternal morbidity and maternal (RR 0.80) and neonatal mortality (RR 0.70) (Villar et al 2006).

Further reviews of studies involving over 15,000 women, however, have supported calcium's preventative role with researchers demonstrating significant risk reduction in both low-risk (RR 0.48) and high-risk women (RR 0.22), hence, concluding calcium supplementation should be recommended for those women with a low calcium intake who are at risk of developing gestational hypertension (Crowther et al 1999, Hofmeyr et al 2003, 2006, 2007).

There is currently no unanimous explanation for calcium's protective effect (Villar et al 2003). While the antagonistic relationship between calcium and lead has been previously hypothesised to be involved (Sowers et al 2002), recent evidence of calcium's lack of effect on platelet count, plasma urate and proteinuria, in spite of reducing pre-eclamptic incidence, implies that high-dose calcium effectively lowers blood pressure without influencing the condition's underlying pathology (Hofmeyr et al 2008).

A small number of studies have investigated the effects of calcium in combination with other nutrients, including antioxidant and omega-3 oils in this population. One randomised, placebo-controlled, double-blind study involving a sample of 48 primigravidas, using a combination of 600 mg/day calcium and 450 mg/day of conjugated linoleic acid (CLA) from weeks 18–22 until delivery, resulted in a significantly reduced incidence of pregnancy-induced hypertension (8% vs 42% of the control group) (Herrera et al 2005). Further studies are warranted to elicit the individual impact of both nutrients and to determine the superiority of sole or combination treatment.

Leg cramps

Calcium supplements are commonly prescribed in pregnancy when leg cramps are a problem. A Cochrane review of five trials involving 352 women taking various supplements for the treatment of leg cramps in pregnancy included only one placebo-controlled trial of calcium. From this, researchers concluded that any improvement in cramps in those groups treated solely with calcium was likely due to a placebo effect, with significant findings limited to the groups taking other nutrients (Young & Jewell 2002).

Fetal growth

The greatest period of fetal mineral accretion has been identified as the gestational period of 20–33 weeks, with daily needs escalating from 50 mg/day to 330 mg/day at its peak. The average newborn contains about 20–30 g calcium, and one study of 256 women in their second trimester showed that supplementation in women with poor calcium status significantly increased neonatal bone mineral content, as determined by X-ray absorptiometry measurements at 1-week post-partum (Koo et al 1999). However, the full relationship between maternal calcium intake and fetal growth, particularly in non-deficient women, has yet to be elucidated (Prentice 2003). One suggested effect of gestational mineral intake has been the determination of calcium concentration in the mother's breast milk, while it has been established that this concentration is not the result of calcium intake postpartum (Prentice et al 1999).

Lead toxicity

Increased blood lead levels are commonly a result of bone resorption during pregnancy and are considered a potential risk to fetal and infant health. Lead can be transferred to the fetus and infant via cord blood and breastmilk. Several studies suggest a low placental barrier to lead, with 79% of the mobilised lead from maternal bone passed to the infant (Dorea & Donangelo 2005). While a number of studies have indicated lead levels in the breastmilk of Australian women appear to be well within a safe range, recent data from a study conducted by Ettinger et al revealed that even low lead content in human milk appears to be highly influential on the lead levels of infants in their first month of life (Ettinger et al 2004). A separate review published in 2005 discussed additional related trends such as increased lead concentrations in cord blood during winter months, because of lower vitamin D status (Dorea 2004).

A RCT of 617 lactating women supplemented with high-dose calcium carbonate found that the women in the calcium group showed significant reductions in blood lead levels. Those subjects who showed improved compliance and also had baseline higher bone lead content produced an overall reduction of 16.4% (Hernandez-Avila et al 2003). Similar positive findings came from a study in Mexico of 367 lactating women; however, the maximal reduction in lead concentrations reached only 10% (Ettinger et al 2006). Nevertheless, when considered together these results suggest that calcium supplementation may represent an important interventional strategy, albeit with a modest effect, for reducing infant lead exposure.

Neonatal benefits

Calcium supplementation during pregnancy has been postulated to have prolonged benefits in the offspring, as indicated in a study of nearly 600 children aged 5–9 years whose mothers had previously participated in a calcium trial during their pregnancy. The children demonstrated reduced SBP, compared with the children whose mothers had taken placebo, with significance reached particularly for those in the upper BMI bracket (Belizan et al 1997). More recent reviews, while still demonstrating some association between gestational calcium supplementation and reduced blood pressure and incidence of hypertension in the offspring (particularly older children e.g. 7 years), highlight the weakness of the evidence to date, including small sample sizes, methodological issues and the fact that most of the studies have been conducted in developed countries where calcium intake is more likely to be adequate (Bergel & Barros 2007, Hiller et al 2007).

Dyspepsia

A first-line over-the-counter (OTC) treatment for heartburn, indigestion and dyspepsia has often been an antacid, based on calcium carbonate in combination with magnesium and aluminium salts. Calcium in combination with the other ingredients reduces stomach acid and increases the rate of gastric emptying (Vatier et al 1996). In trials comparing H_2 blockers with calcium carbonate tablets, calcium was found to be equipotent, yet delivered a more rapid response and shorter duration of action (Feldman 1996). There have been many papers highlighting the dangers of prolonged use of these traditional antacids; however, pure calcium carbonate formulas attract the least concern, with the incidence of 'milk alkali syndrome' resulting from their overuse reported to be rare (Ching & Lam 1994, Herzog & Holtermuller 1982).

Prevention of cancer

Interest in a relationship between dairy consumption and cancer incidence continues to grow, with evidence of both protective and contributory effects dependent upon both cancer type and timing of exposure. The consumption of dairy products, however, represents a mix of numerous variables and biological pathways that potentially convey these underlying actions, from which calcium's role is difficult to extricate (van der Pols et al 2007). An interventional study of calcium (1400–1500 mg/day), alone or with vitamin D_3 (1100 IU/day), compared to placebo over 4 years, offers more specific information regarding calcium's role in cancer (Lappe et al 2007). The study, conducted in 1179 women of more than 55 years, was primarily designed to assess effects on fracture incidence; however, upon further analysis also demonstrated significant risk reduction (RR 0.40) for all cancer incidence

amongst the calcium and vitamin D group. When the analysis was restricted to only those cancers diagnosed after the first year of treatment, the RR became 0.23. While the group receiving calcium alone also demonstrated a reduced risk, the researchers speculate that this may not be robust and conclude that vitamin D is the key variable in reduced incidence of all cancer.

Prevention of colorectal cancer and recurrence of adenomatous polyps

Currently, the gold standard for measuring risk reduction by an intervention in colorectal cancer investigates the incidence of recurrence of adenomatous polyps following removal of all colonic polyps by polypectomy; further analyses evaluate reduction of total adenomatous polyps and reduction of advanced polyps as defined by size and the presence of severe dysplasia. Reasonably consistent evidence suggests that calcium supplementation of 1200 mg/d reduces total adenomas by approximately 20% and advanced adenomas by about 45% (Holt 2008). Interestingly, some studies show that calcium's protective effect against recurrent adenomas is largely restricted to individuals with baseline serum 25-hydroxy vitamin D above the median (≈ 29 ng/mL). These data, together with more recent findings (Mizoue et al 2008), strongly point to the importance of both calcium and vitamin D for reducing colorectal cancer risk and altering adenoma recurrence (Grau et al 2003, Holt 2008, Oh et al 2007).

Interactions between calcium and other variables in colorectal carcinogenesis have also been explored, revealing gender-specific results; protective in males but not in females in most (Ishihara et al 2008, Jacobs et al 2007, Ryan-Harshman & Aldoori 2007), but not all, studies. Further research, including re-analysis of the Women's Health Initiative (WHI) findings pertaining to colorectal cancer incidence, has elucidated oestrogen's critical modifying effect upon calcium, whereby the higher oestrogen levels of both menstruating and postmenopausal women taking HRT negate calcium's otherwise protective effect (Ding et al 2008). Explanations for this phenomenon include oestrogen's influence upon calcium distribution: removing it from circulation for bone deposition and competition for binding evident between vitamin D and oestrogen (Ding et al 2008, Oh et al 2007).

Early hypotheses regarding calcium's general protective effects focused on its ability to bind bowel-irritating substances secreted into bile. This notion is further supported by a number of studies demonstrating enhanced chemoprotection when high doses of calcium have been combined with dietary factors such as reduced fat and increased carbohydrate, fibre and fluid intakes (Hyman et al 1998, Rozen et al 2001, Schatzkin & Peters 2004).

One significant development in our understanding has been the discovery of human parathyroid calcium-sensing receptors in the human colon epithelium, which function to regulate epithelial proliferation and differentiation. New in vitro studies suggest that expression of these receptors may be induced by the presence of extracellular calcium and vitamin D, therefore promoting greater differentiation of the epithelial cells (Chakrabarty et al 2005, Holt 2008) and inducing apoptosis (Miller et al 2005).

A 2005 Cochrane review examining the effect of supplementary calcium on the incidence of colorectal cancer and the incidence or recurrence of adenomatous polyps included two double-blind, placebo-controlled trials with a pooled population of 1346 subjects. Doses of supplementary elemental calcium used were 1200–2000 mg/day for 3–4 years. Reviewers concluded that, while the evidence to date appears promising and suggests a moderate degree of prevention against colorectal adenomatous polyps, more research with similar findings is required before this can be translated into any preventative protocol (Weingarten et al 2005).

Clear parameters for dosing are not yet available, with some studies showing no further benefit above 700–800 mg/day of total calcium, while other studies suggest an ongoing inverse dose-dependent relationship without cutoff (Schatzkin & Peters 2004). Current evidence for a combined protective role of calcium, either dietary or supplemental, and vitamin D, particularly in men and postmenopausal women not taking HRT, is strong and further elucidation of the independent and combined effects of these nutrients will assist in the development of preventative protocols.

Other cancers

Ongoing research regarding calcium's potential role in a range of other cancers suggests a possible protective effect against breast and ovarian cancers (Genkinger et al 2006, McCullough et al 2005, 2008); however, the research remains preliminary and largely of epidemiological design. A greater body of evidence has developed regarding the interplay between calcium and prostate cancer, with initial findings touting a positive association between dairy product consumption, total dietary calcium intake (especially >1500 mg/day) and risk. The results of ongoing extensive, prospective epidemiological research involving hundreds of thousands of men, however, have been conflicting, both confirming (Ahn et al 2008, Gao et al 2005) and negating (Huncharek et al 2008a, Park et al 2007a & b) earlier evidence. Two important details have recently emerged regarding the potential interaction between calcium and prostate cancer risk with several studies consistently demonstrating that calcium derived from supplements does not convey a greater risk (Ahn et al 2008, Baron et al 2005, Park et al 2007a) and limiting calcium as a risk factor only when consumed as dairy products, while greater non-dairy calcium intake appears to lower the risk (Allen et al 2008, Park et al 2007b). A prospective study of serum calcium adds to the riddle, revealing that results in the highest tertile typically more than 9 years prior to diagnosis were strongly associated with increased risk of fatal prostate cancer (Skinner & Schwartz 2008); however, such results may be indicative of calcium dysregulation rather than high intakes.

Hypertension

Ongoing broad-scale international epidemiological data, including prospective studies, link low dietary calcium intake, with a slightly increased risk of hypertension (Alonso et al 2005, Elliott et al 2008, Geleijnse et al 2005, Wang et al 2008). Conversely, increased dietary calcium, typically in the form of low-fat dairy products, has been shown to be independently protective (RR 0.87 for highest quintile of calcium intake) (Alonso et al 2005, Wang et al 2008). A recent study found that high dietary calcium was associated with SBP/DBP reductions of −2.42/−1.48 mmHg, after controlling for other known risk factors (Elliott et al 2008). This effect was more pronounced when accompanied by increased magnesium and phosphorus consumption. Interestingly, neither high-fat dairy products nor calcium supplements convey protection (Wang et al 2008)

Additional findings attracting attention include epidemiologic links between markers of low calcium status or calcium metabolism abnormalities, hypertension and insulin resistance. Supporting the possible link between these phenomena are the results of a Japanese study of 34 non-diabetic hypertensive and 34 non-diabetic normotensive women. Multiple group assessments revealed statistically significant increased urinary calcium, lower BMD, depressed serum calcium and elevated circulating PTH in the hypertensive sample (Gotoh et al 2005).

Underlying mechanisms for calcium's protective effect are speculated to involve reduced calcium influx into cells, inhibiting vascular smooth muscle cell constriction, reduced activity of the renin–angiotensin system and improved Na/K balance (Wang et al 2008).

A 2006 Cochrane review of 13 RCTs involving 485 volunteers found that calcium supplementation significantly reduced SBP (mean difference: −2.5 mmHg), but not DBP (mean difference: −0.8 mmHg) compared with controls (Dickinson et al 2006). The authors temper their conclusion, stating that the quality of included trials was poor and the heterogeneity between trials means there is a tendency to overestimate treatment effects. Earlier, an extensive systematic review, updated in 1999 to include 42 randomised comparative trials, showed modest reductions in both SBP and DBP (−2 mmHg and −1 mmHg, respectively) with 1–2 g/day calcium over a 4–14-week intervention (Griffith et al 1999). Dietary calcium appeared to have a larger effect than supplementation, a finding reiterated in more recent studies (Wang et al 2008). The clinical significance of these small effects has been questioned and the recommendation of calcium as a therapy for all types of hypertension appears premature (Kawano et al 1998), particularly in light of more recent negative findings from the WHI, which investigated the effects of 1 g of calcium together with 400 IU of vitamin D over a median follow-up period of 7 years in postmenopausal women (Margolis et al 2008). Some studies have proposed that it is only a particular hypertensive subset that is calcium responsive. A number of researchers, for example, have hypothesised a physiological correlation between 'salt sensitive' hypertension and responsiveness to calcium treatment (Coruzzi & Mossini 1997, Resnick 1999). The link may be that sodium excess encourages calcium losses. This theory is further supported by a recent epidemiological study demonstrating that, while blood pressure was inversely correlated with dietary calcium, further analysis revealed sodium intake to be the primary influence, increasing pressures while concomitantly reducing BMD (Woo et al 2008).

Premenstrual syndrome

Of all the vitamins and minerals used in the treatment of premenstrual syndrome (PMS), calcium supplements show overwhelmingly positive results.

One of the earliest trials to show that calcium supplementation can alleviate symptoms in PMS was conducted in 1989 (Thys-Jacobs et al 1989). A randomised, double-blind, crossover trial involving 33 women with confirmed PMS compared the effects of daily 1000 mg calcium carbonate with placebo over 6 months. Results showed that 73% of women reported improved symptoms while taking calcium supplementation, whereas 15% preferred placebo. The premenstrual symptoms responding significantly to calcium supplementation were mood changes, water retention and premenstrual pain. Menstrual pain was also significantly alleviated.

In 1993, the *American Journal of Obstetrics and Gynecology* published a study that compared the effects of calcium (587 mg or 1336 mg) and manganese (1.0 mg or 5.6 mg) on menstrual symptoms. Ten women with normal menstrual cycles were observed over four 39-day periods during the trial (Penland & Johnson 1993). The researchers found that increasing calcium intake reduced mood, concentration and behavioural symptoms generally and reduced water retention during the premenstrual phase. Additionally, menstrual pain was reduced.

A more recent large, double-blind, placebo-controlled, randomised parallel-group study was conducted in the United States and supports the previous findings (Thys-Jacobs et al 1998). Four hundred and sixty-six premenopausal women with confirmed moderate to severe PMS were randomly assigned to receive either 1200 mg elemental calcium (from calcium carbonate) or placebo for three menstrual cycles. Symptoms were documented daily by the subjects based on 17 core symptoms and four symptom factors (negative affect, water retention, food cravings and pain). Additionally, adverse effects and compliance were monitored daily. During the luteal phases of both the second and third treatment cycles, a significantly lower mean symptom score was observed in the calcium group. By the third treatment cycle, calcium treatment resulted in a 48% reduction in total symptom score compared with baseline, whereas placebo achieved a 30% reduction. Furthermore, all four symptom factors responded in the calcium-treated group.

A 1999 review of multiple trials investigating calcium supplementation as an effective therapy for PMS has found overwhelming positive results (Ward & Holimon 1999).

Some researchers in this area have hypothesised that part of the PMS aetiology lies in calcium dysregulation in the luteal phase and have highlighted the dramatic similarities between symptoms of PMS and hypocalcaemia (Thys-Jacobs 2000). Recent data from the Nurses' Health Study II support this theory, with evidence of low calcium and vitamin D levels in PMS populations when compared to controls (Bertone-Johnson et al 2005).

Weight loss

Although the underlying mechanism of action remains unclear, there is general acceptance that high calcium intake, particularly in the form of dairy products, and more recently calcium-fortified soy (Lukaszuk et al 2007), depresses PTH levels and $1,25(OH)_2D$, which in turn decreases intracellular calcium, thereby potentially inhibiting lipogenesis and stimulating lipolysis (Major et al 2007, McCarty & Thomas 2003, Schrager 2005, Zemel et al 2004). Additional proposed actions include increased rates of faecal fat and energy excretion (14.2 g/day vs 5.9 g/day and 1045 kJ/day vs 684 kJ/day), as observed in a preliminary study of 10 subjects during a 1-week high-calcium and normal protein diet (1800 mg/day and 15% of total energy intake, respectively) (Jacobsen et al 2005). More recent evidence also points to a potential satiety effect (Kabrnova-Hlavata et al 2008).

A prolific researcher in this area is Zemel (2004, Zemel et al 2004, 2005a, 2005b), having published three small trials investigating the effects of dietary and supplemental calcium in patients for weight maintenance or weight loss. These trials have consistently yielded positive results, demonstrating that in addition to enhanced weight loss on isocaloric and identical macronutrient profiles, with or without energy restriction, a diet providing high calcium levels of 1100–1200 mg/day results in central fat loss and corresponding improvements in blood pressure, insulin sensitivity and retention of lean tissue. Australian researchers, Bowen et al, have also demonstrated similar results (Bowen et al 2004). Zemel et al conclude that dietary calcium and, in particular, dairy-based foods are the most effective form of calcium for weight loss and that results are significant within 12 weeks.

An early review by Teegarden (2003), bringing together trials dating back 10 years to the first rat studies and updated in 2005, while acknowledging the promising data in relation to increased consumption of dairy products and weight management which had emerged over the intervening 2 years, noted the limitations of the current body of evidence that required addressing to elucidate the full extent of calcium's effect on weight. A more recent meta-analysis of 13 RCTs investigating calcium interventions ranging between 610 mg and 2400 mg/day over a period of 12 weeks–36 months, failed to demonstrate a positive effect on weight loss for either calcium supplements or dairy products; however, once again methodological concerns were raised (Trowman et al 2006). In spite of this, studies have continued to emerge yielding positive findings in postmenopausal women as part of the WHI study (calcium and vitamin D treatment reducing risk of weight gain by 11%) (Caan et al 2007) and in overweight and obese type 2 diabetic patients (> 8% more weight loss in those consuming calcium in the highest compared with the lowest tertile) (Shahar et al 2007). Additionally, one small study demonstrated an augmenting effect of calcium (1200 mg together with 400 IU vitamin D/day) over 15 weeks on weight loss-induced beneficial changes to blood lipids and lipoproteins (Major et al 2007).

In contrast to this, there have been a number of studies reporting negative results. A trial of isocaloric energy-restricted diets in 54 overweight subjects with either low or high calcium intake from dairy products found that over 12 months there was no significant difference in weight loss between the two groups (Harvey-Berino et al 2005). Other studies incorporating calcium supplements of 1000 mg/day yielded negative results over three 25-week periods in pre- and postmenopausal women (Shapses et al 2004), as did a longitudinal study of dietary habits in adolescents (Berkey et al 2005), and calcium augmentation of a 3-week weight management program in overweight individuals; however, in the latter both the dose and the duration of the study appear inadequate (Kabrnova-Hlavata et al 2008).

Finally, caution is being encouraged by many authorities who are keen to remind researchers that epidemiological data have positively linked high dairy diets with a range of other conditions, most notably prostate cancer (Lanou 2005).

Nephrolithiasis

In spite of previous concerns regarding a causal relationship between dietary or supplemental calcium intake and the recurrence of oxalate stones, recent studies demonstrate that this fear appears unfounded. Collectively, the evidence points more towards a protective effect for increased dietary calcium, in relation to both urinary oxalate concentrations (Taylor & Curhan 2004) and reduced stone formation (Goldfarb 2009). The current view is that, rather than being a contributing factor for oxalate stones, dietary calcium, through its binding of oxalate in the gut, can minimise recurrence, as substantiated by other studies (Curhan et al 1997, Liebman & Chai 1997).

One study comprised 120 men with recurrent calcium oxalate stones due to idiopathic hypercalciuria and who were randomly assigned to either a low-calcium diet or low-animal protein, low-salt normal-calcium diet and assessed for changes in frequency of stone formation. Results clearly showed reduced oxalate excretion in those on a normal calcium intake, as well as a greater decrease in calcium oxalate saturation (Borghi et al 2002). In another study of 14 healthy men, assessment of the influence of dietary calcium on the given amount of oxalate demonstrated that with the inclusion of additional calcium (1121 mg) urinary oxalate levels increased in the control but not in the treatment group (Hess et al 1998).

OTHER USES

Hyperlipidaemia

In a randomised, placebo-controlled crossover trial of 56 patients with mild–moderate hypercholesterolaemia on a controlled low-cholesterol diet, calcium

Clinical note — Is calcium supplementation a risk for increased vascular events?

Recently, concern has emerged regarding a potential increase in cardiovascular events associated with long-term high-dose calcium supplementation. This is largely the result of a New Zealand RCT investigating the effect of calcium supplements (1000 mg/d) administered to 1471 healthy postmenopausal women over 5 years (Bolland et al 2008). The primary outcome of this study was bone density; however, the researchers also hypothesised that a secondary effect of the treatment would be a reduction in heart attacks, based on existing observational studies highlighting calcium's positive effect on blood lipids and blood pressure (Nainggolan 2008). However, much to the researchers' surprise, secondary analysis of the data revealed that women taking calcium supplements experienced higher rates of myocardial infarction (RR 1.49), all vascular events (RR 1.21) and stroke (RR 1.37), translating to 23.3/1000 persons annually versus 16.3/1000 persons annually for the women taking placebo. While the authors conclude that their study does not unequivocally demonstrate causality, they cite three other large studies with somewhat similar findings, including secondary analyses of the WHI which yielded a RR of 1.18 for older heavier women taking calcium and vitamin D. Speculation regarding a potential mechanism of action includes raised serum calcium which may accelerate vascular calcification, predictive of vascular events. The authors also flag the possibility that, similar to the WHI findings, a particular subset of individuals may be at an elevated risk due to increasing age (average age of study participants was 74 years), preexisting cardiovascular disease and declining renal function.

While such findings initially cause substantial alarm and warrant further thorough investigation, the fact that a comparable number of other large calcium studies, e.g. Iowa Women's Health Study, Boston Nurses' Health Study, have failed to demonstrate this relationship, or in fact have found a protective effect, must also be considered. In addition to this, it is interesting to reflect on the possible interplay between calcium, magnesium, oestrogen and cardiovascular risk, as have Seelig et al (2004). These researchers propose that an elevated ratio of Ca:Mg induces a procoagulatory environment, which would theoretically be compounded by exogenous oestrogen in the form of HRT. In accordance with this, they have hypothesised that the increased rates of cardiovascular events seen amongst the WHI participants is a consequence of these interactions and excessive calcium supplementation without magnesium is inherently dangerous in such a population.

carbonate supplementation was shown to significantly reduce LDL levels by 4.4%, with additional 4.1% increases in HDL levels. No other effects on other blood lipids or blood pressure were observed (Bell et al 1992). Another small study demonstrated an augmenting effect of calcium (1200 mg together with 400 IU vitamin D/day) over 15 weeks on weight loss-induced beneficial changes to blood lipids and lipoproteins, with significantly greater reductions in total:HDL, LDL:HDL and LDL levels (Major et al 2007).

Dry eye

A controlled double-masked study of petrolatum ointment containing 10% w/w calcium carbonate applied on the lower lid twice daily for 3 months resulted in significant improvements in all criteria assessed. However, significance over placebo was only found in ocular surface staining, therefore determination of the action of petrolatum needs to be established and controlled in future studies to identify the therapeutic value of calcium (Tsubota et al 1999).

Fluorosis

Calcium has been shown to reduce the clinical manifestations of fluorosis in children exposed to contaminated water (Gupta et al 1996).

DOSAGE RANGE

Australian RDIs

- Infants
  - 1–3 years: 500 mg/day.
  - 4–8 years: 700 mg/day.
- Children
  - 9–11 years: 1000 mg/day.
  - 12–18 years: 1300 mg/day.
- Adults
  - < 70 years: 1000 mg/day.
  - > 70 years: 1300 mg/day.
- Pregnancy: 1000–1300 mg/day.
- Lactation: 1000–1300 mg/day.

According to clinical studies

- Osteoporosis prophylaxis: 1500 mg/day in combination with accessory nutrients (e.g. zinc, manganese, copper and fluoride, HRT or antiresorptive drugs).
- Premenstrual syndrome: 1200–1600 mg/day.
- Prevention of preeclampsia: 2000 mg/day.
- Increased BMD in children with low intake: 100 mg/day.
- Supplementation during pregnancy to increase mineral accretion in fetus: 2000 mg/day for last trimester.
- Allergic rhinitis: 100 mg/day.
- Hyperacidity: 500–1500 mg/day as required.
- Hyperlipidaemia: 400 mg three times daily.
- Hypertension: 1000–2000 mg/day.
- Dry eye: 10% w/w calcium carbonate in petrolatum base applied twice daily.
- Fluorosis in children: 250 mg/day.
- Prevention of colorectal cancer: 1200 mg/day.
- Weight loss: 1000–1200 mg/day long term.

ADVERSE REACTIONS

Oral administration of calcium supplements may cause gastrointestinal irritation, constipation and flatulence.

Hypercalcaemia
Increased serum calcium may be associated with anorexia, nausea and vomiting, constipation, hypotonia, depression and occasionally lethargy and coma. Prolonged hypercalcaemic states, especially if associated with normal or elevated serum phosphate, can precipitate ectopic calcification of blood vessels, connective tissues around joints, gastric mucosa, cornea and renal tissue (Wilson et al 1991).

SIGNIFICANT INTERACTIONS
Calcium carbonate when taken as an antacid alters the absorption and excretion of a wide range of drugs. Please refer to a drug interaction guide for specific concerns. Only those interactions encountered with oral administration of calcium supplements will be included in this section.

Alendronate
Calcium causes decreased absorption of this drug. However, as calcium supplementation is a fundamental adjuvant to the prevention of BMD loss, supplementation should still be encouraged — separate doses by at least 2 hours.

Atenolol
Simultaneous use can reduce bioavailability of both agents — separate dose by 2 hours.

Caffeine
Caffeine increases urinary excretion of calcium — ensure adequate calcium intake and monitor for signs and symptoms of deficiency.

Calcium channel blockers
Calcium supplements can have an antagonistic effect on the desired action of calcium channel blockers that could precipitate the re-emergence of arrythmias — avoid high-dose supplements unless under professional supervision.

Cardiac glycosides
Administered concurrently, high-dose calcium supplements can act synergistically with these drugs, which may induce arrythmias and potentiate their toxicity — use this combination with caution.

Corticosteroids
Both oral and long-term inhaled corticosteroids inhibit vitamin D-mediated calcium absorption: overall levels of calcium may be decreased — ensure adequate calcium intake and monitor for signs and symptoms of deficiency. Consider supplementation with long-term drug therapy.

Etidronate
Calcium may reduce drug absorption; however, adequate calcium is required for optimal drug effects — separate doses by at least 2 hours.

Excess dietary fat
This increases urinary excretion of calcium — ensure adequate calcium intake and monitor for signs and symptoms of deficiency.

Excess fibre, including guar gum
May simply delay or decrease absorption of calcium — separate doses by at least 2 hours.

Levothyroxine
Calcium administered concurrently may reduce drug absorption — separate doses by at least 4 hours.

Lysine
Additive effects may occur as lysine enhances intestinal absorption and reduces renal excretion of calcium — potentially beneficial interaction.

Magnesium
Magnesium decreases calcium absorption as they compete for the same absorption pathway — separate doses by at least 2 hours.

Oestrogen and progesterone
Calcium supplementation in combination with these hormones will have an additive effect on minimising bone resorption in postmenopausal women — potential beneficial interaction, so consider increasing intake.

Phosphorus
Excess intake (soft drinks, meat consumption) can increase urinary excretion of calcium — ensure adequate calcium intake and monitor for signs and symptoms of deficiency.

Tetracyclines
Calcium supplements form complexes with these antibiotics and render 50% or more insoluble, therefore reducing the efficacy of the drug and absorption of calcium — separate doses by at least 2 hours.

Thiazide diuretics
These diuretics decrease urinary excretion of calcium. Monitor serum calcium and look for signs of hypercalcaemia, such as anorexia, polydipsia, polyuria, constipation and muscle hypertonia when using high-dose calcium supplements. Contributing risk factors are the presence of hyperparathyroidism or concurrent use of vitamin D.

Zinc
Calcium supplementation has been shown in some studies to increase faecal losses of zinc (McKenna et al 1997) — ensure adequate zinc intake and monitor for signs and symptoms of deficiency.

CONTRAINDICATIONS AND PRECAUTIONS
People with hyperparathyroidism, chronic renal impairment or kidney disease, sarcoidosis or other granulomatous diseases should only take calcium supplements under medical supervision. Calcium supplementation is contraindicated in hypercalcaemia.

PREGNANCY USE
Many trials have established the safety of calcium supplementation during pregnancy in doses up to 2000 mg elemental calcium per day.

PRACTICE POINTS/PATIENT COUNSELLING

- Calcium is an essential mineral required for the proper functioning of numerous intracellular and extracellular processes, including muscle contraction, nerve conduction, beating of the heart, hormone release, blood coagulation, energy production and maintenance of immune function.
- Low-calcium states are associated with several serious diseases such as colorectal cancer, osteoporosis types I and II, hypertension, preeclampsia and eclampsia.
- Although supplementation is traditionally used to correct or avoid deficiency states, research has also shown a role in the prevention of osteoporosis, preeclampsia and management of numerous disease states
- Clinical studies show that calcium supplementation may have benefits in premenstrual syndrome, hypertension, weight loss and reducing incidence of some cancers.
- Calcium can interact with numerous drugs and should be used with caution by people with renal disease or hyperparathyroid conditions.

PATIENTS' FAQs

What will this supplement do for me?

Calcium is essential for health and wellbeing. Although used to prevent or treat deficiency states, and primarily associated with BMD, it is also beneficial in a wide range of conditions such as prevention of preeclampsia, premenstrual syndrome, some forms of hypertension, maintenance of fetal growth, treatment of lead toxicity and PMS. It is considered to be a critical nutrient in pregnancy.

When will it start to work?

This will depend on the indication it is being used to treat; however, in most instances long-term administration is required (i.e. months to years).

Are there any safety issues?

In very high doses, calcium supplements can cause some side effects, including constipation, but generally calcium is considered very safe and has a wide therapeutic range. High-dose supplements should not be used by people taking some medications. Caution should also be exercised with high doses in individuals with preexisting cardiovascular disease. (See *Significant interactions* above for specific information.)

Calendula

HISTORICAL NOTE Calendula is indigenous to Eastern Europe and the Mediterranean where its medicinal value has been respected since ancient times. Calendula was popular in Ancient Greece and in earlier Indian and Arabic cultures. It has been a common garden plant since the 12th century and it is mentioned in several older herbals. The name calendula comes from the Latin *calends*, meaning the first day of the month, referring to the plant's near continual flowering habit.

COMMON NAME
Marigold

OTHER NAMES
Pot or garden marigold, gold-bloom, holligold.

Field marigold (*Calendula arvensis*) is also used medicinally for the same indications because it has similar constituents.

BOTANICAL NAME/FAMILY
Calendula officinalis (family Asteraceae [Compositae or Daisy])

PLANT PARTS USED
The flowers are primarily used, but the stems, younger leaves, seeds and roots all have medicinal properties.

CHEMICAL COMPONENTS
The major constituents are triterpene saponins (2–10%) based on oleanolic acid and flavonols (3-O-glycosides of isorhamnetin and quercetin), including astragalin, hyperoside, isoquercitrin and rutin, as well as the carotenoids flavoxanthin and auroxanthin (Bako et al 2002). The triterpendiol esters faradiol laurate, faradiol myristate and faradiol palmitate have been identified as the major active compounds, which are also used as marker compounds for standardisation of calendula extracts (Hamburger et al 2003, Zitterl-Eglseer et al 2001). The terpenoids faradiol, amidiol and calenduladiol have been shown to have anti-inflammatory activity (Neukirch et al 2005).

Other constituents include essential oil, sesquiterpenes, including caryophyllene, and triterpenes, including amyrins, lupeol and lupenone. Calendula also contains polysaccharides (WHO 2003), as well as minerals such as calcium, sodium, potassium, magnesium, iron, copper and manganese (Ahmed et al 2003).

MAIN ACTIONS

Antimicrobial
Hydro-alcoholic extracts have been shown to have antibacterial, antiviral and antifungal activities. The in vitro antifungal activity of calendula flower extracts has been investigated against *Aspergillus niger*, *Rhizopus japonicum*, *Candida albicans*, *C. tropicalis* and *Rhodotorula glutinis*. Calendula extract showed a high degree of activity against all fungi and the inhibitory effect was comparable to that of standard antifungals (Kasiram et al 2000). A flower extract has been shown to inhibit trichomonas. The oxygenated terpenes are thought to be the main active compounds (Gracza & Szasz 1968, Samochowiec et al 1979). A 70% hydro-alcoholic extract demonstrated virucidal activity against influenza virus and suppressed the growth of HSV (Bogdanova et al 1970). Calendula flower extract has also been shown to possess anti-HIV and anti-EBV activity in vitro (Kalvatchev et al 1997, Ukiya et al 2006).

Promotes wound healing
An ointment containing 5% calendula flower extract, as well as an ointment containing two different fractions of calendula extract combined with allantoin, have been shown to stimulate physiological regeneration and epithelialisation in experimentally induced surgical wounds. The effect is thought

to be due to more intensive metabolism of glycoproteins, nucleoproteins and collagen proteins during regeneration of the tissues (Klouchek-Popova et al 1982).

Anti-inflammatory

Anti-inflammatory activity has been demonstrated in several animal models. Pretreatment with an 80% hydro-alcoholic extract reduced carrageenan-induced rat paw oedema at a dose of 100 mg extract/kg. Endomethacin 5 mg/kg was shown to be 4-fold more potent in the same experiment (Mascolo et al 1987). Both a 70% hydro-alcoholic extract and a CO_2-extract have been shown to inhibit experimentally induced inflammation and oedema. The triterpenoids were shown to be the main active anti-inflammatory compounds, with the faradiol monoester appearing to be the most relevant compound due to its quantitative prevalence (Della et al 1994). A freeze-dried extract of calendula was found to suppress both the inflammatory effect and leukocyte infiltration in an inflammatory model induced by the simultaneous injection of carrageenan and PGE_1 (Shipochliev et al 1981).

Ten triterpenoid glycosides (including four new compounds) were isolated from calendula and tested for anti-inflammatory activity. Of these, nine were found to be effective against 12-O-tetradecanoylphorbol-13-acetate–induced inflammation in mice (Ukiya et al 2006).

OTHER ACTIONS

Reduces oedema

Oral administration of a triterpene-containing fraction prevented the development of ascites and increased survival time compared with controls in mice inoculated with a carcinoma (Boucaud-Maitre et al 1988). The main triterpendiol esters of calendula, the faradiol esters, have been shown to possess anti-oedema activity by inhibiting croton oil-induced oedema of the mouse ear (Zitterl-Eglseer et al 1997).

Immunomodulation

Isolated polysaccharides have been shown to stimulate phagocytosis of human granulocytes (Varljen et al 1989, Wagner et al 1985). A 70% ethanol extract of calendula was shown to completely inhibit the proliferation of lymphocytes in the presence of phytohaemagglutinin in vitro (Amirghofran et al 2000).

Antioxidant

Calendula has free radical scavenging and antioxidant activity, with aqueous extracts having greater activity than methanolic extracts, with antioxidant activity being related to the total phenolic content and flavonoid content (Cetkovic et al 2004).

The butanolic fraction of a calendula extract has been shown to reduce superoxide and hydroxyl radicals, suggesting a free radical scavenging effect. Lipid peroxidation in liver microsomes is also reduced (Cordova et al 2002). Isorhamnetin glycosides isolated from calendula have been shown to inhibit the activity of lipo-oxygenase (Bezakova et al 1996).

Antispasmodic activity

Calendula has demonstrated anti-spasmodic activity in isolated gut preparations (Bashir et al 2006). These effects appeared to be due to calcium channel blocking and cholinergic activity.

Hypoglycaemic activity

A methanolic extract and its butanol-soluble fraction have been found to have hypoglycaemic and gastroprotective effects and to slow gastric emptying. From the butanol-soluble fraction, four new triterpene oligoglycosides, calendasaponins A, B, C and D, were isolated, together with eight known saponins, seven known flavonol glycosides, and a known sesquiterpene glucoside. Their structures were elucidated on the basis of chemical and physicochemical evidence. The principal saponin constituents, glycosides A, B, C, D and F, exhibited potent inhibitory effects on an increase in serum glucose levels in glucose-loaded rats, gastric emptying in mice, and ethanol and indomethacin-induced gastric lesions in rats (Yoshikawa et al 2001).

Hypolipidaemic activity

Oral administration of an isolated saponin fraction has been shown to reduce serum lipid levels in hyperlipidaemic rats (ESCOP 1996).

Hepatoprotective

Calendula extracts have been shown to have hepatoprotective effects on rat hepatocytes both in vitro and in vivo (Barajas-Farias et al 2006, Rusu et al 2005), with cytotoxic and genotoxic effects being evident at very high doses (Barajas-Farias et al 2006, Perez-Carreon et al 2002).

CLINICAL USE

Calendula is generally used in the treatment of inflammatory skin disorders or inflammation of the mucosa and as an aid to wound healing (Blumenthal et al 2000, ESCOP 1996). It is used both internally and topically for a variety of indications.

Wounds and burns

Historically, calendula flower preparations have been used to accelerate the healing of wounds, burns, bruises, grazes and minor skin infections. In recent times, it has been investigated for its effects on wound healing in a variety of experimental models and clinical studies as either a stand-alone topical treatment or in combination with other ingredients.

In an RCT involving 254 patients treated with adjuvant radiotherapy for breast cancer, topical treatment with calendula to the irradiated skin was found to be significantly more effective than trolamine in reducing acute dermatitis, with patients receiving calendula having less frequent interruption of radiotherapy and significantly reduced radiation-induced pain (Pommier et al 2004). In another controlled trial involving 34 patients with venous leg ulcers, a calendula extract applied twice daily for 3 weeks was found to produce a statistically significant acceleration in healing compared to a saline solution (Duran et al 2005).

Calendula ointment (8%, 1:10 tincture in 70% alcohol) is a useful adjuvant treatment during cosmetic surgery, according to a study of 19 cleft-lip patients with discoloured scar tissue. Pretreatment with the calendula ointment under a gauze dressing every evening for 1 month improved the results of dermatography, a refined tattooing technique used to improve the appearance of scars (Van der Velden & Van der Dussen 1995). Another clinical study used a mixture of chlorhexidine acetate and a 2% calendula extract as a haemostatic aerosol, producing good results (Garg & Sharma 1992).

A larger, open, randomised parallel study of 156 patients in four burn centres in France compared the effects of three different topical ointments (calendula, a proteolytic ointment and vaseline) on the management of second and third degree burns. A thick layer of the test ointment was applied daily under a closed dressing until grafting or spontaneous healing occurred and effectiveness was evaluated between the 8th and 12th day of treatment. Failure was defined as the presence of an eschar, local infection, premature treatment discontinuation or failure to complete the study. A marginally significant difference in favour of calendula over vaseline was observed and calendula was significantly better tolerated than the other treatments (Lievre et al 1992).

Prophylactic treatment with calendula ointment has also been used successfully to reduce the incidence and severity of bedsores in an open multicentre study. In other studies, positive results have been demonstrated in the treatment of poor venous return associated with ulcers, thrombophlebitis and other cutaneous changes such as inflammation, cracks and eczema (Issac 1992).

In practice, calendula is sometimes used together with St John's wort for stronger effects. The combination of *Calendula arvensis* (field marigold) and *Hypericum perforatum* oils has been shown to improve the epithelial reconstruction of surgical wounds in childbirth with caesarean section (Lavagna et al 2001).

A combination of calendula, *Arctium lappa* and *Geranium robertianum* has also been shown to improve healing of ulceration in 52 patients suffering herpetic keratitis compared with treatment with acyclovir alone (Corina et al 1999).

Commission E approves the external use of calendula for poorly healing wounds and leg ulcers (Blumenthal et al 2000).

Gastrointestinal inflammatory disorders (in combination)

An oral mixture of *Symphytum officinalis* (comfrey) and calendula was beneficial in the treatment of duodenal ulcers and gastroduodenitis according to a study involving 170 patients. Of these, 137 were treated with the herbal combination and 33 also received an antacid. A dramatic 90% of treated patients became pain free and 85% had a reduction in dyspeptic complaints. Gastric acidity showed a statistically insignificant tendency to decrease in both groups. Gastroscopy later revealed that the ulcers had healed in 90% of patients (Chakurski et al 1981). Interestingly, a smaller study conducted by the same researchers involving only 32 patients with the same condition failed to detect a beneficial effect (Matev et al 1981).

A further study by the same authors found another mixture containing calendula to be beneficial in the treatment of chronic colitis. A combination of *Taraxacum officinale*, *Hypericum perforatum*, *Melissa officinalis*, *Calendula officinalis* and *Foeniculum vulgare* was shown to relieve the spontaneous and palpable pains along the large intestine in over 95% of the patients ($n = 24$) by day 15 of treatment. Defecation was normalised in patients with diarrhoea and constipated patients were successfully treated with the addition of *Rhamnus frangula*, *Citrus aurantium* and *Carum carvi*. The pathological admixtures in faeces disappeared (Chakurski et al 1981).

Although encouraging, the role of calendula as a stand-alone treatment is difficult to determine from these studies. Additionally, the oral ingestion of comfrey is not recommended due to potential hepatotoxic effects.

Gingivitis

Calendula has been shown in an open, clinical study to be beneficial in the treatment of chronic catarrhal gingivitis (Krazhan & Garazha 2001). Interestingly, calendula extract failed to show any significant activity in vitro against common oral microorganisms in a second study that tested it against the saliva and dental plaque from 20 infants (Modesto et al 2000); however, a homeopathic preparation of calendula has been found to inhibit *Streptococcus mutans* (Giorgi et al 2004).

Commission E approves the internal and topical use of calendula flowers for inflammation of the oral and pharyngeal mucosa (Blumenthal et al 2000).

NAPPY RASH

Efficacy and safety of two baby creams in nappy rash

In a postmarketing surveillance study (Guala et al 2007), 82 infants aged between 3 days and 48 months were randomised to receive either calendula cream (Weleda) or Babygella for treatment of their nappy rash. Both preparations were judged by physicians and mothers as useful, however mothers tended to describe the calendula cream more frequently than Babygella as very good rather than satisfactory. The calendula cream also contained other anti-inflammatory and healing ingredients such as chamomile and zinc, making the contribution of calendula hard to judge.

OTHER USES

The British Herbal Pharmacopoeia recommends calendula for gastric and duodenal ulcers, amenorrhoea, dysmenorrhoea and epistaxis (BHMA 1983). Topically it is recommended for leg ulcers, varicose veins, haemorrhoids, eczema and proctitis. The specific indications are for enlarged or inflamed lymphatic nodes, sebaceous cysts, duodenal ulcers, and acute and chronic inflammatory skin conditions. Its

styptic activity makes it a popular topical treatment for bleeding.

DOSAGE RANGE

- Dried herb: 1–2 g as an infusion daily in divided doses.
- Liquid extract (1:2): 15–30 mL/week for internal use or 1.5–4.5 mL/day in divided doses. Dilute 1:3 for external application.
- Tincture (1:5): 0.3–1.2 mL three times daily.
- Calendula oil can be produced by steeping fresh flowers in vegetable oil for 1 week. Strain before use.

TOXICITY

Calendula has low toxicity. No symptoms of toxicity were found after long-term administration of a calendula extract in animal studies (Elias et al 1990, ESCOP 1996). A study evaluating an excessive dose (5 g/kg) in rats found no toxicity, however signs of liver and kidney burden were noted (Silva et al 2007). Calendula has been found to be neither mutagenic nor carcinogenic (Elias et al 1990).

ADVERSE REACTIONS

Irritant dermatitis from calendula has been reported (Paulsen 2002, Reider et al 2001) but is rare. Sesquiterpene lactones are the most important allergens present in Compositae species, but there are also a few cases of sensitisation from a coumarin, a sesquiterpene alcohol and a thiophene (Paulsen 2002).

A study of over 1000 patients randomly chosen from several different patch test clinics identified only one who reacted to calendula (Bruynzeel et al 1992). Patch test results need to be carefully interpreted because false positives can occur, as the following case shows. A 35-year-old woman with recalcitrant atopic dermatitis, with a positive patch-test reaction to Compositae mix, was told she was allergic to calendula. However, it turned out that she followed a self-devised diet consisting largely of food products of the Compositae family (which includes lettuces and artichoke). On excluding these foods her skin condition improved quickly. This case report underscores the difficulty in determining the relevance of positive patch tests, and shows that thorough analysis of positive patch tests, by both patient and physician, may reveal unexpected or less common sources of contact allergens (Wintzen et al 2003).

SIGNIFICANT INTERACTIONS

Controlled studies are not available to assess the interaction potential of calendula.

CONTRAINDICATIONS AND PRECAUTIONS

Use with caution in patients with confirmed allergy to herbs or foods from the Compositae family.

PREGNANCY USE

Insufficient reliable information available to assess safety.

PATIENTS' FAQs

What will this herb do for me?

Calendula is used for inflammatory skin conditions, including poor wound healing, burns and ulcers, due to its non-irritant, antiseptic and healing properties. Internally it is used for inflammation and ulceration of the digestive tract.

When will it start to work?

Topical effects are quickly established and should improve with continuous use. Internal use may take longer.

Are there any safety issues?

Although there have been some reports of allergic reactions to calendula, these are very rare. Calendula is generally well tolerated by children and adults.

PRACTICE POINTS/PATIENT COUNSELLING

- Calendula has antimicrobial and anti-inflammatory activity and promotes wound healing.
- European text books recommend calendula for inflammation of the skin, poorly healing wounds, bruises, boils, rashes, bed sores, dermatitis resulting from chilblains, wound healing after amputations, cracked nipples during pregnancy and lactation, acne, sunburns, burns and nappy rashes. Calendula is also indicated for pharyngitis and tonsillitis (Bisset 1994, Bruneton 1999, Evans 2002, Issac 1992).
- There is some evidence from clinical trials that calendula may be beneficial in the treatment of burns, wounds and gastrointestinal inflammation and ulceration.
- People who are sensitive or allergic to foods or plants from the Compositae family should use calendula with caution.

Carnitine

BACKGROUND AND RELEVANT PHARMACOKINETICS

Carnitine was discovered in 1905, although its role in metabolism was only described in the mid 1950s and deficiency symptoms outlined in 1972. It is a trimethylated amino acid, roughly similar in structure to choline, that is ingested through the diet and also synthesised from lysine and methionine in the body. To do this, a large number of cofactors are required, such as *S*-adenosyl methionine (SAMe), methionine, magnesium, vitamins C, B_6, B_2, B_3, iron, alpha-ketoglutarate and oxygen (Kelly 1998).

Clinical note — Acetyl-L-carnitine shows promise as a strong therapeutic agent

Acetyl-L-carnitine, an ester form of L-carnitine, has also been investigated for its use in the treatment of Alzheimer's disease (Brooks et al 1998, Pettegrew et al 1995, Sano et al 1992, Thal et al 1996); depression (Garzya 1990), physical and mental fatigue, cognitive status and physical function in the elderly (Malaguarnera et al 2008); diabetic (De Grandis & Minardi 2002), peripheral (Onofrj et al 1995), and antiretroviral toxic neuropathy (Youle & Osio 2007) as well as prevention of neuropathy in chemotherapy (Bianchi et al 2005, Maestri et al 2005). It has also been researched for fatigue in multiple sclerosis (Tomassini et al 2004); fibromyalgia syndrome (Rossini et al 2007), Peyronie's disease (Biagiotti & Cavallini 2001), degenerative cerebellar ataxia (Sorbi et al 2000) and cognitive disturbances in chronic alcoholics (Tempesta et al 1990).

Dietary carnitine is absorbed in the intestine via a combination of active transport and passive diffusion (Li et al 1992). Mucosal absorption is saturated at around 2 g carnitine (Harper et al 1988), however more recent data suggest that mean plasma concentrations do not increase with doses over 0.5 g three times daily (Bain et al 2006). The bioavailability of carnitine is difficult to establish as reports vary widely from 16 to 87% (Harper et al 1988, Rebouche & Chenard 1991). Peak blood levels occur 3.5 hours after digestion and excretion is primarily via the kidneys (Bach et al 1983).

CHEMICAL COMPONENTS

L-Carnitine is the form most commonly used. As the D form is not biologically active, there is concern that it might interfere with the use of the L isomer by competitive inhibition and thus cause L-carnitine deficiency (Tsoko et al 1995).

FOOD SOURCES

Red meat is the richest dietary source. Vegetarian sources include avocado and tempeh (Hendler & Rorvik 2001). Human colostrum also contains carnitine (Wahlqvist 2002).

DEFICIENCY SIGNS AND SYMPTOMS

L-Carnitine deficiency leads to an accumulation of free fatty acids in the cell cytoplasm and of acyl-coenzyme A (CoA) in the mitochondria. This produces a toxic effect and disturbs fatty acid use for energy production (Kletzmayr et al 1999).

Deficiency symptoms (Kelly 1998) include the following:

- hypoglycaemia
- progressive myasthenia
- hypotonia
- fatigue
- cardiomyopathy
- congestive heart failure
- encephalopathy
- hepatomegaly
- neuromuscular disorders
- failure to thrive in infants
- muscle fatigue and cramps
- myoglobinaemia following exercise.

Elevation of triglycerides may also occur due to the role of carnitine in fatty acid metabolism.

Clinical note — Primary carnitine deficiency: an uncommon inherited disorder

Primary carnitine deficiency is an uncommon inherited disorder, related to a functional defect in plasma membrane carnitine transport in muscle and in the kidneys. These conditions have been classified as either systemic or myopathic (Evangeliou & Vlassopoulos 2003, Matera et al 2003). Systemic carnitine deficiency is reflected by low levels of carnitine in plasma and muscle and may result in cardiomyopathy, skeletal myopathy, hypoglycaemia and hyperammonaemia (Hendler & Rorvik 2001). Myopathic deficiency presents with normal plasma but low muscle carnitine levels and is a defect of carnitine transport across the muscle cell membrane (Winter et al 1987).

Primary deficiency

People at risk of primary deficiency are vegetarians, preterm infants and infants receiving a carnitine-free formula, and those with an inherited functional defect.

Secondary deficiency

Secondary carnitine deficiency is associated with several inborn errors of metabolism and acquired medical or iatrogenic conditions, such as the following (Evangeliou & Vlassopoulos 2003):

- genetic defects of metabolism, including methylmalonic aciduria, cytochrome C oxidase deficiency, fatty acyl-CoA dehydrogenase deficiency
- medications (Patients taking valproate and the anti-HIV drug azidothymidine are at risk.)
- dialysis (Carnitine depletion in haemodialysis patients is caused by insufficient carnitine synthesis and particularly by loss through the dialytic membranes. Many studies have shown that L-carnitine supplementation leads to improvements in several complications seen in uraemic patients, including cardiac complications, impaired exercise and functional capacities, muscle symptoms, increased symptomatic intradialytic hypotension, and erythropoietin-resistant anaemia, normalising the reduced carnitine palmitoyl transferase activity in red cells [Matera et al 2003].)
- liver disease, which impairs the last stage of carnitine synthesis, resulting in deficiencies in cardiac and skeletal muscle
- chronic renal failure and renal tubular disorders, in which excretion of carnitine may be excessive
- intestinal resection
- coeliac disease (A case report exists of a 48-year-old man developing encephalopathy due to carnitine deficiency as a result of coeliac disease [Karakoc et al 2006]. In patients with idiopathic dilated cardiomyopathy associated with coeliac disease, a gluten-free diet has been shown to increase serum carnitine levels [Curione et al 2005].)

- preterm neonates (Develop carnitine deficiency due to impaired proximal renal tubule carnitine re-absorption and immature carnitine biosynthesis.)
- hypopituitarism (Martindale 1999)
- adrenal insufficiency (Hendler & Rorvik 2001)
- advanced AIDS (Hendler & Rorvik 2001)
- vitamin C deficiency (Hendler & Rorvik 2001)
- other chronic conditions — diabetes mellitus, heart failure, Alzheimer's disease.

MAIN ACTIONS

Carnitine is involved in a myriad of biochemical processes important for health and wellbeing.

Cellular energy production

Carnitine assists the transport of fat across cell membranes in muscle tissue for use as an energy source (Wahlqvist 2002). It is essential for mitochondrial fatty acid oxidation, which is the primary fuel source for the heart and skeletal muscles and therefore required for proper functioning (Evangeliou & Vlassopoulos 2003, Kelly 1998). This process is also required in order to maintain CoA levels. The combination of exercise training and L-carnitine (4 g/day) supplementation does not appear to augment fatty acid-binding protein (FABPc) expression and beta-hydroxyacyl CoA dehydrogenase (beta-HAD) activity in human skeletal muscle, indicating that combined treatment does not exert an additive effect in fat metabolism and would thus be unlikely to enhance exercise performance (Lee et al 2007).

Improves blood sugar control

Administration of L-carnitine reduces insulin secretion and improves peripheral glucose use (Grandi et al 1997) and tissue insulin sensitivity (Negro et al 1994).

Cellular function and integrity

Carnitine is involved in the protection of membrane structures, stabilising a physiological CoA-sulfate hydrate/acetyl-CoA ratio, and reduction of lactate production (Matera et al 2003).

OTHER ACTIONS

Increases male fertility

Based on the high concentrations of L-carnitine in the epididymis, it has been proposed that spermatozoa, which require beta oxidation for energy, may require L-carnitine for proper maturation (Lenzi et al 1992). Human trials have found carnitine therapy (2–3 g/day) to be effective in increasing semen quality, sperm concentration and total and forward sperm motility, especially in groups with lower baseline levels (Lenzi et al 2003). One trial also reported that improvements in sperm motility were only observed in the presence of normal mitochondrial function, determined by phospholipid hydroperoxide glutathione peroxidase levels (Garolla et al 2005).

Some studies suggest that a combination of L-carnitine (LC) and acetyl-L-carnitine (ALC) may provide benefit for the treatment of idiopathic asthenospermia and improve semen quality (Cheng & Chen 2008). However, a small RCT using L-carnitine (2000 mg) and L-acetyl-carnitine (1000 mg) per day for 24 weeks failed to demonstrate improvements in sperm motility or total motile sperm counts in men with idiopathic asthenospermia (Sigman et al 2006). A meta-analysis comparing LC and/or LAC therapy to placebo found significant improvements in pregnancy rate ($P < 0.0001$), total sperm motility ($P = 0.04$), forward sperm motility ($P = 0.04$) and atypical sperm cells ($P < 0.00001$) but not sperm concentration or semen volume (Zhou et al 2007).

Antioxidant

Carnitine acts as an antioxidant in the cell membrane, preventing protein oxidation and pyruvate and lactate oxidative damage (Peluso et al 2000). In vitro studies suggest a dose-dependent inhibition of lipid peroxidation of linoleic acid emulsion superior to (alpha)-tocopherol. In addition, L-carnitine may have an effect on superoxide anion radical scavenging, hydrogen peroxide scavenging, total reducing power and metal chelating on ferrous ions (Gulcin 2006).

Prevents apoptosis

In vitro and animal studies show that L-carnitine can prevent apoptosis of skeletal muscle cells (Vescovo et al 2002). In patients with HIV it decreases numbers of $CD4^+$ and $CD8^+$ cells undergoing apoptosis, and significantly increases $CD4^+$ counts (Moretti et al 2002).

Neuroprotective

Animal studies have demonstrated a reduction in mortality and neuronal degeneration in experimentally induced neurotoxicity (Binienda et al 2004) and a reduction in hypoglycaemia-induced neuronal damage (Hino et al 2005) in rats that were pretreated with carnitine. In vitro studies suggest that the anti-apoptotic and antioxidant actions of L-carnitine contribute to the neuroprotective effect (Ishii et al 2000, Tastekin et al 2005).

Lipid-lowering

The role of carnitine in fatty acid metabolism suggests a potential role in hyperlipidaemia. Several studies have indicated that oral L-carnitine significantly reduces lipoprotein-a levels; however, effects on other lipids are inconsistent. According to human trials the addition of L-carnitine (2 g/day) to simvastatin therapy (20 mg/day) appears to lower lipoprotein-a serum levels in patients with type 2 diabetes mellitus (Solfrizzi et al 2006). In a separate placebo-controlled, double-blind randomised study L-Carnitine (2 g/day) significantly reduced serum lipoprotein-a levels in 77.8% of subjects receiving active treatment after 12 weeks. No significant change was observed in other lipid parameters (Sirtori et al 2000). L-Carnitine (2 g/day) was also shown to significantly lower lipoprotein-a levels at 3 and 6 months in a double-blind placebo-controlled trial of 94 hypercholesterolaemic patients with newly diagnosed type 2 diabetes (Derosa et al

2003). In a trial of children with hyperlipidaemia, lipoprotein-a levels were only reduced in those with type II homozygotes and other lipid parameters worsened (Gunes et al 2005).

L-Carnitine has also been shown to decrease apolipoprotein B levels in paediatric peritoneal dialysis patients (Kosan et al 2003). A study of elderly people taking L-carnitine (2 g twice daily) demonstrated improvements in total serum cholesterol, LDL-cholesterol, HDL-cholesterol, triglycerides, apoproteins A1 and B at 30 days (Pistone et al 2003). Animal studies have also suggested the potential for carnitine to lower triglyceride levels (Eskandari et al 2004); however, clinical trials using oral doses in type 2 diabetes have indicated an increase in triglycerides (Rahbar et al 2005). Further human trials are required to confirm which population groups may benefit from carnitine supplementation.

CLINICAL USE

Carnitine supplementation may be administered as intravenous or oral doses. This review will only focus on oral supplementation as this is the form generally used by the public and available over the counter.

Treatment of deficiency

L-Carnitine supplementation is traditionally used to treat or prevent deficiency. It is indicated in primary L-carnitine deficiency and secondary deficiency due to inborn errors of metabolism or haemodialysis. L-Carnitine 50–200 mg/kg/day has been shown to normalise plasma carnitine levels within 10 days (Campos et al 1993).

Apnoea of prematurity

Preterm neonates develop carnitine deficiency due to impaired proximal renal tubule carnitine re-absorption and immature carnitine biosynthesis (Evangeliou & Vlassopoulos 2003) and are at risk of developing apnoea of prematurity. Despite a promising preliminary study, a blinded, randomised, placebo-controlled study found that infants who received supplemental carnitine did not demonstrate any reduction in apnoea of prematurity, days requiring ventilator or nasal continuous positive airway pressure, or the need for supplemental oxygen therapy (O'Donnell et al 2002). In a RCT premature neonates supplemented with carnitine (20 mg/kg/day) gained weight more rapidly and showed improvement in periodic breathing compared to placebo although other respiratory markers were unaffected (Crill et al 2006). A 2004 Cochrane review was unable to locate studies of significant quality to confirm any effects (Kumar et al 2004a). Further studies are needed to determine the role of this treatment in clinical practice as present evidence does not support its use (Kumar et al 2004b).

Cardiovascular disease

L-Carnitine supplementation in doses ranging from 2 g to 4 g/day has been investigated in a number of controlled studies involving subjects with angina, heart failure, cardiogenic shock, cardiomyopathy and post myocardial infarction. Overall, positive results have been obtained and reduced mortality reported for some populations.

Chronic stable angina

Controlled studies indicate that L-carnitine supplements increase exercise tolerance and reduce frequency of angina attacks, enabling some patients to reduce nitrate requirements.

One RCT of 47 patients with chronic stable angina found that 2 g L-carnitine taken daily for 3 months moderately improved the duration of exercise and the time taken for ST changes to recover to baseline (Iyer et al 2000). This study confirmed the results of an earlier multicentre, double-blind, randomised, placebo-controlled crossover trial that examined the effects of L-carnitine 1 g twice daily for 4 weeks in 44 men with stable chronic angina (Cherchi et al 1985). This study showed that active treatment resulted in increased exercise tolerance and reduced ECG indices of ischaemia in stable effort-induced angina. A meta-analysis also highlighted a significant reduction in the number of angina attacks and nitrate requirements with doses of 2 g/day (Fernandez & Proto 1992).

Post-myocardial infarction (MI)

L-carnitine supplementation may lead to a reduction in early mortality (assessed at day 5) without affecting the risk of death and heart failure at 6 months in patients with anterior acute MI (Tarantini et al 2006). A dose of 4 g/day L-carnitine over 12 months improved quality of life and increased life expectancy in patients who had suffered an MI, according to a controlled study (Davini et al 1992). This included an improvement in heart rate, systolic arterial pressure, a decrease in anginal attacks, and improvement in the lipid profile. Changes were also accompanied by lower mortality in the treated group (1.2% vs 12.5% in the control group).

In a randomised, double-blind placebo-controlled trial, the effects of oral L-carnitine (2 g/day) for 28 days were assessed in patients with suspected acute MI. Total cardiac events, including cardiac deaths and non-fatal infarction, were 15.6% in the carnitine group and 26.0% in the placebo group. Angina pectoris (17.6% vs 36.0%), New York Heart Association class III or IV heart failure plus left ventricular enlargement (23.4% vs 36.0%) and total arrhythmias (13.7% vs 28.0%) were significantly less in the carnitine group compared with placebo (Singh et al 1996).

Cardiomyopathy

Cardiomyopathy appears to cause leakage of carnitine from heart stores, which may make cardiac tissue vulnerable to damage; however, it is unclear whether carnitine leakage is a cause or effect of cardiomyopathy (Baker et al 2005). Long-term placebo-controlled studies (10–54 months) using an oral dose of 2 g/day L-carnitine for treatment of heart failure caused by cardiomyopathy found a statistically significant advantage in survival rates with carnitine treatment (Rizos 2000). In patients with idiopathic dilated cardiomyopathy associated with coeliac disease, a gluten-free diet has been shown to increase serum carnitine levels (Curione et al 2005).

Cardiogenic shock

Several studies confirm the role of L-carnitine in the reversible phase of cardiogenic shock in terms of enzymic protection in the course of cellular oxidative damage. This has been reflected in improved survival rates (Corbucci & Lettieri 1991, Corbucci & Loche 1993).

Congestive heart failure

In congestive heart failure a specific myopathy secondary to myocyte apoptosis triggered by high levels of circulating TNF-alpha has been described. The role of carnitine in preventing apoptosis in skeletal muscle and reducing TNF-alpha provides a theoretical basis for its use in the treatment of myopathy associated with congestive heart failure (Vescovo et al 2002).

Myocarditis resulting from diphtheria

Two studies using D,L-carnitine (100 mg/kg/day in two divided doses orally for 4 days) found a reduction in the incidence of, and mortality from, myocarditis in diphtheria (Ramos et al 1984, 1992).

Non-ST elevation acute coronary syndrome (NSTEMI)

In a RCT 96 patients with NSTEMI were randomised to treatment or control group. All patients received percutanenous coronary intervention within 24 h from the onset of chest pain. The treatment group also received L-carnitine (5 g IV bolus followed by 10 g/day IV infusion for 3 days) and demonstrated significantly lower levels of cardiac markers (creatine kinase-MB and troponin-I) (Xue et al 2007).

Peripheral vascular disease

Due to its anti-ischaemic activity, L-carnitine supplements have also been used in peripheral vascular disease. A double-blind crossover study supports this use, finding L-carnitine supplements (2 g/day) taken for 3 weeks increased walking time in people with peripheral vascular disease (Brevetti et al 1988). A derivative of L-carnitine, known as propionyl-L-carnitine, taken for 6 months (2 g/day orally) has also demonstrated significant improvements in walking distance and speed in patients with claudication (Hiatt et al 2001).

Hyperthyroidism

Considering that this condition is associated with reduced body stores of carnitine and that L-carnitine is a peripheral antagonist of thyroid hormone action in some tissues according to in vivo studies, carnitine treatment has been investigated in hyperthyroidism.

One 6-month, randomised, double-blind placebo-controlled trial involving 50 women with induced suppression of thyroid-stimulating hormone showed that doses of 2 g or 4 g/day oral L-carnitine both reversed and prevented symptoms of the disease and had a beneficial effect on bone mineralisation (Benvenega et al 2001).

Male fertility

Some studies suggest that a combination of L-carnitine (LC) and acetyl-L-carnitine (ALC) may provide benefit for the treatment of idiopathic asthenospermia and improve semen quality (Cheng & Chen 2008). A placebo-controlled, double-blind crossover trial of 100 infertile males (aged 20–40 years) found that L-carnitine therapy (2 g/day) was effective in increasing semen quality, sperm concentration and total and forward sperm motility, especially in groups with lower baseline levels (Lenzi et al 2003). The positive effects on sperm motility have also been shown in previous trials using L-carnitine 3 g/day (Costa et al 1994, Vitali et al 1995). In a later trial, improvements in sperm motility were only observed in the presence of normal mitochondrial function, determined by phospholipid hydroperoxide glutathione peroxidase levels (Garolla et al 2005). A meta-analysis comparing LC and/or ALC therapy to placebo found significant improvements in pregnancy rate ($P < 0.0001$), total sperm motility ($P = 0.04$), forward sperm motility ($P = 0.04$) and atypical sperm cells ($P < 0.00001$) but not sperm concentration or semen volume (Zhou et al 2007). One small RCT of 21 men (12 in the treatment group, 9 in the placebo group) with idiopathic asthenospermia showed that a combination of L-carnitine (2000 mg) and L-acetyl-carnitine (1000 mg) taken daily over 24 weeks failed to demonstrate improvements in sperm motility or total motile sperm counts (Sigman et al 2006).

Ergogenic aid

L-Carnitine is a popular supplement amongst athletes in the belief that it will increase performance and recovery. This concept is largely based on the fact that carnitine assists in the transport of fat across cell membranes in muscle tissue and is involved in cellular energy production. However, the combination of exercise training and L-carnitine (4 g/day) supplementation does not appear to augment fatty acid-binding protein (FABPc) expression and beta-hydroxyacyl CoA dehydrogenase (beta-HAD) activity in human skeletal muscle, suggesting that combined treatment does not exert an additive effect in fat metabolism and would thus be unlikely to enhance exercise performance (Lee et al 2007).

Carnitine reduces insulin secretion and significantly improves peripheral glucose use, when administered with glucose, according to human research (Grandi et al 1997). There is evidence that L-carnitine supplementation may increase maximal oxygen consumption, stimulate lipid metabolism and reduce post-exercise plasma lactate (Karlic & Lohninger 2004). A recent trial reported that acute intake of L-carnitine (2 g) one hour prior to exercise did not appear to affect metabolic or blood lactate values of badminton players, although there was a significant difference in exercise maximum heart rate in male participants ($P < 0.05$) (Eroglu et al 2008).

In a placebo-controlled crossover trial using an L-carnitine–L-tartrate (LCLT) supplement (2 g L-carnitine/day) for 3 weeks, researchers suggested that LCLT supplementation was effective in assisting recovery from high-repetition squat exercise (Volek et al 2002). A similar trial of the same dose and duration suggested that recovery from post-resistance-exercise may be mediated by upregulation of androgen

receptor content (Kraemer et al 2006). However, other clinical trials using 2 g L-carnitine twice daily for 3 months found no significant increase in muscle carnitine content, mitochondrial proliferation, or physical performance (Wachter et al 2002). Similarly a study using glycine propionyl-L-carnitine (GPLC, 1–3 g/day) for 8 weeks in conjunction with aerobic-exercise training failed to demonstrate improvement in muscle carnitine content, aerobic- or anaerobic-exercise performance (Smith et al 2008).

Ergogenic aid in cardiovascular disease

Trials in subjects with cardiovascular disorders have been more promising. This is supported by the clinical trial discussed earlier involving patients with chronic stable angina (Iyer 2000). In addition, a clinical trial using 1 g L-carnitine or placebo three times daily for 120 days has indicated a potential for improved performance and effort tolerance in patients with cardiac insufficiency (Loster et al 1999).

Ergogenic aid in chronic obstructive pulmonary disease (COPD)

Compared to placebo, L-carnitine (2 g/day) for 6 weeks can significantly improve inspiratory muscle strength (14 ± 5 vs 40 ± 14 cmH_2O) and exercise tolerance (walking test) (34 ± 29 vs 87 ± 30 m, $P < 0.05$) in COPD patients, as well as reducing lactate production (2.3 ± 0.7 vs 1.6 ± 0.7 mM, $P < 0.05$) (Borghi-Silva et al 2006).

OTHER USES

Fatigue

Chronic fatigue syndrome

Studies investigating whether people with CFS have lower levels of free L-carnitine have shown contradictory results (Jones et al 2005), and trials using L-carnitine supplementation in CFS have generally produced mixed results (Plioplys & Plioplys 1995, 1997, Soetekouw et al 2000). One randomised controlled trial did find that 1 g L-carnitine (three times daily) produced a significant clinical improvement, especially between the fourth and eighth week of treatment (Plioplys & Plioplys 1997).

Fatigue in cancer patients

In a trial of advanced cancer patients 76% were found to be carnitine deficient. In a subset of patients (those whose carnitine levels increase with supplementation) doses up to 3 g/day is deemed to be safe and may reduce fatigue (Cruciani et al 2006).

Fatigue in coeliac disease patients

L-Carnitine blood levels are low in coeliac disease patients most likely due to reduced OCTN2 levels (the specific carnitine transporter). In 60 coeliac disease patients, L-carnitine supplementation (2 g/day) for 180 days has been shown to be safe and effective in ameliorating fatigue measured by the Scott-Huskisson Visual Analogue Scale for Asthenia compared with placebo ($P = 0.0021$) (Ciacci et al 2007).

Attention deficit hyperactivity disorder

In a randomised, double-blind, placebo-controlled double-crossover trial, treatment with L-carnitine (100 mg/kg twice daily, maximum 4 g/day) over 24 weeks significantly decreased the attention problems, delinquency and aggressive behaviour in boys with ADHD (Van-Oudheusden & Scholte 2002). At 6-month follow-up 19 of 24 boys had responded to treatment as judged by parents and teachers.

Diabetes

Only high circulating serum insulin concentrations (≥ 90 mU/L) are capable of stimulating skeletal muscle carnitine accumulation (Stephens et al 2007). Carnitine is essential for lipid and carbohydrate metabolism, and correct metabolic control. It has been suggested that some people with diabetes may have reduced levels of total and free carnitine (Mamoulakis et al 2004). Administration of L-carnitine reduces insulin secretion and improves peripheral glucose use (Grandi et al 1997) and tissue insulin sensitivity (Negro et al 1994). Additionally in type 2 diabetes, L-carnitine (1 g 3 times daily) significantly lowers fasting plasma glucose, but may increase fasting triglycerides (Rahbar et al 2005). Although promising, further research is required to elucidate the possible benefits and safety of carnitine supplementation in this population.

Type 1 diabetes

L-Carnitine (2 g/m^2/day) in the early stage (stage 1a) of type 1 diabetes may improve nerve conduction velocity suggesting benefits for the treatment of sub-clinical neuropathy (Uzun et al 2005).

Haemodialysis

Carnitine depletion in haemodialysis patients is caused by insufficient carnitine synthesis and excessive loss through the dialytic membranes (Matera et al 2003). Carnitine supplementation has been approved by the US FDA for the treatment and prevention of carnitine depletion in dialysis patients. Supplementation in such patients is said to improve lipid metabolism, protein nutrition, antioxidant status and anaemia, and may reduce the incidence of intradialytic muscle cramps, hypotension, asthenia, muscle weakness and cardiomyopathy (Bellinghieri et al 2003). In maintenance haemodialysis patients L-carnitine supplementation (20 mg/kg) has been associated with protein-sparing effects during hyperinsulinaemia (Biolo et al 2008). L-carnitine supplementation (10 mg/kg orally), immediately after haemodialysis sessions 3 times/week for 12 months induced regression of left ventricular hypertrophy (LVH) in patients with normal cardiac systolic function undergoing haemodialysis (Sakurabayashi 2008).

However, the routine use of L-carnitine in dialysis patients to manage anaemia and refractory dialysis-associated hypotension is contentious and some authors believe that there is insufficient evidence to support this indication (Steinman et al 2003).

Hepatic encephalopathy

Hepatic encephalopathy (HE) is a major complication of cirrhosis. A recent systematic review suggested that L-acyl-carnitine is promising as a safe and effective treatment for HE (Shores & Keeffe 2008). Human trials have demonstrated a protective effect of L-carnitine (2 g twice daily) in ammonia-precipitated hepatic encephalopathy in cirrhotic patients at 30 days and more significantly at 60 days (Malaguarnera et al 2003).

Rett syndrome

A case is reported of a 17-year-old girl with Rett syndrome whose condition improved while using L-carnitine (50 mg/kg/day). Upon cessation, she relapsed, whereas re-establishing the treatment saw improvements after 1 week. More specifically, alertness increased, she started reaching for objects with both hands, and answered simple questions with one or two words. Interestingly, serum carnitine levels (free and total) were within normal limits before and after L-carnitine treatment (Plioplys & Kasnicka 1993). An 8-week randomised, placebo-controlled, double-blind crossover trial of L-carnitine has since been completed detecting improvements on the Hand Apraxia Scale and in the subjects' general wellbeing (Ellaway et al 1999).

Beta thalassaemia major

L-Carnitine appears to be a safe and effective adjunctive therapy in thalassaemia patients, especially younger patients. L-Carnitine therapy (50 mg/kg/day) for 6 months resulted in a significant increase in oxygen consumption, cardiac output and oxygen pulse at maximal exercise ($P < 0.001$, $P = 0.002$ and $P < 0.001$, respectively). There was also a significant increase in the blood transfusion intervals after L-carnitine administration ($P = 0.008$) (El-Beshlawy et al 2007). Additionally L-carnitine (100 mg/kg/day) for one month may prevent RBC deterioration in beta-thalassaemia major patients (Toptas et al 2006).

Ageing

In a randomised, double-blind, placebo-controlled trial of 84 elderly subjects (aged 70–92 years) who experienced onset of fatigue after slight physical activity, L-carnitine (2 g twice daily) for 30 days resulted in significant improvements in total fat mass, total muscle mass, lipid profiles, as well as overall improvements in physical and mental fatigue (Pistone et al 2003). Similarly in a placebo-controlled, randomised, double-blind, two-phase study of 66 centenarians with onset of fatigue even after slight physical activity, L-carnitine (2 g/day) treated centenarians showed significant improvements compared with the placebo group. Improvements included total fat mass (–1.80 vs 0.6 kg; $P < 0.01$), total muscle mass (3.80 vs 0.8 kg; $P < 0.01$), plasma concentrations of total carnitine (12.60 vs –1.70 micromol; $P < 0.05$), plasma long-chain acylcarnitine (1.50 vs –0.1 micromol; $P < 0.001$), and plasma short-chain acylcarnitine (6.0 vs –1.50 micromol; $P < 0.001$). Significant differences were also found in physical fatigue (–4.10 vs –1.10; $P < 0.01$), mental fatigue (–2.70 vs 0.30; $P < 0.001$), fatigue severity (–23.60 vs 1.90; $P < 0.001$), and Mini-Mental State Examination (MMSE) (4.1 vs 0.6; $P < 0.001$) (Malaguarnera et al 2007).

Animal studies have demonstrated that supplementation of carnitine (300 mg/kg/day) and lipoic acid (100 mg/kg/day) for 30 days protects mitochondria from ageing by raising mitochondrial energy production and reversing the age-associated decline in mitochondrial enzyme activity (Savitha et al 2005). Studies using standard oral doses of L-carnitine in humans are required to confirm these effects.

Weight loss

Carnitine is a popular supplement for weight loss when combined with an exercise program. This is based on its biochemical role in the production of energy from fatty acids. Carnitine deficiency impairs fatty acid beta-oxidation and may partly explain weight gain in valproate-treated patients. However, L-carnitine (15 mg/kg/day) for 26 weeks failed to improve weight loss outcomes in valproate-treated bipolar patients consuming an energy-restricted, low-fat diet (Elmslie et al 2006). Currently, one clinical trial that has investigated carnitine supplementation together with an aerobic training program failed to detect a significant effect on weight loss (Villani et al 2000).

DOSAGE RANGE

- Deficiency: L-carnitine 50–200 mg/kg/day.
- Most conditions: L-carnitine 2–4 g/day in divided dose.

Note: Maximum plasma concentration may be achieved at 500 mg. Therefore individual doses exceeding this level may not provide any additional benefits (Bain et al 2006). Larger doses should be divided.

According to clinical studies

- Cardiovascular disorders: 2 g/day for at least 3 months may improve exercise tolerance and recovery in people with conditions such as chronic stable angina and cardiac insufficiency, and may also reduce lipoprotein-a levels and improve peripheral vascular disease.
- Hyperthyroidism: 2–4 g/day in divided doses.
- Chronic fatigue syndrome: 1 g three times daily.
- Ergogenic aid: 2 g/day.
- Fertility: 2–3 g/day may be useful to increase sperm motility and concentration.
- Peripheral vascular disease: 2 g/day.
- COPD: 2 g/day.
- Thalassaemia (as adjunct): 50 mg/kg/day.
- Ageing (to reduce fatigue): 2 g daily or twice daily.

ADVERSE REACTIONS

Carnitine is well tolerated at recommended doses. Mild gastrointestinal symptoms including abdominal cramps, diarrhoea, nausea and vomiting, heartburn or gastritis may occur. Mild myasthenia has been reported in uraemic patients using the D,L form (Hendler & Rorvik 2001). Changes in body odour have also been noted (Sigma-Tau Pharmaceuticals 1999, Van-Oudheusden & Scholte 2002).

SIGNIFICANT INTERACTIONS

Anticoagulants

According to one case report, L-carnitine 1 g/day may potentiate the anticoagulant effects of acenocoumarol (also known as nicoumalone or acenocumarin) (Martinez et al 1993). Use this combination with caution. Monitor bleeding time and signs and symptoms of excessive bleeding.

Anticonvulsants (including valproate, phenobarbital, phenytoin, carbamazepine)

Trials with children and adults have shown a reduction in carnitine levels during anticonvulsant therapy (Hug et al 1991, Rodriguez-Segade et al 1989). A study evaluating carnitine deficiency in children and adolescents with epilepsy found 27.3% taking valproic acid and 14.3% taking carbamazepine showed low free-carnitine levels. Polytherapy, female sex, psychomotor or mental retardation and abnormal neurological examination appeared to increase the risk of hypocarnitinaemia. Patients taking topiramate or lamotrigine or on a ketogenic diet did not appear to be affected (Coppola et al 2006). L-Carnitine deficiency may cause or potentiate valproate toxicity and supplementation is known to reduce the toxicity of valproate, as well as symptoms of fatigue. In a trial using L-carnitine for acute valproate poisoning no adverse events were noted (LoVecchio et al 2005). Increased carnitine intake may be required with long-term therapy — potentially beneficial interaction under professional supervision.

Betamethasone

A RCT has shown that a combination of low-dose betamethasone (2 mg/day) and L-carnitine (4 g/5 days) was more effective in the prevention of respiratory distress syndrome (7.3% vs 14.5%) and death (1.8% vs 7.3%) in preterm infants than high-dose betamethasone given alone (8 mg/2 days) (Kurz et al 1993) — beneficial interaction possible under professional supervision.

Chemotherapy

Adriamycin (doxorubicin)

Animal studies suggest long-term carnitine administration may reduce the cardiotoxic side effects of adriamycin (Kawasaki et al 1996). A small randomised placebo-controlled trial attempted to determine these effects in humans, administering 3 g L-carnitine before each chemotherapy cycle, followed by 1 g L-carnitine/day during the following 21 days to the treatment group. The trial reported no cardiotoxicity in either group and was able to demonstrate stimulation of oxidative metabolism in white blood cells through carnitine uptake (Waldner et al 2006). Increased carnitine intake may be required with long term therapy — potentially beneficial interaction only under professional supervision.

Carboplatin

Treatment with carboplatin appears to result in marked urinary losses of L-carnitine and acetyl-L-carnitine, most likely due to inhibition of carnitine reabsorption in the kidney (Mancinelli et al 2007).

Cisplatin

Research into the use of L-carnitine 4 g/day for 7 days showed a reduction in fatigue resulting from treatment with cisplatin (Graziano et al 2002) — beneficial interaction is possible under professional supervision.

HIV drugs (zidovudine)

In vitro studies indicate prevention of muscle damage due to carnitine depletion (Dalakas et al 1994, Moretti et al 2002, Semino-Mora et al 1994). Patients with HIV infection undergoing highly active antiretroviral therapy can be carnitine deficient and supplementation of L-carnitine has been proposed to 'increase the number of CD4 cells and reduce lymphocyte apoptosis; improve symptoms of polyneuropathy; prevent cardiovascular damage from wasting and diarrhoea syndromes; decrease serum levels of triglycerides and TNF(alpha)' (Ilias et al 2004). Beneficial interaction is possible. Increased carnitine intake may be required with long-term therapy — use under professional supervision.

HMG CoA-reductase inhibitors (statins)

According to human trials the addition of L-carnitine (2 g/day) to simvastatin therapy (20 mg/day) appears to lower lipoprotein-a serum levels in patients with type 2 diabetes mellitus (Solfrizzi et al 2006). Beneficial interaction possible.

Interferon-alpha

Clinical trials with patients being treated with IFN-alpha for hepatitis C observed reduced fatigue when carnitine 2 g/day was co-administered (Neri et al 2003). L-Carnitine may reduce hepatic steatosis associated with IFN alpha and ribavirin treatment in patients with hepatitis C (Romano et al 2008). Increased carnitine intake may be required with long-term therapy — potentially beneficial interaction under professional supervision.

Interleukin-2 immunotherapy

Clinical trials using L-carnitine (1 g/day orally) found that it may be used successfully to prevent cardiac complications during IL-2 immunotherapy in cancer patients with clinically relevant cardiac disorders (Lissoni et al 1993). Thus a beneficial interaction is possible under professional supervision.

CONTRAINDICATIONS AND PRECAUTIONS

- Chronic liver disease — may impair metabolism or increase biosynthesis of L-carnitine (Krahenbuhl 1996).
- Seizures — may increase incidence of seizures in those with a pre-existing condition (Sigma-Tau Pharmaceuticals 1999).

PREGNANCY USE

Insufficient reliable information is available. However, animal studies have revealed no evidence of decreased fertility or harm to the fetus (Hendler & Rorvik 2001). In fact, some research suggests a role for carnitine.

Requirements for carnitine may increase during pregnancy and a small trial found a positive effect in women diagnosed with placental insufficiency taking 1 g L-carnitine twice daily (Genger et al 1988). Due to the role of L-carnitine in the synthesis of surfactant, trials have also been conducted using L-carnitine in combination with low-dose betamethasone in women with imminent premature delivery, with an improvement in respiratory distress syndrome and mortality rates (Kurz et al 1993).

PRACTICE POINTS/PATIENT COUNSELLING

- Carnitine is an amino acid that is ingested through the diet and also synthesised from lysine and methionine in the body.
- It is involved in numerous biochemical processes and is essential for energy production in the mitochondria of every cell.
- Vegetarians, and preterm infants or those on a carnitine-free formula, are at risk of deficiency. Secondary risk factors include genetic defects of metabolism, liver and renal disease, dialysis, certain medicines and hypopituitarism.
- L-Carnitine 2 g/day for 3 months has been shown to improve exercise tolerance and recovery, especially in people with cardiovascular disorders such as chronic stable angina and cardiac insufficiency. Preliminary evidence also suggests a possible role in hyperthyroidism, male infertility and peripheral vascular diseases such as intermittent claudication.
- Carnitine supplements are also used to promote weight loss and as an ergogenic aid, although large controlled studies are unavailable to assess their effectiveness.

PATIENTS' FAQs

What will this supplement do for me?

L-Carnitine supplements improve clinical outcomes in people with cardiovascular disorders by reducing the frequency of angina attacks, and improving outcomes after heart attack, cardiogenic shock and in cardiomyopathy. It may also reduce symptoms in hyperthyroidism, increase male fertility, increase walking distance in people with peripheral vascular disease and reduce the side-effects of some medicines.

When will it start to work?

People with cardiovascular disorders such as chronic stable angina and cardiac insufficiency should experience benefits within 1–3 months.

Are there any safety issues?

Carnitine is well tolerated, but people with chronic liver disease or epilepsy should use it with caution.

Celery

HISTORICAL NOTE Celery is widely used as a food. The ancient Greeks used celery to make a wine called selinites, which was served as an award at athletic games. Dioscorides described celery as an effective remedy for 'heated stomach' and breast lumps and used it as a diuretic for urinary retention and dropsy.

OTHER NAMES
Smallage, marsh parsley, wild celery

BOTANICAL NAME/FAMILY
Apium graveolens (family Umbelliferae [Apiaceae])

PLANT PART USED
Fruit (seed)

CHEMICAL COMPONENTS
Celery is high in minerals, including sodium (Murphy et al 1978), and contains furocoumarins such as psoralen and bergapten (Beier et al 1983). The major constituents of celery seed oil include pinene and D-limonene (Saleh et al 1985). Celery also contains flavonoids, such as apigenin, luteolin and isoquercitrin, and phenolic acids and alkaloids (Fisher & Painter 1996).

MAIN ACTIONS

Anti-inflammatory activity
Celery has been found to have anti-inflammatory activity, with suppression of carrageenan-induced paw oedema observed in rats (Al-Hindawi et al 1989, Ziyan et al 2007). Several constituents show anti-inflammatory activity, such as apigenin, eugenol, ferulic acid, luteolin and bergapten (Duke 2003); and also apiin (Mencherini et al 2007). Studies in rats suggest that some celery seed extracts are highly effective in suppressing experimental arthritis without exhibiting any gastrotoxicity (Whitehouse et al 1999). Further in vivo studies suggest that celery seed extracts were gastroprotective for NSAID gastropathy and that this effect is mediated through non-prostaglandin mechanisms (Whitehouse et al 2001). Luteolin may also be useful for mitigating neuroinflammation (Jang et al 2008).

Cholagogue
Aqueous celery extract has also been found to increase bile acid excretion and lower total serum cholesterol levels in genetically hypercholesterolaemic rats (Tsi & Tan 2000).

Chemoprotective
Human in vivo trials imply that apiaceous vegetable intake may be chemopreventive by inhibiting cytochrome P450-mediated carcinogen activation (Peterson et al 2006). Based on in vivo studies in mice, it has been suggested that the phthalide components of celery may be effective chemoprotective agents (Zheng et al 1993). Other studies show that celery consumption, in particular due to its flavones luteolin and apigenin (Lim do et al 2007, Meeran 2008), has been linked to a reduced risk of developing colon cancer (Slattery et al 2000), stomach cancer (Haenszel et al 1976), liver cancer (Sultana et al 2005) and lung cancer (Galeone et al 2007).

Antioxidant
There are a number of studies providing evidence of the anti-oxidative effects of some constituents in celery (Popovic et al 2006, Yeh & Yen 2005, Zidorn et al 2005).

Lipid lowering activity
One study of vegetables, including celery, showed that cooking enhanced the amount of phytosterols which are known to decrease plasma cholesterol, mainly the atherogenic LDL cholesterol (Kaloustian et al 2008). In vivo trials of aqueous celery extract on rats showed a significant reduction in total serum cholesterol (Tsi 1995, 1996).

OTHER ACTIONS
Celery is said to have antirheumatic, carminative, antispasmodic, diuretic, antihypertensive and urinary antiseptic activity. Celery extracts have also been found to have significant activity as a mosquito repellent (Pitasawat et al 2007, Tuetun et al 2004, 2005, 2008). Research has shown that the flavones and coumarins, as well as the nutritional compounds, of vegetables including celery, have immunomodulatory functions (Cherng et al 2008). Some antimicrobial activity is also reported from in vitro studies of the essential oil component (Misic et al 2008), while other studies show celery extracts to be ineffective against gram-negative bacteria (Watt et al 2007). In vitro tests reveal the flavone apigenin has multiple effects on osteoblasts, suggesting that it could prevent bone loss in vivo (Bandyopadhyay et al 2006) and be a useful pharmacological tool for the treatment of osteoporosis (Choi 2007).

CLINICAL USE
Celery has not been significantly investigated under clinical trial conditions, so evidence is mainly derived from in vitro and animal studies and is largely speculative.

Osteoarthritis
Evidence of anti-inflammatory activity in experimental models provides a theoretical basis for its use; however, controlled trials are not available to determine effectiveness.

A small uncontrolled trial of 15 patients with chronic arthritis found that treatment with celery seed extract significantly reduced pain symptoms after 3 weeks (Bone 2003).

Urinary tract infection
Celery is used in combination with other herbal medicines for the treatment of this condition. Although it is not certain that the herb has antibacterial activity against microorganisms implicated in urinary tract infection, it is used for its diuretic effect.

OTHER USES

Traditional
Celery has been traditionally used as a diuretic, to improve appetite and digestion, and as a treatment for nervousness and hysteria. The British Herbal Pharmacopoeia gives the specific indication of celery for rheumatoid arthritis and depression (Fisher & Painter 1996).

Oriental medicine uses the seeds to treat headaches and as a digestive aid and emmenagogue.

In Trinidad and Tobago, celery is used as a heart tonic and for low blood pressure (Lans 2006); while in some parts of Indonesia it is one of a number of kitchen plants used in saunas for post-partum recuperation (Zumsteg & Weckerle 2007).

Animal studies on isolated constituents from celery have been found to be valuable in the treatment of acute ischaemic stroke via multiple mechanisms, such as strong anti-oedema activity (Deng 1997) as well as anti-oxidation, anti-apoptosis and anti-inflammatory actions (Chang 2003). Animal studies also demonstrate that the phthalide components improve cognitive impairment induced by chronic cerebral hypoperfusion, indicating its therapeutic potential for the treatment of dementia caused by decreased cerebral blood flow (Peng 2007).

DOSAGE RANGE
- Fluid extract (1:2): 4.5–8.5 mL/day in divided doses.
- Decoction of dried fruit: 0.5–2 g three times daily.

TOXICITY/ADVERSE REACTIONS
Celery can cause food allergy (Luttkopf et al 2000), with cross-reactivity to a number of other foods (Moneret-Vautrin et al 2002, Vieths et al 2002). Topical exposure to celery may cause contact dermatitis, angio-oedema and urticaria (Kauppinen et al 1980). Photodermatitis has been recorded with occupational exposure (Seligman et al 1987) and celery has been suggested to cause ocular phototoxicity (Fraunfelder 2004).

SIGNIFICANT INTERACTIONS
Controlled studies are not available, so interactions are based on evidence of activity and are largely theoretical and speculative.

NSAIDs
Celery seed extract may reduce gastrointestinal symptoms associated with NSAIDs — beneficial interaction possible.

Pentobarbital
Celery juice has been found to prolong the action of pentobarbital in rats (Jakovljevic et al 2002)— use with caution.

Warfarin
Celery contains naturally occurring coumarins, which may theoretically exert anticoagulant effects; however, interaction is unlikely (Heck et al 2000, Myers 2002) — observe with high-dose extracts.

Thyroxine
Celery seed might decrease the effects of levothyroxine replacement therapy according to one case report — observe patient.

Sodium valproate
In animal studies celery was found to have a protective effect against sodium valproate's well established toxicity to the testes and sperm production (Hamza & Amin 2007).

Psoralen–UVA (PUVA) therapy
Although celery has been found to contain psoralens, celery extract does not seem to be photosensitising, even after ingestion of large amounts; however, it may increase the risk of phototoxicity with concurrent PUVA therapy (Gral et al 1993) — use with caution.

CONTRAINDICATIONS AND PRECAUTIONS
Usual dietary intakes are likely to be safe.

PREGNANCY USE
Likely to be safe when consumed in dietary amounts; however, safety is not known when used in larger quantities.

PRACTICE POINTS/PATIENT COUNSELLING
- Celery has been traditionally used as a diuretic. It is used to treat osteoarthritis and demonstrates anti-inflammatory activity in experimental models. Celery is likely to be safe when used in quantities commonly used in foods; however, there is the possibility for allergy and contact sensitivity.
- It is prudent to avoid using celery seed essential oil in amounts greater than those ingested when used as a food.

Chamomile

HISTORICAL NOTE Chamomiles have been used as medicines since antiquity and traditionally grouped in botanical texts under the same general heading. They were probably used interchangeably. Roman chamomile was reportedly used to embalm the Egyptian Pharaoh, Ramses II, and is thought to have been introduced into Britain by the Romans during their conquests. The Anglo-Saxons used chamomile, presumably the Roman chamomile, as one of their nine sacred herbs. Culpeper lists numerous ailments for which chamomile was used, such as jaundice, fevers, kidney stones, colic, retention of urine and inflammation of the bowel (Culpeper 1995). It was also widely used to treat common conditions in children, including colic in infants, teething pains and fever (Grieve 1976). It is used in the treatment of gout and to reduce the severity of sciatic pain, either taken internally or applied as a poultice externally (Culpeper 1995). Today, chamomile tea is one of the most popular herbal teas in Australia and New Zealand, and extracts are also used in cosmetics, as bath preparations, in hair dye for blonde hair, shampoos, mouthwashes and preparations to prevent sunburn (Foster & Leung 1996).

COMMON NAME

German chamomile

OTHER NAMES

Wild chamomile, single chamomile, Hungarian chamomile, pin heads matricaria, blue chamomile, Flos chamomillae vulgaris (Lat)

BOTANICAL NAME/FAMILY

Chamomilla recutita (L.) (family Asteraceae [Compositae])

There has been considerable confusion over botanical classification since the plant formerly known as *Matricaria recutita* L. was added to the genus *Chamomilla* in 1974. *Matricaria chamomilla* L. is also used.

PLANT PARTS USED

Flower heads, gathered in summer when they are dry, and carefully dried at low temperatures. Essential oil extracted by steam distillation of the flower heads.

CHEMICAL COMPONENTS

- Essential oil (see below) 0.24–1.9%.
- Flavonoids (including flavonols and methoxylated flavones), apigenin (other flavonols are partially hydrolysed to apigenin leading to concentrations of up to 8%), apigetrin (apigenin-7-D-glucoside), apigenin-7-acetylglucoside, apiin (apigenin-7-apiosylglucoside), rutin (quercetin-3-rutinoside), luteolin, quercimeritrin (quercetin-7-D-glucoside), quercetin and isorhamnetin.
- Coumarins — umbelliferone (7-hydroxycoumarin) and herniarin (methyl ether of umbelliferone).
- Proazulenes (sesquiterpene lactones), including matricin, matricarin and desacetylmatricarin.
- Plant acids (acidic mucilage), fatty acids, polysaccharide, choline, amino acids.

Essential oil

Chamomile extract produced by a cold extraction process is yellow; steam distillation produces the blue essential oil. This is derived from matricin, also known as proazulene or prochamazulene, a precursor of chamazulene.

Chamazulene (1–15%), farnesene, alpha-bisabolol and bisabolol oxides A and B (up to 50% of the essential oil; proportions vary depending on the chemotype), bisabolone oxide, chamazulene (from matricin on distillation), matricin, chamaviolin, spathulenol and *cis*- and *trans*-enyne dicyclo ethers (spiroether, polyacetylenes).

German chamomile has four chemotypes (variations of the plant product according to chemical composition). These relate to slight variations in the bisabolol oxide content of the essential oil (Gasic et al 1986). Chemotypes, which contain highest levels of alpha-bisabolol (known as C and D chemotypes), should be sourced when an essential oil is required for antiphlogistic or spasmolytic properties.

Clinical note — The difference between German and Roman chamomile

Chamomilla recutita is widely distributed in wastelands and in the neglected fields of Europe, particularly in Croatia and Hungary. Selected varieties are cultivated (Bruneton 1995). Many plants are referred to as chamomile or have the word 'chamomile' as part of their common name. Of the large number of species of chamomile growing in Europe, North Africa and the temperate region of Asia, five grow wild in the United Kingdom and Europe. Wild varieties are German chamomile (*C. recutita*), Roman chamomile (*C. nobile* (L.)), foetid or stinking mayweed (*Anthemis cotula*), corn chamomile (*Anthemis arvensis*), and yellow chamomile (Grieve 1976).

Roman chamomile, or *Chamaemelum nobile* (L.) (*Anthemis nobile* L.) is the 'chamomile' often referred to in English herbals. It has similar uses to the German chamomile, such as an aromatic bitter for digestive conditions, antispasmodic agent, mild sedative, and topically for its anti-inflammatory and mild analgesic properties.

MAIN ACTIONS

Anti-inflammatory

Chamomile extract and various isolated constituents within chamomile have demonstrated anti-inflammatory activity in a variety of tests.

Chamomile extract showed anti-inflammatory effects when applied topically in animal models

of inflammation (Al-Hindawi et al 1989, Plevova 1999, Shipochliev et al 1981). In a comparative trial, hydro-alcoholic extracts of chamomile produced anti-inflammatory actions when applied topically in the croton ear test in the mouse. The hydro-alcoholic extract reduced oedema in a dose-dependent manner and was equivalent in effectiveness to benzydamine at twice the usual clinical dose, but hydrocortisone was found to be the most effective treatment (Tubaro et al 1984).

Another comparative study investigated the anti-inflammatory effects of an extract prepared from dried flowers, an extract based on fresh flowers, and the volatile oil, in croton oil-induced dermatitis of mouse ear. The activity of fresh chamomile equaled the activity of the reference drug (benzydamine).

The anti-inflammatory activity of the herb appears to be due to several different constituents, chiefly apigenin, matricin, chamazulene and alpha-bisabolol, although others may also exist.

The previous study determined that apigenin exerts the strongest anti-inflammatory action, which is 10 times greater than matricin, which is 10 times greater than chamazulene (Della Loggia et al 1990). Another study evaluated the effects of apigenin on the lipopolysaccharide-induced proinflammatory cytokines IL6 and TNF-alpha in vitro and in vivo (Smolinski & Pestka 2003). Apigenin reduced IL6, but not TNF-alpha in vitro. Pretreatment with the flavone (50 mg/kg) reduced IL6 by 35% and TNF-alpha by 33% in vivo as compared with control animals. Alpha-bisabolol has demonstrated anti-inflammatory and analgesic effects in a number of experimental inflammatory models: rat paw oedema, adjuvant arthritis of the rat, ultraviolet erythema of the guinea pig, and yeast fever of the rat (Jakovlev et al 1979). Sodium azulene sulphate, a water-soluble derivative of azulene, has demonstrated the ability to reduce plasma exudation in a recently developed model of capsaicin-induced pharyngitis (Sakai et al 2005).

Most studies have investigated the effects of topically applied chamomile or isolated constituents; however, one study using the carrageenan inflammation test on rat paws showed that orally administered matricin produces anti-inflammatory activity that was greater than chamazulene and almost as effective as (-)-alpha-bisabolol (Jakovlev et al 1979, Shipochliev 1981a).

Chamazulene has been found to inhibit leukotriene B4 formation and blocks chemical peroxidation of arachidonic acid (Safayhi et al 1994).

Antipuritic

An ethyl acetate extract and essential oil of chamomile have both shown antipuritic activity after a single dose in vivo (Kobayashi et al 2005). Additionally, the antipuritic effects of the antihistamine H1 antagonists, oxatomide and fexofenadine, were significantly increased by the ethyl acetate extract.

Antispasmodic

Chamomile extract and several constituents demonstrate a dose-dependent antispasmodic effect in vitro. The major activity is related to bisabolol, spiroethers and apigenin. (-)-alpha-bisabolol has an effect equal to papaverine; apigenin was the most potent flavonoid, being significantly more potent than papaverine. The extract of chamomile also has a good spasmolytic activity (Achterrath-Tuckermann et al 1980).

Sedative

Shinomiya et al found that 300 mg/kg of chamomile extract significantly decreased sleep latency in a sleep-disturbed rat model, demonstrating benzodiazepine-like activity (Shinomiya et al 2005). Extracts of chamomile showed sedative activity on the mouse CNS (Della Loggia et al 1981), and extracts of chamomile, as well as isolated apigenin, have been shown to bind to benzodiazepine receptors in vitro. Apigenin showed antianxiety and sedative activity with intraperitoneal injection in mice (Viola et al 1995).

Ovariectomised rats given inhalations of chamomile oil showed decreased levels of stress-induced ACTH levels compared with controls; the experiment suggested an activity similar to benzodiazepine agonists (Yamada et al 1996).

Antimicrobial

According to in vitro studies, the essential oil has bactericidal and fungicidal activities against gram-positive bacteria (*Bacillus subtilis*, *Staphylococcus aureus*) and *Candida albicans* in concentrations above 0.05% v/v, but has no effect against the gram-negative bacteria *Escherichia coli*, *Pseudomonas aeruginosa* (Aggag & Yousef 1972) and *Salmonella typhimurium* (Gomes-Carneiro et al 2005). In contrast, extracts of chamomile have demonstrated antimicrobial activity against *E. coli* (Ceska et al 1992). The growth of *S. aureus*, *Streptococcus mutans* and group B streptococcus was inhibited by chamomile extract at concentrations of 10 mg/mL (Cinco et al 1983), whilst a very low concentration of the essential oil (0.0075% v/v) effectively inhibited *Helicobacter pylori* (Weseler et al 2005).

Extracts of chamomile may also inhibit *Herpes simplex* virus (HSV). One study found that a semi-purified extract of chamomile was effective in inhibiting HSV in vitro (Suganda et al 1983), whilst another found the essential oil to have significant virucidal activity against HSV type 2 (Koch et al 2008). In vitro tests using apigenin have identified inhibitory activity against HIV activation, possibly by affecting viral transcription (Critchfield et al 1997, Trovato et al 2000).

Anti-ulcer

Chamomile extract protected rats from developing experimentally induced ulcers. Bisabolol (and extracts of chamomile) prevented the formation of ulcers in experimental animals exposed to indomethacin (NSAID) stress, and alcohol; and reduced the healing time of ulcers induced by chemical stress (acetic acid) or by heat coagulation.

Wound healing

Alpha-bisabolol promotes granulation and tissue regeneration in burns and ulcers, and protects

against their formation (Szelenyi et al 1979). Oral administration of an aqueous extract of chamomile (120 mg/kg/day) significantly decreased healing time for excision, incision and dead space wounds in vivo (Nayak et al 2007). Another study evaluated the topical application of chamomile in vivo and found that it significantly improved healing time for second degree burns (Jarrahi 2008).

OTHER ACTIONS

Immune enhancement

Chamomile extract increased T-lymphocyte rosette formation in vitro in blood samples taken from ear, nose and throat patients with immunodeficiency (Kliachko et al 1994). The polysaccharides (heteroglycans) showed significant immunostimulating activities according to the granulocytes and carbon clearance tests (Wagner et al 1985).

Antioxidant

Chamazulene is a potent antioxidant. It inhibits lipid peroxidation in vitro (Goeters et al 2001) in a dose–concentration- and time-dependent manner (Rekka et al 1996).

Choleretic

Chamomile increases the production of bile by the liver (Pasechnik 1966).

Drug dependence

Chamomile extract was shown to inhibit the development of morphine dependence and expression of abstinence syndrome in rats. Chamomile reduced frequencies of behaviours associated with withdrawal (paw tremor, rearing, teeth chattering, body shakes, ptosis, diarrhoea and urination) and weight loss (Gomaa et al 2003).

Anticarcinogenic

Apigenin inhibits carcinogenesis in a number of in vitro and animal studies (Aguilera et al 2000, Ali-Shtayeh et al 2000, Birt et al 1986, 1997, Lepley & Pelling 1997, Lepley et al 1996, Panes et al 1996, Patel et al 2007, Srivastava & Gupta 2007, Umezu 1999, Wei et al 1990).

Uterine effects

Water extracts of chamomile increased uterine tonus in isolated rabbit and guinea pig uterine horn (Shipochliev 1981b).

Pigmentation

Chamomile extract has been found to decrease UV-induced pigmentation as well as the hyperpigmentation found in lentigo senilis (aged or liver spots). Endothelin-1 is a cytokine responsible for stimulating melanocyte function leading to hyperpigmentation. Chamomile has been shown to interrupt the endothelin-1-induced signalling, thereby reducing the ability of melanocytes to proliferate and to synthesise melanin (Ichihashi et al 1999).

CLINICAL USE

Chamomile is most widely taken as a tea, often after meals or as an alternative to caffeine-containing beverages. In clinical practice, the oral dose form most often used is a concentrated extract, in order to produce stronger therapeutic effects. It is also used as a topical treatment in some indications.

Skin conditions

Chamomile is used topically for a variety of dermatological conditions. The most tested topical product is commercially known as Kamillosan.

Wound healing

According to a double-blind trial, external application of a chamomile extract improves wound healing. In the study, chamomile extract significantly decreased weeping and improved wound healing after dermabrasion of tattoos (Glowania et al 1987).

Eczema

In one comparative study, 161 patients with eczema on the arms and lower legs were treated with 0.25% hydrocortisone, 5% bufexamac (NSAID), 0.75% fluocortin (glucocorticoid) or a chamomile cream commercially known as Kamillosan. The chamomile cream was as effective as hydrocortisone and was superior to the other two treatments (Aertgeerts et al 1985). (Kamillosan is reportedly made from a high bisabolol-containing chemotype of chamomile.)

Dermatitis

A study involving experimentally induced toxic dermatitis found that chamomile ointment (Kamillosan) produced a more soothing effect on human skin than a chamomile ointment base or hydrocortisone ointment 0.1% (Nissen et al 1988). (Note: the hydrocortisone cream used in this study was quite weak compared with the usual strength of 0.5–2.5%.)

Chamomile cream helped to protect against skin radiation damage in breast cancer patients receiving radiation (Maiche et al 1991). Chamomile cream (Kamillosan) has been shown to be slightly less effective than 0.25% hydrocortisone, but superior to fluocortin butyl ester and 5% bufexamac in relieving inflammation associated with dermatoses (Aertgeerts 1984, Aertgeerts et al 1985).

Commission E approves the external use of chamomile for inflammation of the skin and mucous membranes, as well as for bacterial skin diseases, including those of the oral cavity and gums (Blumenthal et al 2000).

Sedation

Both oral dose forms and the essential oil of chamomile are used for this indication.

A placebo-controlled study involving 22 volunteers found that inhalation of chamomile oil produced sedative effects and improved mood (Roberts & Williams 1992). Chamomile tea (two teabags in 175 mL of hot water) given to 12 patients during cardiac catheterisation induced a deep sleep in

10 patients, even though the procedure usually causes pain and anxiety (Gould et al 1973).

Gastrointestinal conditions

Chamomile is widely used to relieve stomach cramping, dyspepsia and flatulence. The herb's antispasmodic and relaxant effects provide a theoretical basis for its use in these conditions.

In an open, multicentre study, 104 patients with gastrointestinal complaints, including gastritis, flatulence and minor spasms of the intestines, were treated for 6 weeks with 5 mL/day of an oral chamomile preparation (standardised to contain 50 mg alpha-bisabolol and 150–300 mg apigenin-7-glucoside per 100 g). By self-evaluation, all patients improved with 44.2% becoming symptom free (Stiegelmeyer 1978).

Diarrhoea in children

In Europe, chamomile is widely used to treat a variety of paediatric complaints.

A prospective, double-blind, randomised trial was used to document the efficacy of a preparation containing chamomile extract and pectin (Diarrhoesan) in children aged 6 months–5.5 years with uncomplicated diarrhoea. The chamomile preparation reduced the duration and severity significantly faster than placebo (de la Motte et al 1997). A larger multicenter, double-blind, RCT involving 255 patients was designed to further evaluate the apple pectin and chamomile preparation for acute diarrhoea in children aged between 6 months and 6 years (Becker et al 2006). Stool frequency was significantly reduced in the treatment group as compared to placebo. Commission E approves chamomile for gastrointestinal spasms and inflammatory diseases of the gastrointestinal tract.

Antibacterial preparations

A phase III, double-blind, placebo-controlled clinical trial of 164 patients assessed the efficacy of chamomile mouthwash in preventing 5-fluorouracil-induced stomatitis and found no difference between chamomile and placebo (Fidler et al 1996).

OTHER USES

The British Herbal Pharmacopoeia (1983) recommends chamomile for flatulent nervous dyspepsia, travel sickness, nasal catarrh, nervous diarrhoea and restlessness. Externally, chamomile is recommended for haemorrhoids, mastitis and leg ulcers. The specific indication is for gastrointestinal disturbance with nervous irritability in children and for teething and colic in infants.

Commission E approves the use of inhalations for inflammation and irritation of the respiratory tract and baths and irrigations for anogenital inflammation (Blumenthal et al 2000).

Oral mucositis/recurrent aphthous stomatitis

Methotrexate-induced oral mucositis in a 76-year-old woman was successfully treated by chamomile mouthwash in a recently reported case study (Mazokopakis et al 2005). The mouthwash consisted of 8 g of flower heads steeped in 1000 mL of boiling water for 15 min and then used as a gargle four times daily.

The fluid extract of chamomile appears to exert an analgesic effect on the oral mucosa. Thirty-four patients applied chamomile extract directly to their mouth ulcer(s) and then repeated this process at intervals of 5, 10 and 15 min in an unblinded, uncontrolled clinical trial. The effect was rated as excellent by 82% and good by 18% of participants using an Analogical Visual Scale (Ramos-e-Silva et al 2006).

Preventing postoperative sore throat

Chamomile extract spray administered before intubation was not able to prevent postoperative sore throat and hoarseness compared with saline spray in a randomised, double-blind study (Chan et al 2003).

Haemorrhagic cystitis

Chamomile extract decreased the symptoms of haemorrhagic cystitis. Thirty-two patients were randomly assigned to receive either the antibiotic cotrimoxazole (trimethoprim/sulfamethoxazole) alone or with a chamomile extract administered on day one as a bladder instillation, followed by daily hipbath use. Symptoms were evaluated after 10 days and indicated that the chamomile group experienced more rapid alleviation of symptoms than the group treated with only cotrimoxazole. The product used was Kamillenextrakt, an ethanolic extract of chamomile flowers (Barsom et al 1993).

DOSAGE RANGE

Internal use

- German chamomile is used either as a tea made from the dried flower heads, or as an extract.
- Dried flower heads: 2–8 g three times daily by infusion.
- Fluid extract (1:2): 3–6 mL/day.
- Tincture (1:5): 3–10 mL three times daily.
- The quality of chamomile varies greatly. For maximum efficacy, use high-grade chamomile (high in alpha-bisabolol). Standardised extracts are usually standardised to either bisabolol or apigenin.

External use

- The dried flowers can also be made into a poultice with the addition of hot water and applied directly to the skin, or the tea can be used to bathe inflamed skin and eyes.
- Essential oil (external use): Five drops per 100 mL of oil, or per 100 g of cream or ointment.
- In baths and water for compresses, the dose should not exceed 10 drops.
- Inhalation: Five drops of essential oil in 1 L hot water.

ADVERSE REACTIONS

Allergic reactions

Occasional rare cases of allergic skin reactions have been reported. However, a bibliographic review of 50 reports of 'chamomile' sensitivity revealed that in only five papers was the botanical identification

of the plant material correlated with *Chamomilla recutita*. In the majority of other instances, the effects were caused by species of the genus *Anthemis*, frequently also called chamomile. Experimental studies on pigs using a rigorous testing technique proved that *C. recutita* possesses low sensitising capacity. The suspected allergen is the sesquiterpene lactone, anthecotulide, found in *Anthemis cotula* L. (stinking mayweed), which only occurs in trace amounts in the bisabolol oxide B-chemotype of genuine chamomile (Hausen et al 1984). Allergic conjunctivitis has been reported with the use of chamomile tea eyewashes, and the pollens contained in the teas have been identified as the allergens responsible. The reaction occurred after first exposure and was thought to be due to cross-reactivity to *Artemesia* pollen (Subiza et al 1989). Pollens are not likely to be present or active in aqueous alcohol extracts of chamomile.

German chamomile is thought to be less allergenic than Roman chamomile, but any variety of chamomile can potentially cause allergic reactions. An enema made from German chamomile (Kamillosan) given during labour to a 35-year-old woman with no history of atopy resulted in life-threatening anaphylaxis and fatal asphyxia of the newborn (Jensen-Jarolim et al 1998). Chamomile enemas are not a usual form of administration.

SIGNIFICANT INTERACTIONS

Controlled studies are not available; therefore, interactions are based on evidence of activity and are largely theoretical and speculative.

Benzodiazepines

Theoretically, an additive CNS depressant and antispasmodic effect can occur with concurrent use. Observe patients taking this combination, although the combination may be clinically useful when used under supervision.

Warfarin

A case of multiple internal haemorrhage in a 70-year-old woman using topical and oral chamomile products in conjunction with warfarin has been described (Segal et al 2006). Observe.

Drugs metabolised by CYP3A4

Chamomile has been shown to inhibit cytochrome 3A4 enzymes in vitro (Budzinski et al 2000, Ganzera et al 2006, Gomes-Carneiro et al 2005). The clinical significance of this is unknown; however, drugs that are metabolised by these enzymes could theoretically be affected. Until this can be confirmed or refuted in a clinical study, observe for interactions.

NSAIDS

Chamomile extract protected test animals from experimentally induced ulcers — beneficial interaction.

CONTRAINDICATIONS AND PRECAUTIONS

Chamomile is contraindicated in hypersensitivity or known allergy to chamomile or other members of the Asteraceae family (e.g. yarrow, tansy, feverfew, daisy, ragweed).

A recent investigation found that 7.5% of the 200 samples evaluated were contaminated with *Clostridium botulinum* spores (Bianco et al 2008). This could be potentially dangerous for infants. The investigators found that the presence of these spores was significantly higher in bulk chamomile sold by weight as opposed to packaged tea ($P = 0.005$). Caution is advised when giving chamomile to children aged less than 12 months.

PREGNANCY USE

Safety has not been established scientifically; however, no teratogenic effects have been observed in vivo.

PRACTICE POINTS/PATIENT COUNSELLING

- German chamomile has demonstrated anti-inflammatory, antispasmodic, sedative and antimicrobial activity.
- It is taken orally either as a tea or tincture, used externally as a poultice, cream or ointment or inhaled as an essential oil.
- Internally, it is used to relieve flatulence, gastrointestinal spasm, dyspepsia and induce a sense of relaxation. It is also used for infants with teething pain and colic.
- Externally, chamomile preparations are used to treat dermatitis, enhance wound healing, nappy rash and soothe irritated skin. Comparative studies show that it has an anti-inflammatory effect equivalent to low-dose hydrocortisone preparations.
- There is some evidence from clinical trials to support the use of chamomile in the treatment of wounds, eczema, dermatitis, nervousness and tension, diarrhoea in children and for the symptoms of haemorrhagic cystitis (in association with antibiotic therapy).

PATIENTS' FAQs

What will this herb do for me?

Chamomile is taken to relieve stomach spasms and flatulence, to induce relaxation and promote sleep. It is also popular for children with teething pain and digestive complaints such as colic or diarrhoea. Applied externally as a cream, ointment or poultice, it is used to reduce skin irritation and inflammation.

When will it start to work?

Chamomile relieves gastrointestinal symptoms quickly, within several minutes. For more chronic problems, it may need to be used long term.

Are there any safety issues?

Chamomile is considered a very safe herb. While there have been reports of allergic reactions, the majority have been due to adulteration with other herbs. Chamomile tea is more likely to cause allergic reactions than either extracts or essential oil. Chamomile should not be used by persons with hypersensitivity or known allergy to chamomile or other members of Asteraceae family (e.g. yarrow, tansy, feverfew, wormwood).

Chaste tree

HISTORICAL NOTE Chaste tree fruits and leaves were a popular remedy in ancient Greece and Rome to promote celibacy. Leaves of the chaste tree were worn by vestal virgins in ancient Rome as a symbol of chastity. In the 17th century it was written that the chaste tree is a 'remedy for such as would willingly live chaste' (Gerard 1975). The dried fruits of the chaste tree have a peppery taste and smell and were used in place of pepper in monasteries to 'check violent sexual desires', hence one of its common names, Monk's Pepper. The berries have also been used to reduce fever and headaches, stimulate perspiration and dispel wind. However, since ancient times the chaste tree has primarily been used for a variety of gynaecological purposes, primarily menstrual abnormalities, mastalgia, to aid in expulsion of the placenta after birth, to facilitate lactation, and to promote menstruation. A commercial preparation of chaste tree has been available in Germany for over 50 years and it is still commonly used for menstrual irregularities.

OTHER NAMES

Vitex, agnus castus, chasteberry, monk's pepper, gattilier, hemp tree, Keusch-Lamm-Fruechte, wild pepper.

BOTANICAL NAME/FAMILY

Vitex agnus-castus (family Labiatae)

PLANT PART USED

Dried, ripened or fresh ripe fruits (berries)

CHEMICAL COMPONENTS

Vitex agnus-castus contains many different chemical constituents, including luteolin-like flavonoids (casticin, orientin, isovitexin), iridoid glycosides, aucubin, eurostoside, agnuside, essential fatty acids and the essential oils cineole, limonene and sabinene.

MAIN ACTIONS

Vitex displays multiple mechanisms of action identified through in vitro and experimental model research.

One major area of activity is the pituitary–hypothalamic axis.

Decreases prolactin release

The most thoroughly studied mechanism for vitex is its interaction with dopamine receptors in the anterior pituitary. Several studies have indicated that vitex acts on dopamine D_2 receptors and decreases prolactin levels (Berger et al 2000, Halaska et al 1998, Jarry

et al 1994, Meier & Hoberg 1999, Meier et al 2000, Milewicz et al 1993, Sliutz et al 1993, Wuttke et al 2003). It is likely that this mechanism is responsible for the symptom-relieving effects seen with vitex in mastodynia and hyperprolactinaemia (Meier & Hoberg 1999, Milewicz et al 1993, Splitt et al 1997) and provides some rationale for its use by herbalists in disorders complicated by hyperprolactinaemia, such as amenorrhoea, mastalgia or polycystic ovarian syndrome.

Results from one study involving healthy males propose that this effect is dose-dependent, as lower doses (120 mg) were found to increase secretion and higher doses (204–480 mg) were found to decrease secretion (Merz et al 1996).

A study using the vitex extract BNO 1095 (70% ethanol, 30% H_2O extract, Bionorica AG, Neumarkt, Germany) identified that the major dopaminergic compounds are the clerodadienols, which act as potent inhibitors of prolactin release; however, other active compounds of lesser activity were also identified (Wuttke et al 2003). Dopaminergic bicyclic diterpenes have also been isolated that inhibit cAMP formation and prolactin release in rat pituitary cell cultures (Jarry et al 2006).

Oestrogen receptor binding

Vitex contains oestrogenic compounds, the flavonoids penduletin and apigenin. Vitex extract showed significant competitive binding to oestrogen receptors alpha and beta in vitro (Liu et al 2001, Jarry et al 2003, Wuttke et al 2003).

Increases progesterone levels

In vitro research has found that vitex stimulates progesterone receptor expression (Liu et al 2001). A randomised controlled trial of women with hyperprolactinaemia showed that vitex extract (20 mg daily) normalises progesterone levels after 3 months' treatment (Milewicz et al 1993).

Opioid receptors

A recently published study reported that a methanol extract of vitex had affinity to the μ-opiate receptor (Webster et al 2006). Of note, this receptor is the primary action site for beta-endorphin in vivo, a peptide which assists in regulating the menstrual cycle through inhibition of the hypothalamus–pituitary–adrenal axis.

> ***Clinical note — The opiate system and PMS***
> The opiate system consists of mu, delta and kappa opiate receptors and endogenous opiate peptides such as beta-endorphin (Webster et al 2006). The opiate system plays an essential role in regulating tonic pain perception, mood, appetite, and other functions. PMS is characterised by a reduction of opiate activity and the severity of symptoms such as anxiety, food cravings, and physical discomfort is inversely proportional to the amount of decline in beta-endorphin levels in the luteal phase. Based on recent research, the symptom-relieving effects of vitex in PMS may be due to direct activation of analgesic and mood regulatory pathways via opiate receptor activation and/or reversal of the loss of opiate inhibition in the luteal phase.

Cytotoxic activity

Cytotoxic activity has been reported for an ethanolic extract of the dried ripe fruit of vitex against various human cancer cell lines (Ohyama et al 2003, 2005, Weisskopf et al 2005). The extract increased intracellular oxidative stress and mitochondrial damage leading to apoptosis. In vitro studies demonstrate that vitex extract inhibits the proliferation of human prostate epithelial cell lines via apoptosis (Weisskopf et al 2005).

OTHER ACTIONS

Conflicting results have been obtained in studies with regard to the effect on follicle-stimulating hormone (FSH) and luteinising hormone (LH) levels. One clinical study found that vitex extract did not alter FSH or LH levels, whereas another showed that it increased LH release (Lauritzen et al 1997, Milewicz et al 1993). Inconsistent results may be due to variations in chemical constituent levels present in the different test herbal products.

CLINICAL USE

Although double-blind studies have recently been conducted with chasteberry, uncontrolled trials go back to the 1940s when a product known as Agnolyt was tested. The product was developed and patented by Dr Gerhard Madaus in Germany and contained *Vitex agnus-castus*. Several different vitex products have been investigated to date including: Agnolyt (standardised to 3.5–4.2 mg of dried chasteberry extract), *Vitex agnus-castus* L. extract Ze 440 (each 20 mg tablet standardised for casticin and agnuside), Femicur (contains 1.6–3.0 mg of dried extract per capsule) and Mastodynon (53% v/v ethanol), a homeopathic preparation. The BNO 1095 extract contains 4.0 mg of dried ethanolic (70%) extract of vitex (corresponding to 40 mg of herbal drug) and is found in Agnucaston®/Cyclodynon® (manufacturer: Bionorica AG, Neumarkt, Germany).

Premenstrual syndrome

Vitex is an effective and well-tolerated treatment for mild, moderate and severe premenstrual syndrome (PMS) according to clinical trials (Atmaca et al 2003, Berger et al 2000, Dittmar 1992, Lauritzen et al 1997, Loch et al 2000, Schellenberg 2001, He et al 2009). According to these studies, the PMS symptoms that respond best to treatment are breast tenderness, irritability, depressed mood, anger, mood changes, headache and constipation. The most studied extract investigated in PMS is Ze440 and, more recently, BNO 1095 extract (see *Clinical note,* p 307).

A multicentre, randomised, controlled, double-blind study investigating the effects of vitex (Ze440) for PMS involved 170 women and was published in the British Medical Journal (Schellenberg 2001). Of the group, 13% were also taking oral contraceptive pills (OCP). Treatment with a 20 mg tablet of dry extract of chasteberry taken daily resulted in a significant improvement of PMS symptoms,

particularly headache, breast fullness, irritability, anger and mood changes. Over 50% of women in the active treatment group achieved at least a 50% reduction in symptoms. Similar results were obtained in a 2006 prospective, open, non-comparative study of 121 women with moderate to severe PMS who took vitex (BNO 1095) over three menstrual cycles. Assessment using the validated PMS Diary (PMSD) and the PMTS score showed that the severity of PMS symptoms consistently decreased during treatment (Prilepskaya et al 2006).

The results were confirmed once again in a 2009 multicentre randomised, placebo-controlled study completed in China, testing vitex (BNO 1095) extract over three menstrual cycles in 202 women with moderate to severe PMS. Women taking hormonal contraceptives, antidepressants, selective serotonin reuptake inhibitors (SSRIs) or prolactin inhibitors during last 6 months were not included. Treatment with vitex extract BNO 1095 produced a significantly greater decrease in the total score for PMSD in the luteal phase and PMTS self-assessment compared to placebo after two menstrual cycles, with the differences between placebo and active treatment groups becoming even more significant after 3 months treatment. This further supports the use of vitex in PMS and indicates that full benefits require at least three menstrual cycles to become established (He et al 2009).

Previously, a number of open studies had generally produced positive results for Vitex as a symptomatic treatment in PMS. One multicentre, open-label study showed that daily treatment with a 20 mg tablet of vitex (Ze440) over three menstrual cycles significantly reduced the Moor menstrual distress self-assessment questionnaire (MMDQ) with 46% of women experiencing a 50% reduction in the MMDQ. Treatment also reduced the duration of PMS symptoms from 7.5 days to 6 days and was as effective for women taking OCP as for those who were not (Berger et al 2000). Once treatment was stopped, PMS symptoms gradually returned to baseline within three further cycles. The largest multicentre trial was an open study of 1634 women with PMS, which found that treatment with vitex (Femicur) for three menstrual cycles decreased the number of PMS symptoms in 93% of subjects (Loch et al 2000). Symptoms completely resolved in 40% of subjects and 94% overall rated vitex treatment as well tolerated. An early study using vitex (Agnolyt) in 1542 women with PMS reported an improvement in symptoms with an average dose of 42 drops daily taken for an average of 25 days (Dittmar 1992 as reported in Ulbricht & Basch 2005). According to Ulbricht and Basch (2005), three earlier uncontrolled studies produced inconclusive results.

Comparison to SSRI drugs

In 2003, a randomised 8-week study involving 42 women compared the effects of 20–40 mg daily of fluoxetine, a SSRI, and 20–40 mg of vitex extract and found no statistically significant difference between the groups with respect to the rate of responders (Atmaca et al 2003). More specifically, patients with premenstrual dysphoric disorder responded well to both treatments; however, fluoxetine was more effective for psychological symptoms such as depression and irritability, whereas the herbal extract was more effective for diminishing physical symptoms such as breast tenderness, cramps, food cravings and swelling. Unfortunately, the authors did not report the type of vitex extract used in the study.

Clinical note — Ze440 extract

The naming of the Ze440 extract (Premular in Australia) is derived from the name Zeller, the 135-year-old Swiss company manufacturing it, combined with a unique number ascribed during the initial studies. In order to ensure that products deliver consistent results, Ze440 is measured by both composition and consistency from batch to batch. To promote product uniformity, every batch is grown, harvested and manufactured into tablets under controlled conditions and is extracted in a standardised method that ensures consistent and high levels of the important lipophilic compound casticin and an established marker compound, the iridoid glycoside named agnuside.

Comparison to vitamin B6

Although vitamin B6 (pyroxidine) is a popular treatment for PMS symptoms, the results from a double-blind comparative study have found that vitex (Agnolyt) is as effective and possibly more so (Lauritzen et al 1997). The randomised, double-blind study of 175 women compared vitex, pyridoxine and placebo. In the study, 77% of women receiving vitex reported symptom alleviation compared with 61% with pyridoxine (200 mg/d), which was considered a small but significant difference. Additionally, physician assessments were more likely to rate treatment with vitex as 'excellent' compared with pyridoxine.

Commission E approves the use of vitex for premenstrual syndrome.

Mastalgia

Mastalgia is considered to relate to latent and increased basal prolactin levels; therefore, agents that reduce prolactin levels are anticipated to reduce symptoms. Vitex is a popular treatment for cyclical mastalgia as it interacts with dopamine D_2 receptors to reduce prolactin levels.

In two randomised, double-blind studies, vitex (Mastodynon) effectively reduced premenstrual mastalgia (Halaska et al 1998, Splitt et al 1997, Wuttke et al 2003). Subjects completed a visual analogue scale (VAS) and rated their breast pain from 0 (lowest breast pain) to 10 (extremely strong breast pain). Active treatment reduced the mastalgia score by 35–40%, an effect significantly stronger than that of placebo (25%). One of these studies also demonstrated that treatment with vitex reduced serum prolactin levels (Splitt et al 1997, as reported in Wuttke et al 2003). According to Halaska et al (1998), symptom relief was experienced after the first month of treatment

with continued improvements experienced after the second and third months.

Commission E approves the use of vitex for this indication.

Irregularities of the menstrual cycle

Vitex is used to normalise menstruation in women with shortened, lengthened or infrequent menstruation, particularly when low progesterone and luteal phase defects are suspected. In practice, vitex has also been used traditionally to treat both amenorrhoea and menorrhagia. Herbalists speculate that beneficial effects obtained in practice may be due to the herb's ability to reduce elevated prolactin levels in these conditions. This is particularly indicated where chronic stress is also present as this has an effect on the hypothalamus–pituitary axis resulting in elevated prolactin levels (Mills 2000, Trickey 1998). Whilst the use of vitex in all these indications has not yet been tested under double-blind conditions, one randomised controlled trial of women with luteal phase defect due to latent hyperprolactinaemia demonstrated that vitex extract (20 mg daily) effectively reduced prolactin levels and normalised luteal phase length and progesterone levels after treatment for 3 months (Milewicz et al 1993).

Commission E approves the use of vitex for this indication.

Menopause (in combination)

Vitex has been studied as part of several different polyherbal treatments for effectiveness in treating menopausal symptoms. The use of herbal combinations reflects real-world practice but makes it difficult to assess the value of vitex as a stand-alone treatment for this indication. To date, these studies using combination herbal therapy, including vitex, have produced mixed results.

Vitex (200 mg daily) in combination with other herbs, notably black cohosh, produced a significantly superior mean reduction in menopausal symptoms compared to placebo according to a 2007 randomised controlled study (Rotem & Kaplan 2007). The study of 50 healthy pre and postmenopausal women found herbal treatment improved menopausal symptoms gradually and after 3 months of treatment, there was a 73% decrease in hot flushes and a 69% reduction in frequency of night sweats, accompanied by a decrease in their intensity and a significant benefit in terms of sleep quality. Importantly, hot flushes ceased completely in 47% of women in the study group compared with only 19% in the placebo group. No changes were detected for vaginal epithelium or levels of relevant hormones (oestradiol, follicle-stimulating hormone), liver enzymes or thyroid-stimulating hormone in either group.

An Australian double-blind, randomised, placebo-controlled, parallel study using a combination of vitex with St John's Wort in 100 late-perimenopausal or postmenopausal women experiencing hot flushes and other menopausal symptoms failed to show significant clinical improvements in menopausal symptoms compared to placebo (van Die et al 2009).

Poor lactation

Vitex has been used since ancient times as a galactagogue to promote milk production, especially in the first 10 days after delivery.

Currently, there are no double-blind studies to confirm its efficacy; however, an early uncontrolled study provides some support for the use of vitex in lactation, finding a favourable effect on milk production in 80% of women (Noack 1943). Results from a small study of males suggest that increases in prolactin may be possible with low-dose vitex (120 mg daily) whereas higher doses (480 mg daily) result in decreased levels (Merz et al 1996).

Fertility disorders

Vitex is used in practice with other herbal medicines to enhance fertility in women with progesterone deficiency or luteal phase defects. Currently, no large studies have been published to evaluate the effectiveness of this approach; however, a double-blind, randomised, placebo-controlled study of 96 women with fertility disorders (38 with secondary amenorrhoea, 31 with luteal insufficiency and 27 with idiopathic infertility) used the vitex product Mastodynon with encouraging results (Gerhard et al 1988). Treatment of 30 drops was administered twice daily for 3 months and resulted in women with amenorrhoea or luteal insufficiency achieving pregnancy more than twice as often as the placebo group, with 15 women conceiving during the study period ($n = 7$ with amenorrhoea, $n = 4$ with idiopathic infertility, $n = 4$ with luteal insufficiency). Although promising, this study has been criticised for pooling of diverse conditions, unclear reporting of results and variable significance (Ulbricht & Basch 2005).

Acne vulgaris

An open study of 117 subjects (male and female) with different forms of acne found that after 6 weeks' treatment with a 0.2% dried extract of *vitex agnus-castus* and a topical disinfectant, 70% of cases experienced total resolution with the highest success rates reported for acne vulgaris, follicularis and excoriated acne (Amann 1975). A group that was not treated with the herb took 30–50% longer to achieve similar results. Although encouraging, it is difficult to determine the contribution of vitex treatment to these results. Until controlled studies using vitex as a stand-alone treatment are conducted, the herb's role in this condition is still uncertain.

OTHER USES

Vitex is used to aid the expulsion of the placenta after birth. It is also used to treat fibroids, normalise hormones following the use of OCP, and in cases of premature ovarian failure. Studies on rats suggest that the dopaminergic agonist action of vitex may be useful to reduce or control epileptic seizures (Saberi et al 2008).

DOSAGE RANGE

General guide

- Liquid extract (1:2): 1–2.5 mL in the morning.
- Dried fruit: 1.5–3 g in the morning.

- Dry fruit flesh (solid-dose form): 1000–1800 mg/day.
- Manufacturers have recommended vitex preparations be taken daily as a single dose upon rising, before breakfast, throughout the menstrual cycle.

According to clinical studies

- PMS
  Ze440 extract (Premular) 20 mg daily.
  Femicur 40 mg daily.
- Cyclic mastalgia
  Mastodynon 60 drops daily or 1 tablet daily.
- Menstrual irregularities
  20 mg daily (extract unknown).
- Infertility
  Mastodynon 30 drops twice daily.

ADVERSE REACTIONS

A systematic review of the herb's safety, published in 2005, analysed data from six electronic databases, postmarketing surveillance studies, spontaneous reporting schemes (including WHO), herbalist organisations and manufacturers (Daniele et al 2005). The review concluded that vitex is a safe herbal medicine and any adverse effects associated with its use tend to be mild and reversible. The most common adverse effects are: nausea, headache, gastrointestinal disturbances, menstrual disorders, acne, pruritis and erythematous rash. Additionally, no drug interactions have been reported. More recently, a 2009 placebo-controlled study of 202 women with moderate to severe PMS found no significant difference between incidence of adverse effects in the placebo- or vitex-treated groups (He et al 2009). Headache was reported as one of the more common side effects experienced by both groups which was attributed to the PMS itself and not treatment.

SIGNIFICANT INTERACTIONS

Controlled studies are not available, so interactions are based on evidence of activity and are largely theoretical and speculative.

Dopamine antagonists

An antagonistic interaction is theoretically possible — observe patients.

Oral contraceptives

There has been speculation about the effectiveness of vitex when OCP are being taken. Several clinical studies involving women taking oral contraceptives have confirmed the herb still reduces PMS symptoms and does not affect OCP.

CONTRAINDICATIONS AND PRECAUTIONS

People with tumours sensitive to oestrogen or progesterone should avoid using this herb until safety can be established.

PREGNANCY USE

Vitex is not traditionally recommended in pregnancy. In practice, some herbalists use it during the first 8 weeks of pregnancy in cases of difficult conception.

PRACTICE POINTS/PATIENT COUNSELLING

- Clinical trials support the use of vitex in mild, moderate and severe PMS. It is particularly suited to treating common PMS symptoms such as mood changes and irritability, breast tenderness, headaches and constipation. According to the available evidence, it is more effective than pyridoxine treatment and has a similar response rate to fluoxetine.
- It may also be effective in the treatment of menstrual irregularities and mastalgia.
- Vitex is also used to relieve menopausal symptoms, enhance fertility in women with progesterone deficiency or luteal phase defects, and aid the expulsion of the placenta after birth, reduce fibroids and normalise hormones following the use of oral contraceptives.
- Traditionally, it is described as a galactagogue (i.e. a medicine able to increase milk production in lactation) and is used in low doses for this indication.
- A mechanism of action has not been conclusively identified, but it appears to inhibit prolactin release by selective stimulation of pituitary dopamine D_2 receptors, increase progesterone levels and works via the opiate system.

PATIENTS' FAQs

What will this herb do for me?

Vitex is used to relieve common symptoms of PMS, such as irritability, mood swings, breast tenderness, headache and constipation. It is also used in combination with other herbal medicines to enhance fertility, relieve menopausal symptoms, regulate irregular menstruation, improve acne and promote milk production in new mothers.

When does it start to work?

Most trials show that treatment for at least three menstrual cycles may be required before symptom relief is experienced in PMS.

Are there any safety issues?

In cases of irregular menstruation, investigation for serious pathology should be undertaken before use of this herb.

Chickweed

HISTORICAL NOTE Chickweed is one of the most common weeds worldwide. It has been used since ancient times to treat external inflammatory conditions and is also used as a tasty and nutritious vegetable, as well as poultry fodder to improve egg production.

COMMON NAME
Chickweed

OTHER NAMES
Mouse-ear, star chickweed, starweed, satinflower, starwort, stellaria, winterweed

BOTANICAL NAME/FAMILY
Stellaria media (family Caryophyllaceae)

PLANT PARTS USED
Aerial parts — leaves, stems and flowers

CHEMICAL COMPONENTS
Saponins, coumarins, flavonoids, carotenoids, carboxylic acids, as well as nitrate salts, vitamin C, calcium, iron, vitamins A and C and B-complex vitamins (Fisher & Painter 1996). Chromatography isolates include apigenin 6-C-beta-D-galactopyranosyl-8-C-alpha-L-arabinopyranoside, apigenin 6-C-alpha-L-arabinopyranosyl-8-C-beta-D-galactopyranoside, apigenin 6-C-beta-D-galactopyranosyl-8-C-beta-L-arabinopyranoside, apigenin 6-C-beta-D-glucopyranosyl-8-C-beta-D-galactopyranoside, and apigenin 6,8-di-C-alpha-L-arabinopyranoside (Dong et al 2007).

Chickweed essential oil has been found to contain several well-known contact allergens: borneol, menthol, linalool, 1,8-cineole, and other terpenes such as epoxy-dehydro-caryophyllene, monoterpene alcohol-ester and caryophyllene (Jovanović et al 2003).

MAIN ACTIONS
The pharmacological actions of chickweed have not been significantly investigated, so traditional use and an understanding of the actions of individual constituents is used.

Internal use — antitussive, expectorant and demulcent effects
Herbal saponins are well known to irritate mucous membranes and are successfully used as expectorants (e.g. senega). Herbs, such as chickweed, that

contain saponins are also suspected to have a degree of expectorant activity when used internally; however, this has not been investigated in controlled studies.

External use — soothing irritated skin and enhancing wound healing

Chickweed is traditionally thought to have soothing properties when applied to the skin in an appropriate vehicle, although controlled studies are not available to confirm these effects. The saponin content may account for the herb's ability to help reduce itchiness.

OTHER ACTIONS

An in vitro study identified that a chickweed decoction had activity against human hepatoma cell lines (Lin et al 2002). An ethanolic extract of chickweed has been found to strongly inhibit xanthine oxidase in vitro, suggesting that it may have a use against hyperuricaemia and gout (Pieroni et al 2002).

CLINICAL USE

Chickweed has not been significantly investigated under clinical trial conditions, so evidence is derived from traditional, in vitro and animal studies.

Urticaria, eczema, rashes, burns

Chickweed is most commonly used in external preparations for inflamed and itchy skin conditions such as urticaria, eczema, insect bites and stings, as well as minor wounds and cuts. Anecdotal evidence suggests that it may have some effects; however, controlled studies are not available to confirm effectiveness.

Bronchial phlegm and bronchitis

Taken orally, chickweed is often combined with other herbs for treating conditions characterised by fever and bronchial phlegm; however, controlled studies are not available to confirm effectiveness.

OTHER USES

Chickweed can be eaten raw in salads, served as cooked greens, juiced or infused as a tea. It has also been used as a mild laxative and diuretic substance.

DOSAGE RANGE

- Tincture (1:5): 2–10 mL three times daily.
- Infusion of dried herb: 1–5 g three times daily.
- Chickweed is commonly incorporated into a topical ointment or cream base for external use (1 part chickweed to 5 parts base) and applied as required.

TOXICITY

Allergic skin reactions can occur with topical use.

ADVERSE REACTIONS

There is insufficient reliable information available about the safety of chickweed when used internally or externally. Allergy to chickweed causing contact erythema multiforme has been reported (Jovanović et al 2003), and it is advised to apply a test patch to a small area before applying more widely.

SIGNIFICANT INTERACTIONS

Not known.

CONTRAINDICATIONS AND PRECAUTIONS

Allergic skin reactions can occur with topical use.

PREGNANCY USE

Likely to be safe when consumed in dietary amounts; however, safety is not known when used in larger quantities.

PRACTICE POINTS/PATIENT COUNSELLING

- Chickweed has been traditionally used as an ingredient in herbal creams and ointments to soothe inflamed, itchy skin and promote wound healing. Although controlled studies are unavailable, the pharmacological actions of several constituents within the herb suggest that it may be useful.
- Although it is likely to be safe, it is prudent to avoid using chickweed in pregnancy in amounts greater than those ingested when used as a food.

PATIENTS' FAQs

What will this herb do for me?

When chickweed is applied topically it may soothe inflamed and itchy skin. It is taken orally as a cough suppressant and expectorant.

How quickly will it work?

In practice, topical preparations are reported to produce symptom relief within 30 minutes; however, there are no controlled trials to confirm this.

Are there any safety issues?

Chickweed can be consumed as a food in salads, cooked as greens or prepared as a juice; however, the safety of larger intakes is unknown. Used as part of a herbal cream, it is likely to be safe, although it would be wise to do a test patch in a small area before applying to large areas. The safety of large doses in pregnancy is unknown.

Chitosan

HISTORICAL NOTE With the exception of cellulose, chitin is the most abundant natural polysaccharide on Earth. It is produced by different crustaceans, molluscs, insects, algae, fungi and yeasts. Recently, the commercial value of chitin has increased because of the beneficial properties of its soluble derivatives, which are used in chemistry, biotechnology, agriculture, food processing, cosmetics, veterinary science, medicine, dentistry, environmental protection, and paper or textile production. The most useful chitin derivative is chitosan.

BACKGROUND AND RELEVANT PHARMACOKINETICS

Chitosan is a form of poorly soluble fibre, chemically derived from chitin, which is extracted from the exoskeletons of crustaceans or squid. It is a cationic polysaccharide and is in itself a major source of the nutritional supplement, glucosamine. Similar to other forms of fibre, such as oat bran, chitosan is thought to bind bile acids and dietary lipids. The solubility, biocompatibility and immunological activity and physicochemical properties of chitosan are altered by its molecular weight and degree of N-acetylation. The most biologically effective products contain a chitosan fraction with a low molecular weight, about 8 kD (Synowiecki & Al-Khateeb 2003).

The solubility of chitosan increases in the acidic environment of the stomach, but at a pH above 6.3 (e.g. in the intestines) the amino groups of chitosan and fatty acids, bile acids, cholesterol and lipids form a complex (Ylitalo et al 2002), and the resultant decreased availability of bile acids limits intestinal emulsification and the absorption of lipids, which are then excreted in the faeces.

CHEMICAL COMPONENTS

Chitosan is a cationic polysaccharide prepared by N-deacetylation of chitin.

DEFICIENCY SIGNS AND SYMPTOMS

Chitosan is not an essential nutrient, so deficiencies do not occur.

MAIN ACTIONS

Binds to fat

As it passes through the digestive tract, chitosan binds to ingested fat, bile acids, cholesterol and other lipids, preventing their absorption. The complexes that form between chitosan and various fats are then excreted in the faeces. A human study investigating whether the effect is clinically significant found that a dose of 4.5 g/d, taken in divided doses 30 min before meals, trapped only negligible amounts of fat as measured by fat excretion in stools (Gades & Stern 2003).

Antibacterial and antifungal activity

Animal studies have identified antibacterial activity against *Bifidobacterium* and *Lactobacillus*, which are part of the normal flora of the intestinal tract (Tanaka et al 1997). Clinical trials with a chitosan mouthwash and chewing gum have shown antibacterial activity against *Streptococcus mutans* (Sano et al 2003). Chitosan also inhibits the adhesion of *Candida albicans* to human buccal cells and has antifungal activity (Senel et al 2000).

OTHER ACTIONS

Chitosan can also absorb urea and ammonia and generally displays similar actions to other dietary fibres (Hendler & Rorvik 2001).

CLINICAL USE

The most biologically effective products contain a chitosan fraction having a low molecular weight. Unfortunately, not every clinical study indicates whether low-molecular-weight chitosan has been used. Therefore, aside from the usual variables, discrepant results may be due to differences in the type of chitosan used.

Weight loss

Chitosan is widely marketed as a weight loss aid, primarily due to its ability to bind to fats and reduce their absorption in the digestive tract.

A Cochrane systematic review published in 2005 analysed the results of 14 randomised studies involving 1131 subjects and concluded that use of chitosan resulted in a significantly greater weight loss, decrease in total cholesterol and decrease in systolic and diastolic blood pressure than placebo (Ni et al 2005). The studies had a minimum duration of 4 weeks and were conducted with overweight or obese subjects. With regard to the frequency of adverse events or faecal fat excretion, no clear differences were observed between the placebo and chitosan groups. Although encouraging, the authors noted that the quality of the studies was suboptimal and overall results were variable. A look at the studies of highest quality suggests that the effects are minimal. The mean trial duration was 8.3 weeks (range 4–24 weeks) and eight of the 14 studies combined the use of chitosan or placebo with a low-calorie or weight-reducing diet. Interpretation of the data is not straightforward because the dose of chitosan used in studies varied considerably, from 0.24 g/day to 15 g/day (mean 3.7 g/day) and six of the studies used treatment preparations that contained other active ingredients in addition to chitosan. Additionally, the review excluded some potentially important trials because they did not meet criteria for inclusion (e.g. subjects were not enrolled for being overweight but selected for other reasons).

In 2008, an updated Cochrane systematic review was published which evaluated 15 clinical studies (n = 1219) (Jull et al 2008). Analyses indicated that

chitosan preparations result in a significantly greater weight loss (weighted mean difference −1.7 kg; $P < 0.00001$), decrease in total cholesterol (−0.2 mmol/L; $P < 0.00001$), and a decrease in systolic and diastolic blood pressure compared with placebo. Chitosan treatment was well tolerated, as there were no clear differences between intervention and control groups in terms of frequency of adverse events or in faecal fat excretion. Whilst these results are encouraging, reviewers once again reported that the quality of many studies was suboptimal and analysis of only high quality trials yielded less convincing evidence.

Previously, a 1998 meta-analysis identified five studies evaluating the effectiveness of chitosan for the treatment of obesity (Ernst & Pittler 1998). All studies included were conducted in Italy and published in a single Italian journal over a 2-year period. They concluded that the mean difference in terms of weight reduction between chitosan and placebo was approximately 3.3 kg. It is worth noting that these five studies consistently demonstrated the greatest effects in the 2005 Cochrane systematic review discussed above, were all of short duration, and four of them also included other agents in the chitosan preparations.

A later systematic review conducted by Ernst and Pittler, which included five additional studies, concluded that when these new results were combined with the previous five from the 1998 meta-analysis, the evidence becomes less compelling and raised doubts about the effectiveness of chitosan in weight loss (Pittler & Ernst 2004).

Clearly, further well-reported research is required, using longer time frames and clearly stating the composition of the chitosan preparations.

Hyperlipidaemia

The ability of chitosan to form complexes with various fats, including cholesterol, provides a theoretical basis for its use in hyperlipidaemia. Dietary chitosan has been tested and found to be effective in reducing serum cholesterol levels and atherosclerosis in normal and diabetic mice, and, therefore, has been investigated in the treatment of hypercholesterolaemia in humans (Muzzarelli 1999).

A 2002 review states that in humans, dietary chitosan reduces serum total cholesterol levels by 5.8–42.6% and LDL levels by 15.1–35.1% (Ylitalo et al 2002). Based on these figures, the effects of chitosan range from mild to moderate and appear to be inconsistent for total cholesterol. More specifically, lowering of LDL cholesterol is more consistent, whereas little effect is seen on plasma triglyceride concentration, according to several different experimental and human studies involving obese or diabetic subjects or people with mild to moderate hypercholesterolaemia (Bokura & Kobayashi 2003, Tai et al 2000, Wuolijoki et al 1999, Yihua & Binglin 1997).

Reduction in LDL cholesterol was evident after 4 weeks' treatment with a microcrystalline chitosan (1.2 g twice daily) according to one double-blind study (Wuolijoki et al 1999) and after 8 weeks' treatment using a low dose of 1.2 g/day of chitosan in another double-blind study (Bokura & Kobayashi 2003). However, not all studies have produced positive results. One double-blind study found no effect with 1.5 g chitosan tablets taken three times daily (Zahorska-Markiewicz et al 2002). More recently, no significant effect on total cholesterol, LDL cholesterol or triglycerides was seen in a randomised placebo controlled study, which tested chitosan capsules (1 g twice daily) (Guha et al 2005). The group receiving chitosan did report a significant reduction in mean body weight (3.14% versus 1.29% of body weight, $P < 0.05$) and a significant rise in HDL cholesterol value (3.8% versus 1.07%, $P = 0.02$).

The electrically neutral nature of triglycerides may mean that chitosan is unable to form complexes with it, and, therefore, is unable to influence its absorption.

In contrast, a more recent 2008 study found no significant effects on total cholesterol levels or LDL cholesterol concentration for chitosan after 8 weeks of treatment (Tapola et al 2008). The randomised study involved 65 men and women and compared the effect of two different doses of chitosan to placebo on serum fat-soluble vitamin concentrations, cholesterol concentrations, and other safety parameters (Tapola et al 2008). The doses of chitosan tested were 0, 4.5 or 6.75 g/d and the placebo consisted of 6.75 g/d glucomannan. In addition, no treatment induced a change in levels of serum vitamins (vitamin A, vitamin E, 25-hydroxyvitamin D), carotenes (alpha- and beta-carotene).

Dental plaque prevention

Considering that chitosan has antibacterial activity against *Streptococcus mutans* and antifungal action against *Candida albicans*, it has been added to mouthwashes and gels for dental use. One randomised, crossover clinical trial involving 24 volunteers found that rinsing with a mouthwash containing 0.5% chitosan for 14 days was significantly more effective in reducing plaque formation than placebo (Sano et al 2003). Several clinical studies have investigated the effect of chitosan-containing chewing gum. One clinical study reported that chewing the gum significantly decreased oral bacterial counts and significantly increased salivary secretion (Hayashi et al 2007a). Another confirmed antibacterial activity for the gum, especially reducing total streptococci, mutans streptococci in saliva (Hayashi et al 2007b). Hayashi et al suggested that chewing chitosan-containing gum could be an effective method for controlling the number of cariogenic bacteria in situations where it is difficult for a person to brush their teeth. The gum used in the study was xylitol-based and supplemented with chitosan so it dissolved in saliva at a rate of about 2% (w/v).

Periodontal disease

Chitosan was tested as both a carrier in gel form for the antibiotic metronidazole and as an active agent in the treatment of chronic periodontitis (CP) (Akncbay et al 2007). The chitosan gel (1% w/w) incorporated with or without 15% metronidazole was prepared and applied adjunctive to

scaling and root planing (SRP) and compared to SRP alone (control group-C), in CP patients. All groups experienced significant improvements for clinical parameters between baseline and week 24 ($P < 0.05$). Chitosan was found to be effective in itself as well as in combination with metronidazole in CP treatment due to its antimicrobial properties.

Kidney failure

One open study of 80 patients with renal failure, undergoing haemodialysis, found that 1350 mg of chitosan taken three times daily effectively reduced total serum cholesterol levels (from 10.14 ± 4.40 mmol/L to 5.82 ± 2.19 mmol/L) and increased serum haemoglobin levels (from 58.2 ± 12.1 g/L to 68 ± 9.0 g/L) (Jing et al 1997). After 4 weeks, significant reductions in serum urea and creatinine levels were observed. After 12 weeks, patients reported subjective improvements, such as feeling physically stronger, increased appetite and improved sleep, which were also significantly greater than the placebo group. Importantly, during the treatment period, no clinically problematic symptoms were observed.

Wound healing — topical use

Chitosan is applied to burns and wound dressings in the form of films, bandages, cotton-like materials and non-woven napkins. These dressings have good hydroscopicity, show high bacteriostatic effect and are completely biodegradable in the human body. Another significant advantage is that repeated dressings are usually not needed (Synowiecki & Al-Khateeb 2003). Topical application of chitosan enhances wound healing and has been used to promote donor-site tissue regeneration in plastic surgery. Its use is supported by findings that indicate chitosan accelerates the reformation of connective tissue (Ueno et al 2001).

OTHER USES

Drug delivery systems

Chitosan is considered a good carrier for the controlled release of drugs over an extended period of time (Synowiecki & Al-Khateeb 2003). Additionally, it has been shown to excel in transcellular transport.

Chitosan is also used as a component of different cosmetics, toothpaste, hand and body creams and hair-care products (Synowiecki & Al-Khateeb 2003).

DOSAGE RANGE

- The standard dose of chitosan is 3–6 g/day, taken with food.

According to clinical studies

- Weight loss: 3.0–4.5 g taken daily in divided doses, 30 minutes before meals.
- Hyperlipidaemia: 1.2–4.5 g/day in divided doses.
- Dental plaque prevention: rinse daily with mouthwash containing 0.5%.
  - Periodontal disease: chitosan gel (1% w/w) applied as an adjunct to scaling and root planing.
- Renal failure: 1.35 g taken three times daily.

Clinical note — Periodontal disease

Periodontal disease is a collective term used to describe several pathological conditions characterised by degeneration and inflammation of gums, periodontal ligaments, alveolar bone and dental cementum. It is a localised inflammatory response caused by bacterial infection of a periodontal pocket associated with subgingival plaque. Periodontal disease has been considered as a possible risk factor for other systemic diseases such as cardiovascular diseases and preterm, low-birth-weight infants. Increasingly, chitosan is being used as a polymeric matrix in the form of film enriched with taurine (antioxidant agent). Taurine enhances the wound healing ability of chitosan and is considered beneficial in tissue repair in destructive diseases like periodontitis (Jain et al 2008).

ADVERSE REACTIONS

A systematic review of 14 randomised studies found that the most common side effects reported were constipation, nausea, bloating, indigestion and abdominal pain (Ni et al 2005). Increased water consumption may reduce some of these side effects.

Overall, chitosan is considered very safe and well tolerated according to safety studies in experimental models (Kim et al 2001).

SIGNIFICANT INTERACTIONS

Fat-soluble nutrients

Considering chitosan binds to dietary fats and reduces their absorption, chitosan can also affect the absorption of fat-soluble vitamins. However, the effect may be dose dependent as one study using a dose of 2 g/day found no changes to the levels of vitamins A, D, E and beta-carotene after 4 weeks' use (Pittler et al 1999). A more recent study confirmed that there were no significant effects on serum vitamins (vitamin A, vitamin E, 25-hydroxyvitamin D) and carotenes (alpha- and beta-carotene) with oral chitosan after 8 weeks even at a dose of 6.75 g daily (Tapola et al 2008).

Lipophilic drugs

Considering chitosan binds to dietary fats and reduces their absorption, chitosan can also affect the absorption of lipophilic drugs. Separate doses by at least 2 hours.

Vitamin C

According to a preliminary study in rats, taking vitamin C together with chitosan might provide additional benefit in lowering cholesterol.

CONTRAINDICATIONS AND PRECAUTIONS

Chitosan is contraindicated in people with allergies to shellfish.

PREGNANCY USE

Pregnant women should avoid chitosan as it may reduce absorption of essential dietary nutrients.

PRACTICE POINTS/PATIENT COUNSELLING

- Chitosan is a form of poorly soluble fibre, chemically derived from chitin, which is extracted from the exoskeletons of crustaceans or squid. The most biologically active forms have a low molecular weight.
- It forms insoluble complexes with dietary fats, fatty acids, bile acids, cholesterol and other lipids in the digestive tract and has antibacterial and antifungal activity that is useful in dental hygiene.
- Chitosan is a popular weight loss supplement. Clinical studies have produced mixed results; however, best effects occur when chitosan is used over several months and combined with dietary and lifestyle modifications.
- Overall, evidence generally supports its use in hyperlipidaemia, as it reduces serum levels of total cholesterol and LDL levels, but it has little effect on triglyceride levels.
- Chitosan is contraindicated in people with allergies to shellfish and should be recommended together with a multivitamin supplement with long-term use.

PATIENTS' FAQs

What will this supplement do for me?

Taken orally, chitosan may aid in weight loss when combined with dietary and lifestyle modifications and may reduce cholesterol levels.

When will it start to work?

Effects in weight loss require at least 8 weeks' continual use before effects are seen, according to research, whereas cholesterol lowering requires 4–8 weeks.

Are there any safety issues?

Chitosan is contraindicated in people with allergies to shellfish.

Chondroitin

OTHER NAMES

Chondroitin sulfate, chondroitin sulfuric acid, chondroitin 4-sulfate, chondroitin 4- and 6-sulfate

BACKGROUND AND RELEVANT PHARMACOKINETICS

Chondroitin sulfate is an amino sugar polymer, made up of glucuronic acid and galactosamine that is in the class of large polymers known as glucosaminoglycans or mucopolysaccharides. These compounds act as the flexible connecting matrix between the protein filaments in cartilage and connective tissue (Liesegang 1990). It has been found that serum levels of chondroitin sulfate are increased in patients with both rheumatoid arthritis and osteoarthritis and this may provide the basis for systemic detection of osteoarthritis (Pothacharoen et al 2006).

Chondroitin sulphate molecules represent a heterogeneous population the structure of which varies with source, manufacturing processes, presence

of contaminants, and other factors and, thus, there are a range of structures with differing potential for therapeutic impacts on a range of pathologies (Lauder 2009). There are also differences in the absorption and bioavailability of chondroitin formulations due to differences in molecular mass, charge density, and cluster of disulfated disaccharides of the parental molecules (Volpi 2003). This has led to a call for reference standards having high specificity, purity and well-known physicochemical properties useful for accurate and reproducible quantitative analyses (Volpi 2007).

Chondroitin is generally manufactured from natural sources, such as shark and bovine (usually tracheal) cartilage and may have a molecular weight that varies from 10 to 50 kD, depending on the product's source or preparation (Ross 2000). Low-molecular-weight chondroitin appears to be absorbed orally in both animals and humans (Adebowale et al 2002, Du et al 2004) and displays accumulation after multiple dosing (Adebowale et al 2002). Chondroitin is concentrated in the intestine, liver, kidneys, synovial fluid and cartilage (Conte et al 1995) and the elimination half-life is about 5–6 hours, with 40–50% being excreted in the urine (Conte et al 1991, Ronca & Conte 1993). Oral chondroitin is absorbed as several metabolites, and as the active moiety has not yet been identified it is difficult to establish bioequivalence between different products (Volpi 2003).

CHEMICAL COMPONENTS

Chondroitin sulfate is a linear polymer of two alternating sugars, alpha-D-N-acetylgalactosamine and beta-D-glucuronic acid, with the sulfate moiety being a covalent part of the molecule and not a counter ion as is the case with glucosamine sulfate (Ross 2000).

FOOD SOURCES

Chondroitin is naturally present in the gristle in meat. As a supplement it is generally produced from natural sources, such as shark or bovine (usually tracheal) cartilage or can be manufactured in the laboratory using various methods. The purity and content of products have been questioned in the USA, where it is regarded as a nutritional supplement and its quality is unregulated (Consumer-lab 2009).

MAIN ACTIONS

Chondroprotective effect

Chondroitin appears to protect cartilage by providing it with the raw material required for repair, as well as inhibiting the enzymes in synovial fluid, such as elastase and hyaluronidase, that damage joint cartilage. It improves chondrocyte nutrition by increasing hyaluronic acid production in articular cells (Raoudi et al 2005) and, hence, the fluid content of the extracellular matrix (Sasada et al 2005), which not only acts as a shock absorber but also brings nutrients into the cartilage (Krane & Goldring 1990). In vitro studies have shown that low dose combinations of glucosamine hydrochloride and chondroitin sulfate stimulate collagen and non-collagenous protein synthesis by ligament cells, tenocytes and chondrocytes (Lippiello 2007). An overall chondroprotective effect of chondroitin has also been demonstrated in different animal models. In a rabbit model oral or intramuscular chondroitin sulfate was shown to protect articular cartilage from experimental chymopapain injury (Uebelhart et al 1998a) and inhibit the destruction of the cartilage extracellular matrix (Sumino et al 2005). In a dog model, chondroitin sulfate was seen to stimulate articular cartilage and decrease or delay the alterations of degenerative joint disease (Melo et al 2008). In other animal models, co-administration with glucosamine was shown to prevent both biochemical and histological alterations and provide pain reduction (Silva et al 2009).

It has been suggested that at least some of the chondroprotective action of chondroitin sulfate is due to the provision of a source of additional inorganic sulfur which is essential for glycosaminoglycan (GAG) synthesis as well as being a structural component of glutathione and other key enzymes, coenzymes and metabolites that play fundamental roles in cellular homeostasis and control of inflammation (Nimni et al 2006). This is supported by the finding that chondroprotective action of chondroitin is potentiated by high sulfur mineral water (Caraglia et al 2005).

Anti-inflammatory

Chondroitin exerts an anti-inflammatory action with an inhibitory effect over complement (Pipitone 1991). In an in vitro study of bovine cartilage, chondroitin alone, and in combination with glucosamine, was found to regulate gene expression and synthesis of NO and PGE_2, suggesting a basis for its anti-inflammatory properties (Chan et al 2005). Chondroitin sulfate has been found to increase the levels of antioxidant enzymes and reduce inflammation and cirrhosis of liver tissue in an ovariectomised rat model, suggesting that it enhances antioxidant activity (Ha 2004). It has been suggested that chondroitin's multiple anti-inflammatory effects in chondrocytes and synoviocytes are primarily due to a common mechanism, through the inhibition of NF-ϰB nuclear translocation (Iovu et al 2008).

Viscoelastic agent

Chondroitin sulfate is a viscoelastic agent and together with similar substances such as sodium hyaluronate and hydroxypropyl methylcellulose, is used in ophthalmic surgery to protect and lubricate cells and tissues (Larson et al 1989, Liesegang 1990).

OTHER ACTIONS

There are suggestions from laboratory studies and uncontrolled human trials that chondroitin may have potential antiatherogenic properties (Morrison 1969, 1971, Morrison & Enrick 1973).

A review of the potential therapeutic applications of chondroitin sulfate/dermatan sulfate suggest that chondroitin sulfate may have potential applications in parasitic and viral infections, regenerative medicine and development of antitumour therapies (Yamada & Sugahara 2008).

CLINICAL USE

Osteoarthritis (OA): symptom control and retarding disease progression

There are now a number of reviews and meta-analyses of clinical data (Bruyere & Reginster 2007, Monfort et al 2008, Uebelhart 2008, Vangsness et al 2009), including a critical appraisal of five separate meta-analyses (Monfort et al 2008), which suggest that oral chondroitin sulfate is a valuable and safe symptomatic treatment for OA disease. Chondroitin sulfate appears to produce a slow but gradual reduction of the clinical symptoms of OA. Multiple human clinical trials lasting from a few weeks to 3 years have shown that chondroitin sulfate can significantly alleviate symptoms of pain and improve function in patients with OA of the knee, finger and hip (Bourgeois et al 1998, Bucsi & Poor 1998, Fioravanti et al 1991, Lazebnik & Drozdov 2005, Mazieres et al 2001, Morreale et al 1996, Oliviero et al 1991, Rovetta 1991, Uebelhart 2008) and that these effects last months after the cessation of treatment (Mazieres et al 2005), as well as being evident with intermittent treatment (Uebelhart et al 2004).

There is also evidence from double-blind clinical trials that chondroitin can reverse, retard or stabilise the pathology of OA (Volpi 2005), as evidenced by stabilisation of the joint space (Uebelhart et al 1998b), less progression of erosions (Rovetta et al 2002, Verbruggen et al 1998) and improved articular cartilage thickness (Pipitone et al 1992) and interarticular space, as observed by X-rays (Conrozier 1998, Michel et al 2005, Uebelhart et al 2004). A subanalysis of patients involved in the Glucosamine/Chondroitin Arthritis Intervention Trial (GAIT) study (see below and Glucosamine monograph) further suggests that chondroitin sulfate may have differential effects on OA symptoms depending on the degree of radiographic involvement, and that chondroitin may provide improvements in knee pain in patients with relatively early radiographic disease (Clegg et al 2005). In contrast to the above findings, a 24-month, double-blind, placebo-controlled study of 572 patients conducted as part of the GAIT study did not demonstrate reductions in joint space narrowing although there was a trend for improvement in knees with K/L grade 2 radiographic OA. The authors state, however, that power of this study was diminished by the limited sample size, variance of joint space width (JSW) measurement, and a smaller than expected loss in JS (Sawitzke et al 2008).

Comparisons with NSAIDs

Although chondroitin appears to be at least as effective as non-steroidal anti-inflammatory drugs (NSAIDs) in treating the symptoms of OA (Fioravanti et al 1991, Morreale et al 1996), it has a slower onset of action, taking 2–4 months to establish an effect (Leeb et al 2000, Morreale et al 1996). Chondroitin may, however, provide benefits that persist after treatment is stopped (Mazieres et al 2001, Morreale et al 1996).

Combined use of chondroitin sulfate and glucosamine sulfate

Chondroitin and glucosamine are frequently marketed together in combination products and some studies suggest that this combination is effective in treating symptoms (Das & Hammad 2000, Leffler et al 1999, McAlindon et al 2000, Nguyen et al 2001) and reducing joint space narrowing (Rai et al 2004). These findings are supported by an in vitro study on horse cartilage that found that a combination of glucosamine and chondroitin was more effective than either product alone in preventing articular cartilage glycosaminoglycan degradation (Dechant et al 2005), as well as an in vivo study on rats that found that the combined treatment prevented the development of cartilage damage and was associated with a reduction in IL-1-beta and matrix metalloprotease-9 synthesis (Chou et al 2005). The recent GAIT trial (see Glucosamine monograph) provides further evidence that glucosamine and chondroitin are more effective when given in combination than when either substance is given alone, with the combined treatment being more effective than the cyclooxygenase-2 (COX-2) inhibitor, celecoxib, for treating moderate to severe arthritis compared with chondroitin alone (Clegg et al 2006).

A small, randomised controlled trial (RCT) has suggested that the addition of high-molecular-weight hyaluronate to glucosamine and chondroitin may provide additional benefits to the use of glucosamine and chondroitin alone (Bucci et al 2005).

Topical preparations

A topical preparation containing chondroitin with glucosamine and camphor has been shown to reduce pain from osteoarthritis of the knee in one RCT (Cohen et al 2003).

OTHER USES

Heart disease

There are suggestions that chondroitin in doses of up to 10 g/d may have antiatherogenic actions, beneficial effects on serum lipid levels and may be useful for reducing the risk of myocardial infarction (Morrison 1969, 1971, Morrison & Enrick 1973, Morrison et al 1969).

Snoring

The results of a pilot crossover study of seven subjects suggest that chondroitin sulfate instilled into the nostril at bedtime may reduce snoring (Lenclud et al 1998).

Ophthalmic surgery and dry eyes

Chondroitin sulfate is used as a viscoelastic substance to protect and lubricate cells and tissues during ophthalmic surgery, as well as to preserve corneas before transplantation (Larson et al 1989, Liesegang 1990). In a double-blind, crossover study of 20 subjects, 1% chondroitin sulfate was found to be as effective as polyvinyl alcohol artificial tear formulation and 0.1% hyaluronic acid in reducing itching, burning and foreign body sensation

in people with keratoconjunctivitis sicca (Limberg et al 1987).

Psoriasis

It has been found that some patients with psoriasis experience a significant clinical and histological improvement in their psoriatic lesions after taking chondroitin to treat their OA (Verges et al 2004, 2005).

Interstitial cystitis

A multicentre, community-based clinical practice study suggests that intravesical chondroitin sulphate may have an important role in the treatment of interstitial cystitis (Nickel et al 2009).

DOSAGE RANGE

- Oral doses of chondroitin range from 800–1200 mg/day in either single or divided doses. Intramuscular, intravenous and topical forms are also available.
- A 4–5-month trial is generally used in order to determine whether it is effective for an individual patient.
- A dose-finding study in patients with knee osteoarthritis suggests that administration of 800 mg of chondroitin sulfate orally had nearly the same effects as 1200 mg/day, while the use of a sequential 3 months administration mode, twice a year was also shown to provide the same results as a continuous treatment (Uebelhart 2008).

ADVERSE REACTIONS

Chondroitin is generally deemed to be extremely safe, with the incidence of adverse reactions being comparable to placebo in studies lasting from 2 months to 6 years (Bourgeois et al 1998, Bucsi & Poor 1998, Hathcock & Shao 2007, Leeb et al 2000, McAlindon et al 2000, Uebelhart et al 1998b, Vangsness et al 2009).

Oral chondroitin may cause mild gastrointestinal disturbance. While there is a theoretical risk of anticoagulant activity, this has not been demonstrated in clinical trials (Chavez 1997) and chondroitin has been assessed as having a complete absence of adverse effects and an observed safe level (OSL) at doses of up to 1200 mg/day (Hathcock & Shao 2007).

SIGNIFICANT INTERACTIONS

Controlled studies are not available; therefore, interactions are based on evidence of activity and are largely theoretical and speculative.

Anticoagulants

Additive effect theoretically possible — observe patient.

Non-steroidal anti-inflammatory drugs

Chondroitin may enhance drug effectiveness, suggesting a beneficial interaction is possible — drug dosage may require modification.

CONTRAINDICATIONS AND PRECAUTIONS

Due to theoretical anticoagulant activity, chondroitin should be used in caution in people with clotting disorders.

Some forms of chondroitin are produced from bovine (usually tracheal) cartilage, so it is theoretically possible that it may be a source of transmission of bovine spongiform encephalopathy (mad cow disease) and other diseases. This transmission has not been demonstrated and is deemed unlikely.

PREGNANCY USE

Insufficient reliable information available to advise on safety in pregnancy.

PRACTICE POINTS/PATIENT COUNSELLING

- Chondroitin is a naturally occurring building block of joint tissue and cartilage. Supplements are made from shark cartilage or bovine tracheal cartilage.
- Chondroitin is generally considered effective in treating the pain and disability of osteoarthritis and may act to slow disease progression, although it may take some weeks before a clinical effect is evident.
- It is considered extremely safe and may reduce the need for NSAIDs, which can have serious side effects.
- There may be benefits in taking chondroitin in conjunction with glucosamine for treating arthritis.
- Patients undergoing anticoagulant therapy or with clotting disorders should have their blood clotting monitored while taking chondroitin.

PATIENTS' FAQs

What will this supplement do for me?

Multiple scientific studies have shown that chondroitin sulfate reduces symptoms of OA and may also reduce further progression of the condition. Some people find that they do not require NSAIDs as often when taking it.

When will it start to work?

Symptom relief takes 2–4 months to reach maximal effect, but protection effects on the joints occur only with long-term use of several years.

Are there any safety issues?

Generally considered a very safe treatment and far safer than pharmaceutical anti-inflammatory drugs; however, it should be used with caution by people with clotting disorders or taking anticoagulants.

Chromium

HISTORICAL NOTE In the 1950s, researchers identified the role of chromium in insulin and glucose control (Shwarz & Mertz 1959). The importance of chromium was validated in 1977 when a woman on long-term TPN, without chromium, developed symptoms of diabetes that could not be controlled by insulin. After further investigation it was noted that she was deficient in chromium and when < 50 μg was added to her TPN solution, symptoms resolved. This led to the US FDA listing chromium as an essential trace nutrient (Edmonson 2002). However, problems in elucidating the effects of chromium supplementation persist, due to a lack of practical methods for diagnosing deficiency (Mertz 1998). In recent years researchers have focused on investigating the effects of chromium supplementation on insulin sensitivity and the management and prevention of type 2 diabetes and cardiovascular disease (Hummel et al 2007).

BACKGROUND AND RELEVANT PHARMACOKINETICS

Absorption of chromium occurs by passive diffusion and is inversely related to dietary intake (e.g. from a dose of 10 μg, 2% is absorbed; from a dose of 40 μg, 0.5% is absorbed) (Anderson & Kozlovsky 1985). Absorption may be inhibited by zinc (Hahn & Evans 1975) and phytates, and enhanced by oxalate (Bryson & Goodall 1983) and ascorbic acid (Offenbacher 1994). Unfortunately much of the current information is based on chromium chloride supplements so effects may vary for different forms (Arthur 2008). For instance the complexation of picolinic acid with chromium increases its bioavailability (Edmonson 2002, Press et al 1990). Nicotinic acid is also a metabolite of tryptophan improving the absorption of chromium; however, the picolinate form is the one surrounded by the most controversy.

Chromium is transported around the systemic circulation primarily by transferrin (Campbell et al 1997) potentially competing with iron, and accumulates in kidney, muscle and liver (Hepburn & Vincent 2003). It is excreted primarily in urine, but small amounts are lost in hair, perspiration and faeces.

CHEMICAL COMPONENTS

Chromium exists mostly in two valence states in nature: hexavalent chromium (chromium (VI)) and trivalent chromium (chromium (III)). The hexavalent form is used in industry and is associated with toxicity. Trivalent chromium is an essential trace element in the human body and approved as a supplement.

Supplemental forms used in trials include organic chromium complexes such as chromium picolinate and chromium nicotinate/polynicotinate (niacin-bound chromium NBC) and inorganic salts such as chromium chloride. While a number of different commercial trivalent chromium supplements exist the best evidence is

for the picolinate and polynicotinate forms (Preuss et al 2008).

FOOD SOURCES

Brewer's yeast, wholegrain breads and cereals, cheese, eggs, bananas, spinach, mushrooms, broccoli, organ meats and processed meat products.

DEFICIENCY SIGNS AND SYMPTOMS

Primary deficiency

Symptoms of weight loss, glucose intolerance and neuropathy have been noted in patients on TPN deficient in chromium (Verhage et al 1996). Deficiency may also be a precursor to the development of insulin resistance, and thus associated with hyperglycaemia, hypoglycaemia and obesity. Up to 90% of USA diets have been found to be below the minimum suggested safe and adequate daily intake for chromium of 50 μg/day (Anderson & Kozlovsky 1985).

Secondary deficiency

Factors that may exacerbate deficiency, generally by increasing requirements for or urinary excretion of chromium, include pregnancy, excessive exercise, infection, physical trauma and stress (Anderson 1986). Diets high in simple sugars have been found to increase urinary chromium excretion up to 30-fold, thereby increasing the risk of deficiency (Kozlovsky et al 1986). Corticosteroids also increase urinary losses of chromium (Kim et al 2002).

MAIN ACTIONS

Important cofactor

Chromium is an essential trace mineral required for carbohydrate, lipid, protein and corticosteroid metabolism (Kim et al 2002). It is a key constituent of glucose tolerance factor, together with nicotinic acid and the amino acids cysteine, glycine and glutamic acid.

Clinical note — Problems testing for chromium deficiency

Currently, testing for chromium deficiency involves serum testing. This is problematic as it is still uncertain whether serum levels correlate with tissue levels and, therefore, are truly representative of nutritional status. Studies have shown that subjects with widely varying plasma chromium levels respond favourably to chromium supplementation, suggesting that this marker is misleading (Bahijri 2000). As a consequence, serum tests should not be solely relied upon, leaving the diagnosis of marginal deficiency up to a practitioner's clinical suspicion. Other tests have been proposed such as toenail chromium concentration (Guallar et al 2005) and urinary chromium response to glucose load (Bahijri & Mufti 2002), as conditions that increase circulating glucose and insulin concentrations increase urinary chromium output (Vincent 2004); however, further research is required to confirm the validity of these tests.

Improves blood sugar control

Trivalent chromium is an essential trace element for normal carbohydrate metabolism and insulin sensitivity (Wilson & Gondy 1995), aiding the transport of glucose into cells. Rather than increasing insulin secretion, chromium appears to improve glycaemic control by enhancing the action of insulin; improving the ability of insulin to bind to cells; enhancing beta-cell sensitivity; increasing the number of insulin receptors; and activating insulin receptor kinase, thus increasing insulin sensitivity (Anderson 1997, Edmonson 2002). Additionally, in vitro studies have shown that chromium inhibits the secretion of TNF-alpha, a cytokine known to reduce the sensitivity and action of insulin, and that this appears to be mediated by its antioxidant effects (Jain & Kannan 2001). In vitro studies also show that chromium chloride prevents the increase in protein glycosylation and oxidative stress caused by high levels of glucose in erythrocytes (Jain et al 2006).

Lipid-lowering activity

Although the mechanism of action is yet to be fully explained, studies show that chromium supplementation may decrease triglyceride levels, total and LDL-cholesterol and modestly increase HDL-cholesterol (Bahijri 2000, Lee & Reasner 1994, Press et al 1990, Preuss et al 2000).

Antihypertensive

In rats with sugar-induced blood pressure elevation, niacin-bound chromium lowers systolic blood pressure, at least in part due to its effects on the renin-angiotensin system (Perricone et al 2008).

Antidepressant/neurotransmitter effects

Depression is often associated with insulin resistance, owing to cortisol overproduction (McCarty 1994). The reputed antidepressant effects of chromium may be explained by improvements in insulin sensitivity (Davidson et al 2003) and related increases in tryptophan availability and/or noradrenaline release (McLeod & Golden 2000). Chromium has also been shown to lower the cortisol response to challenge with 5-hydroxy-L-tryptophan (5-HTP) and decrease the sensitivity of 5-HT_{2A} receptors (Attenburrow et al 2002). Influences on serotonergic pathways have also been reported in animal studies using chromium picolinate (Khanam & Pillai 2006) and potassium channels are thought to be involved.

OTHER ACTIONS

Immunomodulation

A review detailing the effects of chromium on the immune system found that chromium has both immunostimulatory and immunosuppressive effects, as shown by its effects on T and B lymphocytes, macrophages and cytokine production (Shrivastava et al 2002).

Bone density protection

It has been suggested that modulation of insulin by chromium may have positive effects on bone density, reducing bone resorption and promoting collagen production by osteoblasts (McCarty

1995). One placebo-controlled study using chromium picolinate (equivalent to 200 μg chromium/day for 60 days) has shown a 47% reduction in the urinary hydroxyproline:creatinine ratio, indicating a decrease in calcium excretion and a potential role in the prevention of osteoporosis (Evans et al 1995).

Antioxidant

A placebo-controlled trial using 1000 μg/day of chromium (as chromium yeast) for 6 months found chromium supplementation to be an effective treatment in reducing oxidative stress in type 2 diabetes patients with severe hyperglycaemia (HbA_{1c} > 8.5%); however, it may act as a pro-oxidant in euglycaemic people (Cheng et al 2004).

Anti-inflammatory

In diabetic rats, chromium supplementation can lower the risk of vascular inflammation. Chromium niacinate appears to be more effective than the picolinate form in lowering blood levels of pro-inflammatory cytokines (TNF-alpha, IL-6) and C-reactive protein, and in reducing oxidative stress and lipid levels (Jain et al 2007).

Increases dehydroepiandrosterone

In a placebo-controlled trial, chromium picolinate (equivalent to 200 μg chromium/day for 60 days) increased dehydroepiandrosterone by 24% in postmenopausal women (Evans et al 1995).

CLINICAL USE

Supplemental forms used in trials include organic chromium complexes, such as chromium picolinate and chromium nicotinate, and inorganic salts such as chromium chloride. Considering chromium is known to improve insulin sensitivity, a theoretical basis exists for its use in conditions associated with insulin resistance such as type 2 diabetes mellitus, gestational diabetes, hypoglycaemia, polycystic ovarian syndrome, obesity and syndrome X. For many of these indications, controlled studies are not yet available. However, there has been investigation into its use in diabetes, hypoglycaemia, hyperlipidaemia and obesity.

Deficiency states: prevention and treatment

Although chromium deficiency is uncommon (Vincent 2004) and mostly described in relation to the use of TPN without chromium, subclinical deficiency states also exist and should respond to supplementation (Verhage et al 1996). Chromium supplementation is also used in cases at risk of deficiency, such as long-term corticosteroid use (Kim et al 2002) or people with a high sugar intake (Kozlovsky et al 1986).

Diabetes

Subjects with diabetes appear to have lower tissue levels of chromium and a correlation exists between low circulating levels of chromium and the incidence of type 2 diabetes (Hummel et al 2007). While still controversial, a number of studies and reviews suggest that chromium supplementation may facilitate insulin signalling and therefore improve systemic insulin sensitivity. A review of 15 clinical studies involving a total of 1690 subjects (1505 of which received chromium picolinate) reported significant improvement in at least one outcome of glycaemic control. The pooled data showed substantial reductions in both hyperglycaemia and hyperinsulinaemia (Broadhurst & Domenico 2006).

A systematic review (Balk et al 2007) identified 41 trials meeting its inclusion criteria (English language; RCT; ≥ 3 weeks duration, ≥ 10 participants). The evidence was limited by 'poor study quality, heterogeneity in methodology and results, and a lack of consensus on assessment of chromium status'; and larger effects were generally reported in the poorer-quality studies. Differences in chromium formulations and dose may have in part accounted for the heterogeneous results. While studies using brewer's yeast demonstrated some increase in net effect, trials directly comparing formulations have not established a difference between the forms. A dose–effect response has also been reported with effects seen at doses of at least 200 μg chromium picolinate/day. Comparisons of 200 μg versus 1000 μg have shown greater effect at the highest dose but this is largely driven by the Anderson (1997) study results, see below. The review authors concluded that positive results with chromium supplementation are more likely in persons with known glycaemic aberrations rather than in healthy subjects (Balk et al 2007). Although it is uncertain why this is the case, the varying responses of glucose and lipid regulation may be partly explained by variations in pretreatment chromium and iron status, and phenotypic characteristics of the studied individuals. Furthermore, baseline insulin sensitivity may be particularly important in predicting a clinical response to chromium (Wang et al 2007).

Type 2 diabetes mellitus (non-insulin-dependent)

Results have shown that chromium supplementation appears to be more effective in patients with type 2 diabetes than in those with type 1 (Ravina & Slezack 1993).

Patients with early-stage type 2 diabetes of less than 2 years' duration were found to have lower chromium plasma levels (33%) and increased chromium excretion (100%) compared with healthy controls. Over a period of time this may contribute to the development of the insulin resistance seen in these patients (Morris et al 1999). Results of some trials suggest that improvements are dose-related but may also be affected by treatment duration, initial chromium status (Ghosh et al 2002, Amato et al 2000) and age. A controlled trial of elderly patients with diabetes (average age 73 years) reported that supplementation with chromium (200 μg twice daily) for 3 weeks improved fasting blood glucose, HbA_{1c}, and total cholesterol levels (Rabinovitz et al 2004), suggesting lower doses may be effective in older patients.

The most promising RCT to date tested chromium picolinate at doses of 200 and 1000 μg/day in subjects with type 2 diabetes who were instructed to maintain their current medications, diet and lifestyle habits. HbA_{1c} values (a marker of long-term

glycaemic control) improved significantly in the higher treatment group after 2 months and in both groups after 4 months' treatment. Fasting glucose was lower in the 1000 μg group after 2 and 4 months (4-month values: 7.1 ± 0.2 mmol/L vs placebo 8.8 ± 0.3 mmol/L). Two-hour glucose values were also significantly lower in the 1000 μg group after both 2 and 4 months (4-month values: 10.5 ± 0.2 mmol/L vs placebo 12.3 ± 0.4 mmol/L). Fasting and 2-hour insulin values decreased significantly in both groups receiving supplemental chromium after 2 and 4 months. Plasma total cholesterol also decreased in the subjects receiving 1000 μg chromium after 4 months (Anderson et al 1997). In people with type 2 diabetes taking sulfonylurea agents, chromium picolinate supplementation (equivalent to 1000 μg chromium) for 6 months significantly improved insulin sensitivity and glucose control; and attenuated bodyweight gain and visceral fat accumulation compared with placebo (Martin et al 2006).

Studies using chromium nicotinic acid have proven more promising with higher doses of nicotinic acid (100 mg/day) (Urberg & Zemel 1987) than those with low-dose nicotinic acid (1.8 mg) (Thomas & Gropper 1996), demonstrating a synergistic effect with chromium (200 μg/day).

Type 1 diabetes mellitus (insulin-dependent)

As chromium appears to improve insulin sensitivity rather than secretion its use in type 1 diabetes is probably limited (Edmondson 2002). One study did show reduced requirements for medication in 33.6% of patients with type 1 diabetes taking 200 μg chromium/day (Ravina & Slezack 1993), and another showed a 30% reduction in insulin requirements in 71% of subjects at the same dose (Ravina et al 1995), but as yet it is unclear which patients might respond to treatment.

Gestational diabetes

Pregnancy can be described as an increased insulin resistance state, which may result in gestational diabetes if the pancreas is unable to increase insulin levels to maintain blood glucose balance (Jovanovic & Peterson 1996). As such, the beneficial effect of chromium on insulin sensitivity provides a theoretical basis for its use in this condition. A small placebo-controlled trial using 4 or 8 μg/kg of chromium daily in gestational diabetes found a significant dose-dependent improvement in fasting insulin, 1-hour insulin and glucose, and postprandial glucose levels after 8 weeks' supplementation (Jovanovic et al 1999).

Corticosteroid-induced diabetes mellitus

Human trials have shown that corticosteroid use significantly increases urinary chromium excretion. Supplementation with chromium picolinate (equivalent to 600 μg chromium/day) in patients experiencing steroid-induced diabetes resulted in decreased fasting blood glucose values (from > 13.9 mmol/L to < 8.3 mmol/L). Furthermore, hypoglycaemic medications were also reduced by 50% in all patients within 1 week (Ravina et al 1999).

Prevention of long-term diabetic complications

Both QTc interval prolongation and chronic hyperinsulinaemia have been associated with atherosclerosis progression and increased cardiovascular morbidity in patients with type 2 diabetes. In a crossover trial of 60 subjects, chromium picolinate (1000 μg/day) for 3 months was shown to reduce both QTc interval duration and plasma insulin levels (Vrtovec et al 2005), probably by reducing the adrenergic activation of the sympathetic nervous system due to hyperinsulinaemia. Benefits were most significant in obese patients with higher peripheral insulin resistance (Vrtovec et al 2005).

Animal studies have found that chromium supplementation in mice with type 2 diabetes reduces the symptoms of hyperglycaemia and improves the renal function by recovering renal chromium concentration (Mita et al 2005, Mozaffari et al 2005) which may hold promise for human trials investigating the potential role of chromium in reducing the incidence of diabetic nephropathy.

Hypoglycaemia

Eight patients with reactive hypoglycaemia were given chromium chloride (equivalent to 200 μg chromium) for 3 months in a double-blind crossover study. Chromium supplementation significantly improved blood sugar regulation, insulin binding to receptors and red blood cells, and alleviated symptoms of hypoglycaemia (Anderson et al 1987).

A double-blind crossover study using chromium chloride (equivalent to 200 μg/day elemental chromium) for 8 weeks found a significant improvement in glycaemic control in subgroups where the 2-hour glucose level was > 10% above or below the fasting level (Bahijri 2000). In these subgroups chromium supplementation resulted in a 2-hour mean not significantly different to the fasting mean, suggesting an amphoteric effect on glycaemic control.

Hyperlipidaemia

It has been suggested that some of the potential benefits of HRT on total and LDL-cholesterol and total:HDL-cholesterol ratio may be related to its ability to improve chromium status (Bureau et al 2002, Roussel et al 2002) and trials yielding both positive and negative results for supplemental chromium in hyperlipidaemia have been reported. In a recent systematic review of 41 trials, eighteen studies, with a total 655 participants, reported lipid data for participants with either type 2 diabetes or glucose intolerance (Balk 2007). Overall, chromium supplementation was not found to exert a statistically significant effect on lipid levels in either group, although brewer's yeast supplementation did result in a statistically significant increase in HDL cholesterol (+0.21 mmol/L) compared to chromium picolinate.

Currently, it is unclear what circumstances or conditions and type of subjects are most likely to respond to treatment, so in practice a treatment trial period is often used to establish usefulness in individual patients.

A placebo-controlled trial using chromium tripicolinate (equivalent to 200 μg chromium/day) for

42 days found a reduction in total cholesterol, LDL and apolipoprotein B (the major protein of the LDL fraction) with a slight increase in HDL and a significant increase in apolipoprotein A1 (the major protein of the HDL fraction) (Press et al 1990). Another RCT of 40 hypercholesterolaemic subjects found that chromium polynicotinate (equivalent to 200 μg elemental chromium) twice daily for 2 months decreased total (10%) cholesterol and LDL-cholesterol (14%) (Preuss et al 2000).

A prospective, double-blind, placebo-controlled crossover study was performed with 30 subjects with type 2 diabetes. Triglyceride levels were significantly reduced (17.4%) and HDL levels increased during the 2 months' chromium picolinate supplementation (Lee & Reasner 1994). This is further supported by other trials (Bahijri 2000).

Another double-blind, placebo-controlled randomised study of young, non-obese adults taking chromium nicotinate (equivalent to 220 μg elemental chromium) for 90 days found no statistically significant differences in lipid levels (total cholesterol, HDL-cholesterol, LDL-cholesterol, triglycerides) at this dose (Wilson & Gondy 1995). Similar results were found in older, non-obese subjects taking 1000 μg chromium picolinate for 8 weeks (Amato et al 2000) suggesting that subjects without identified pre-existing hypercholesterolaemia or other conditions predisposing them to hypercholesterolaemia may not respond to treatment. However, a prospective, double-blind, placebo-controlled crossover study of mostly hispanic patients with type 2 diabetes also elicited disappointing results, finding that only triglyceride levels were significantly reduced (17.4%) (Lee & Reasner 1994).

Obesity

As chromium has a role in maintaining carbohydrate and lipid metabolism, and potentiating insulin action, it has been suggested that chromium supplementation may have effects on body composition, including reducing fat mass and increasing lean body mass (Vincent 2003).

A meta-analysis of RCTs concluded that chromium picolinate elicited a relatively small effect compared with placebo for reducing body weight (Pittler et al 2003). One study, however, did show promising results using 200 μg niacin-bound chromium three times daily (total 600 μg/day) with moderate exercise. At these high doses, while overall reduction in body weight was similar for both the chromium and the placebo groups, total fat loss was more significant in the chromium group, suggesting a muscle sparing effect (Crawford et al 1999). A more recent RCT using chromium picolinate (equivalent to 200 μg chromium/day) for 12 weeks was unable to reproduce these effects (Lukaski et al 2007). Differences in form and dose may help to explain these contradictory results.

Atypical depression

In animal studies of chromium picolinate (8 μg/mL in drinking water) antidepressant effects have been reported (Khanam and Pillai 2006). In humans a small placebo-controlled double-blind study of chromium picolinate (600 μg/day) for 8 weeks was conducted in 15 patients with DSM-IV major depressive disorder, atypical type. Seven (70%) of 10 patients receiving chromium picolinate and none of the placebo group responded to treatment. Six subjects in the chromium group also experienced remission compared with none in the placebo group. However, a significant difference was not detected in the Hamilton Depression Scale at the end of treatment (Chromium, atypical depression 2003, Davidson et al 2003). As depression is a common comorbidity in diabetes, further investigation is warranted.

OTHER USES

While controlled trials are yet to be conducted or are inconclusive in some cases, chromium is also used in the following conditions, based on a theoretical understanding of its pharmacological actions.

Exercise aid

Chromium has demonstrated an ability to enhance insulin-mediated glucose uptake in cultured cells, however supplementation in humans does not appear to exert such benefits. In a small RCT, 16 overweight men were randomised to receive chromium picolinate (equivalent to 600 μg chromium/day) for 4 weeks before being subjected to supramaximal cycling exercises to deplete glycogen stores, followed by high glycaemic index carbohydrate feedings. At this dose, supplementation did not appear to improve glycogen synthesis during the recovery phase (Volek et al 2006).

In addition studies in female athletes have shown no effect on body composition or muscle strength following supplementation with 500 μg chromium picolinate daily during 6 weeks of resistance training (Livolsi et al 2001). In a clinical trial of older women a high-dose chromium picolinate supplement did not affect body composition, skeletal muscle size or maximal strength above that of resistance training alone (Campbell et al 2002). A meta-analysis of trials of dietary supplements for enhancing lean muscle mass and strength during resistance training did not support the use of chromium for this purpose (Nissen & Sharp 2002).

Polycystic ovarian syndrome

The relationship between PCOS and insulin resistance provides a theoretical basis for the use of chromium in this condition. A small study has found that chromium picolinate (200 μg/day) appears to improve glucose tolerance but not ovulatory frequency in women with polycystic ovary syndrome (Lucidi et al 2005). Larger studies are required to investigate the potential benefits of chromium supplementation in this population.

Syndrome X

Syndrome X highlights the link between insulin resistance and lipid profiles. As a number of studies have proved promising in regard to both these factors, a theoretical basis exists for the use of chromium in this condition. Furthermore, the

presence or absence of this syndrome may explain why studies have shown varying responses to treatment with chromium in the past and may provide direction for more consistent trial results in future studies.

Prevention of myocardial infarction

In a population-based case–control study, toenail chromium concentration was inversely associated with the risk of a first myocardial infarction in men. Men with the highest levels of chromium were 35% less likely to have a heart attack than those with the lowest levels (Guallar et al 2005). Future studies are required to determine whether chromium supplementation may be beneficial for the prevention of cardiovascular incidents.

Osteoporosis

Effects on bone resorption, calcium excretion and collagen production suggest a role in the prevention of osteoporosis (Evans et al 1995, McCarty 1995); however, there are no controlled trials to determine clinical effectiveness.

DOSAGE RANGE

The ESADDI is 50–200 μg/day. The most common doses studied include 200, 400, 600 and 1000 μg daily. Doses in the upper range appear to produce more convincing trial results.

Australian adequate intake

- Women: 25 μg/day.
- Men: 35 μg/day.

Chromium picolinate is the best absorbed form, although chromium nicotinate may have a better safety profile and the synergistic effects with nicotinic acid may have further benefits in some conditions, especially with regard to lipid profiles.

ADVERSE REACTIONS

It is important to differentiate between hexavalent chromium (Cr IV) and trivalent chromium (Cr III) when assessing toxicity. Cr IV is used in industry and is highly toxic, whereas Cr III is approved for use as a supplement and does not attract the same concerns. Recent in vitro studies suggest a possibility that Cr III may oxidise to Cr V, a potential carcinogen (Shrivastava et al 2005); however, this requires confirmation from in vivo studies.

Irritability and insomnia have been reported with chromium yeast supplementation (Schrauzer et al 1992).

A follow-up survey of the Anderson trial at 1 year found no side effects for doses up to 1000 μg/day of chromium picolinate (Cheng et al 1999).

Of five anecdotal adverse reports attributed to chromium picolinate and reviewed by Lamson and Plaza (2002), only one reporting transient and vague symptoms was considered to be a possible adverse reaction (Huszonek 1993). Three could not be validated by the reviewers due to concurrent medications (Cerulli et al 1998, Martin & Fuller 1998, Wasser et al 1997), and another involved the inappropriate use of potassium dichromate, a strong oxidising agent known to elicit reactions in a majority of people (Fowler 2000). A case report exists of toxic hepatitis and greatly elevated hepatic chromium levels (>10-fold normal) after 5 months' ingestion of chromium polynicotinate in combination with vegetable extracts (Lanca et al 2002). Whether chromium supplementation was responsible for this incident is currently unclear.

Clinical note — Does chromium picolinate cause cancer?

There has been some concern in the past arising from in vitro studies suggesting chromium picolinate exerts clastogenic effects in hamster ovary cells (Stearns et al 1995a, 2002) and possible DNA damage (Levina & Lay 2008, Speetjens et al 1999). This has been refuted by a number of authors, suggesting the doses tested were several thousand times higher than equivalent human doses (McCarty 1997, Salmon 1996) and that chromium is relatively short lived so that the accumulated doses suggested by researchers (Stearns et al 1995a) were not feasible (Hepburn & Vincent 2003). Furthermore in vivo evidence from animals and humans suggests that under normal circumstances trivalent chromium (Cr III) has only restricted access to cells, which would limit or prevent genotoxic effects. Therefore supplementation at moderate doses is not currently considered to be detrimental (Eastmond et al 2008). It should also be noted that picolinic acid appears to be the source of the concern and other forms of chromium have not been implicated (Bagchi et al 2002, Stearns et al 1995b).

No adverse effects on iron status

As chromium competes with iron for binding to transferrin it has been suggested that high-dose chromium supplementation may adversely affect iron status. While some studies support this (Ani & Moshtaghie 1992), others show that serum iron concentrations and serum ferritin concentrations are unaffected by chromium picolinate supplementation (Campbell et al 1997, Lukaski et al 2007). It would appear that iron does not use all available transferrin and therefore this situation is unlikely under normal conditions.

SIGNIFICANT INTERACTIONS

Corticosteroids

Corticosteroids increase urinary losses of chromium, and chromium supplementation has been shown to aid in recovery from steroid-induced diabetes mellitus. Therefore a beneficial interaction may be possible (Kim et al 2002).

Hypoglycaemic medicines

Chromium may reduce requirements for hypoglycaemic agents (Ravina & Slezack 1993, Ravina et al 1995). While a beneficial interaction is possible, this combination should be used with caution and drug

requirements monitored and adjusted if necessary by a healthcare professional.

Hormone replacement therapy

Women receiving HRT appear to have improved chromium status (Bureau et al 2002, Roussel et al 2002) and the addition of trivalent chromium to 17-beta-oestradiol may enhance IL-6 inhibition in experimental models (Jain et al 2004). Whether this alters chromium requirements is unknown.

Lipid-lowering medicines

Additive effects are theoretically possible as some clinical studies have indicated lipid-lowering effects. Observe patients taking this combination and monitor drug requirements.

CONTRAINDICATIONS AND PRECAUTIONS

Hypersensitivity to chromium.

PREGNANCY USE

Oral ingestion of doses typically found in the diet are likely to be safe. Taken under professional supervision, supplements are also likely to be safe and may be beneficial in the prevention and treatment of gestational diabetes (Jovanovic & Peterson 1996, Jovanovic et al 1999).

PRACTICE POINTS/PATIENT COUNSELLING

- Chromium is an essential trace mineral required for carbohydrate, lipid, protein and corticosteroid metabolism.
- Dietary intakes are generally below the minimum suggested safe and adequate levels, and factors such as high-sugar diets, corticosteroid use, excessive exercise, infection, physical trauma and psychological stress further increase the risk of deficiency.
- Chromium supplements are used in the treatment of type 2 diabetes, hypoglycaemia, gestational diabetes and hyperlipidaemia. However, inconsistent results have been obtained from clinical studies.
- It is also used in the treatment of obesity, atypical depression, syndrome X, PCOS and osteoporosis, and in resistance training.
- Supplemental forms used in trials include organic chromium complexes, such as chromium picolinate and chromium nicotinate, and inorganic salts such as chromium chloride.

PATIENTS' FAQs

What will this supplement do for me?

Chromium is essential for health and wellbeing. It may also have beneficial effects in type 2 diabetes, gestational diabetes, hypoglycaemia and elevated cholesterol and triglyceride levels in some people, although scientific research has produced mixed results.

When will it start to work?

Effects in diabetes and elevated cholesterol or triglyceride levels require 8–12 weeks to establish.

Are there any safety issues?

Used under professional supervision, chromium supplements are considered safe.

Cinnamon

HISTORICAL NOTE Cinnamon has been used since ancient times for a variety of uses and was considered a precious commodity. In ancient Egypt, it was used as a flavouring for beverages, in combination with other spices for embalming, and as a medicinal agent. Ancient Chinese herbals mention it as a medicinal treatment as early as 2700 BC (Castleman 1991) and it has long been used as a remedy for diabetes in China, Korea, Russia and India. In medieval Europe, cinnamon was a common ingredient in cooking, often used together with ginger. Due to the high demand for cinnamon, discovering lands where it grew was a primary motive for a number of explorers' enterprises in the 15th and 16th centuries. Today, two main types of cinnamon are cultivated, *Cinnamomum verum*, also known as Ceylon cinnamon, and *Cinnamomum cassia*, also known as Chinese cinnamon.

OTHER NAMES

Cinnamomum verum: cannelle de ceylan, Ceylon celonzimi cinnamon, Ceylon cinnamon, cinnamon bark, cortex cinnamomi ceylanici, dalchini, ecorce de cannelier de Ceylan, echter, gujerati-dalchini, kannel, kuei-pi, kurundu, kulit kayumanis, ob choei, tamalpatra, wild cinnamon

Cinnamomum cassia Blume: cassia, Chinese cinnamon, dalchini, guipi, kannan keihi, keishi, lavanga-pattai, lurundu, macrophyllos cassia bark tree, rou gui, Saigon cinnamon, saleekha, taj, toko keihi, Viet Nam cinnamon

BOTANICAL NAME/FAMILY

Cinnamomum verum J.S. Presl (also known as *C. zeylanicum* Nees) and *C. cassia* Blume (family Lauraceae)

PLANT PARTS USED

Dried inner bark of the shoots grown on cut stock of *C. verum* or of the trunk bark, freed from the underlying parenchyma; outer cork of *C. cassia* Blume.

CHEMICAL COMPONENTS

Both forms of cinnamon contain an essential oil that consists primarily of cinnamaldehyde (up to 80% in *C. verum* and 90% in *C. cassia*) and differ primarily in their eugenol and coumarin content. The volatile oil from *C. verum* contains 10% eugenol whereas the oil from *C. cassia* contains only trace amounts. Also, *C. cassia* contains coumarin, which is not found substantially in *C. verum*. The bark of *C. verum* contains caryophyllene, cinnamyl acetate and linalool whereas the bark of *C. cassia* contains catechin and 1,8 cineole.

MAIN ACTIONS

The cinnamaldehyde constituent in cinnamon is attributed with producing most of the herb's biological effects. This component is found in large amounts in both forms of cinnamon. More recently, several other constituents have also been tested in isolation and found to exert significant pharmacological effects.

Antibacterial and fungicidal effects

Several in vitro studies have identified broad-spectrum antibacterial and fungicidal effects for both forms of cinnamon. This has been chiefly attributed to cinnamaldehyde although other constituents such as eugenol, carophyllene and 1,8 cineole also exhibit antimicrobial properties.

C. verum demonstrated activity against a wide range of bacteria and fungi including *Bacillus subtilis*, *Escherichia coli*, *Saccharomyces cerevisiae*, *Candida albicans*, *Listeria monocytogenes* and *Salmonella enterica* (De et al 1999, Friedman et al 2002, Matan et al 2006, Simic et al 2004, Tampieri et al 2005).

C. cassia extracts significantly inhibited *Helicobacter pylori* in vitro and produced zones of inhibition greater than or equal to commonly used antibiotics (Tabak et al 1999). The essential oil of *C. cassia* also exhibited strong antifungal properties in vitro (Giordani et al 2006). When tested

with amphotericin, a reduced amount of drug was required for adequate antifungal effects.

Antibacterial activity for the oil has also been demonstrated against antibiotic-resistant *E. coli* and *Staphylococcus aureus* (Friedman et al 2004).

Fungi in bakery products

Antifungal activity against the more common fungi causing spoilage of bakery products, *Eurotium amstelodami*, *E. herbariorum*, *E. repens*, *E. rubrum*, *Aspergillus flavus*, *A. niger* and *Penicillium corylophilum*, was demonstrated for cinnamon oil in vitro (Guynot et al 2003).

Respiratory tract pathogens

An in vitro study of the antibacterial activity of essential oils and their major components against the major bacteria causing respiratory tract infection indicated that cinnamon bark oil was effective against *Haemophilus influenzae*, *Streptococcus pneumoniae* and *S. pyogenes* (Inouye et al 2001).

Oral pathogens

According to in vitro research, cinnamon bark oil is an effective inhibitor of bacteria causing dental caries and periodontal disease (Saeki et al 1989).

Carminative

The essential oil exhibits carminative activity and decreases smooth muscle contractions in guinea-pig trachea and ileum, and in dog ileum, colon and stomach (WHO 2004). The oil has also demonstrated antifoaming activity in a foam generator model for flatulence (ESCOP 2003). The active antispasmodic constituent is considered to be cinnamaldehyde.

Hypoglycaemic activity

Using an experimental model of diabetes, Kim et al observed that cinnamon extract significantly reduced blood glucose levels after two weeks of treatment (Kim et al 2006). A significant decrease in total cholesterol levels and triglycerides and increase in HDL-cholesterol was also found for cinnamon-treated mice.

Enhanced insulin sensitivity

Water soluble compounds extracted from *C. cassia* potentiate insulin activity, as measured by glucose oxidation in the rat epididymal fat-cell assay. The most active compound, methylhydroxy chalcone polymer (MHCP), increased glucose metabolism approximately 20-fold and was an effective mimetic of insulin according to an in vitro study. When combined with insulin, the responses were greater than additive, indicating synergism between the two compounds (Jarvill-Taylor et al 2001). According to Anderson et al (2004), MHCP is actually a water-soluble polyphenolic type-A polymer that increases insulin sensitivity by activating the key enzymes that stimulate insulin receptors, while inhibiting the enzymes that deactivate them. More specifically, extracts of cinnamon activate insulin receptor kinase and inhibit dephosphorylation of the insulin receptor, leading to maximal phosphorylation of the insulin receptor.

The United States Agricultural Research Service has filed a patent application on the active substances.

Antitumour activity

Cinnamon extract displayed anti-tumour activity when administered orally or by intra-tumour injection (Kwon et al 2009). It strongly inhibited the expression of pro-angiogenic factors and master regulators of tumour progression. The effects were seen not only in melanoma cell lines but also in an experimental melanoma model. In addition, cinnamon extract treatment increased the anti-tumour activities of $CD8^+$ T cells by increasing the levels of cytolytic molecules and their cytotoxic activity. These findings are important as tumour cells recruit new blood vessels by excessive production of pro-angiogenic factors that play a pivotal role in tumour progression and tumour survival.

Anti-inflammatory and antioxidant

Potent antioxidant and anti-inflammatory activity for cinnamon bark oil has been demonstrated in vitro and for the dry ethanolic extract in vivo (ESCOP 2003, Jarvill-Taylor et al 2001, Lee et al 2003, Mathew & Abraham 2006).

OTHER ACTIONS

A dose-dependent antinociceptive activity has been demonstrated for *Cinnamomum zeylanicum* when administered orally to mice in the hot plate and acetic acid writhing induced tests (Atta and Alkofahi 1998).

C. cassia also possesses antipyretic activity (Kurokawa et al 1998) and reduced the occurrence of ulcers in rats in a dose-dependent manner in a study that administered an aqueous extract (Tanaka et al 1989).

Besides antispasmodic and broad-spectrum antibacterial and fungicidal activities, cinnamaldehyde exhibits antitumour effects (Kwon et al 1998) and cytotoxicity (Moon & Pack 1983).

CLINICAL USE

Cinnamon has been used as a medicinal agent in several traditional healing systems. In the last two decades, scientific investigation has been undertaken to investigate its clinical effects. Evidence to support its clinical use is still mainly derived from in vitro and in vivo research, and from traditional usage, however an increasing number of clinical trials are now being published.

Dyspepsia and related symptoms

Cinnamon bark oil and crushed cinnamon bark is used in the treatment of dyspeptic conditions, such as mild spastic conditions of the gastrointestinal tract, fullness and flatulence, loss of appetite and diarrhoea. Although controlled studies are unavailable, evidence of antispasmodic and antifoaming activity in animal models and a long tradition of use provide some support for its use in these indications.

Cinnamon bark and Chinese cinnamon are approved by the German Commission E for the

treatment of loss of appetite and dyspeptic complaints such as mild gastrointestinal spasms, bloating and flatulence (Blumenthal et al 1998).

Helicobacter pylori infection

According to a placebo-controlled study of 15 volunteers with documented *H. pylori* infection, an ethanolic extract of cinnamon was ineffective at eradicating the infection when used at a dose of 40 mg twice daily for 4 weeks (Nir et al 2000). Considering this is an extremely low dose, further investigation is required using therapeutic doses in order to adequately test its effectiveness for this indication.

Diabetes

Cinnamon has a long history of use for diabetes in China, India, Korea and Russia. To date, four clinical studies have investigated its effects in this population, producing mixed results.

In 2003, a randomised, placebo-controlled study of type 2 diabetes demonstrated that cinnamon exerts clinically significant glucose- and lipid-lowering effects (Khan et al 2003). The study involved 60 people who were divided into six groups. Groups 1–3 consumed 1, 3 or 6 g of cinnamon daily whereas groups 4–6 were given the equivalent number of placebo capsules and acted as controls. The volunteers were not using insulin therapy and had a fasting blood glucose reading between 140 and 400 mg/dL. After 40 days of treatment, all three doses of cinnamon reduced mean fasting serum glucose by 18 to 29%, triglycerides by 23 to 30%, LDL-cholesterol by 7 to 27%, and total cholesterol by 12 to 26%. No significant changes were observed in the placebo groups. The effect on glucose and lipid levels was sustained 20 days after treatment had ceased, suggesting that cinnamon would not need to be consumed every day. The cinnamon used was *C. cassia*, which was finely ground and put into capsules.

More recently, a 6-week placebo-controlled study was conducted in 25 postmenopausal women with type 2 diabetes and produced different results (Vanschoonbeek et al 2006). Researchers assessed the effects of cinnamon supplementation (*C. cassia*, 1.5 g/day) on fasting blood glucose, insulin and glycosylated haemoglobin concentrations, indices of oral glucose tolerance and whole-body insulin sensitivity, and fasting blood lipid profiles. During the trial, volunteers maintained their normal dietary and physical activities and continued all medication. After 6 weeks, cinnamon supplementation had no significant effect on fasting plasma glucose or insulin concentrations, whole-body oral glucose tolerance, or blood lipid profiles in this sample.

It is not clear why positive results should be observed in the first study and not in the second. The dose of cinnamon used was within the range expected to be active and the same form was used. Vanschoonbeek et al report that baseline values of fasting glucose and triglycerides were different for subjects participating in the two studies and discrepant results may be accounted for by this difference and by a lack of nutritional standardisation in the study by Khan et al.

Most recently, a crossover study of 15 healthy volunteers reported that ingestion of 3 g cinnamon significantly reduced postprandial serum insulin and increased glucagon-like peptide-1 concentrations without significantly affecting blood glucose, glucose-dependent insulinotropic polypeptide, the ghrelin concentration, satiety, or gastric emptying rate. A lower dose of cinnamon (1 g) was also tested and found to have no effects on any measurements (Hlebowicz et al 2009).

Gestational diabetes

A randomised, double-blind placebo controlled study of 51 women with gestational diabetes found that 6 weeks of treatment with 1 g of cinnamon daily produced a trend towards decreased insulin requirements (53.85% cinnamon vs 44% placebo, $P = 0.58$); however, this did not reach significance (Graham et al 2005). The cinnamon used was *C. cassia*. The researchers suggested that a longer duration of treatment may be required to produce better results.

Metabolic syndrome

A water-soluble extract of cinnamon (Cinnulin PF(R) 500 mg/day) significantly reduced fasting blood glucose, systolic blood pressure and increased lean body mass according to a placebo controlled trial of 22 subjects with prediabetes and metabolic syndrome (Ziegenfuss et al 2006). The study was conducted over 12 weeks and also detected small but statistically significant decreases in body fat in the cinnamon treated group when within-group analyses were performed.

Polycystic ovarian syndrome

A pilot study involving 15 non-diabetic women with oligomenorrhoea or amenorrhoea and polycystic ovaries which compared cinnamon (333 mg cinnamon extract taken three times a day) to placebo (Wang et al 2007). The randomised study found oral cinnamon extract resulted in a significant reduction in fasting glucose as well as insulin resistance, as measured by various indices of insulin sensitivity from fasting and oral glucose tolerance test (OGTT) values. Specifically, fasting glucose was reduced by 17% during the 8-week treatment period. The reduction in insulin resistance appears to be mediated through an increase in glucose utilisation, as there were no significant alterations in hyperinsulinaemia measured by fasting insulin or mean insulin levels during OGTT. These preliminary findings are consistent with prior in vivo animal and human studies.

OTHER USES

Traditional uses

Cinnamon has been used traditionally by ancient healers from many backgrounds for stomach cramps, flatulence, nausea, vomiting, diarrhoea, infant colic, common infections and also female reproductive problems such as dysmenorrhoea,

menorrhagia, lactation and pain in childbirth. It has also been used as an ingredient in topical preparations for pain and inflammation. Cinnamon is often used in combination with other herbs and spices for most of these indications. In TCM it is considered to warm the kidneys and fortify yang, so is used for impotence among other indications. In Ayurvedic medicine and in China, Korea and Russia it has long been used as a treatment for diabetes.

Natural food preservative

Spices such as cinnamon have been used traditionally for the preservation of food products. The considerable antimicrobial, fungicidal and antioxidant properties of cinnamon provide a theoretical basis for its use.

DOSAGE RANGE

General guide

- Dried bark (crushed cinnamon): 1.5–4 g taken up to four times daily.
- Fluid extract 1:1: 0.5–1.0 mL taken up to three times daily.
- Tea: half to three-quarters teaspoon of powdered cinnamon in a cup of boiling water taken 2–3 times daily with meals.
- Essential oil: 0.05–0.2 mL diluted in carrier oil.

According to clinical studies

Diabetes

- 3–6 g daily of powdered cinnamon (*C. cassia*) administered in capsules.

Loss of appetite or digestive complaints

- Essential oil: 0.05–0.2 g daily.
- Fluid extract (1:1 g/mL): 0.7–1.3 mL three times daily.
- Infusion or decoction: 0.7–1.3 g in 150 mL water three times daily.
- Tea: 1–4.5 g daily using *C. cassia* bark.

TOXICITY

The oral LD_{50} for cinnamon bark oil in rats is 4.16 g/kg and 3.4 mL/kg body weight.

ADVERSE REACTIONS

When the powdered herb is ingested orally, it is generally well tolerated; however, when cinnamon oil is applied topically, allergic reactions are possible as cinnamaldehyde may cause allergic contact dermatitis (Cheung et al 2003).

SIGNIFICANT INTERACTIONS

Controlled studies are not available, therefore interactions are based on pharmacological activity and are largely theoretical and speculative.

Hypoglycaemic agents

Oral ingestion of cinnamon capsules may reduce blood glucose levels, therefore theoretically, an additive effect is possible with concurrent use — observe; potential beneficial interaction under professional supervision.

CONTRAINDICATIONS AND PRECAUTIONS

Cinnamon is contraindicated in people with an allergy to cinnamon or Peru balsam, in cases of fever of unknown origin, active stomach or duodenal ulcers (WHO 2004).

PREGNANCY USE

C. cassia or *C. zeylanicum/verum* should not be used in pregnancy; however, usual dietary intakes are likely to be safe. Currently, evidence of teratogenicity from animal studies is contradictory.

PRACTICE POINTS/PATIENT COUNSELLING

- Cinnamon has been used since ancient times as a flavouring and medicinal agent.
- It is a natural food preservative with antioxidant and wide ranging antimicrobial and antifungal properties.
- It has been used traditionally to treat dyspepsia, nausea, flatulence, poor appetite, stomach cramps and diarrhoea. Some evidence suggests it may be effective for some of these indications.
- Whether ground cinnamon (*C. cassia*) reduces blood glucose and lipid levels and can be useful for people with type 2 diabetes is uncertain as clinical studies have produced mixed results
- Cinnamon oil can cause allergic contact dermatitis when used topically and should be avoided by people with allergies to cinnamon or Peru balsam, pregnant women or those with active gastrointestinal ulcers.

PATIENTS' FAQs

What will this herb do for me?

Cinnamon is a natural food preservative with wide ranging antimicrobial and antifungal properties. It may improve digestion and ease symptoms of dyspepsia, flatulence and nausea. It may also lower blood glucose, total cholesterol and triglyceride levels, however more research is required to confirm these effects.

When will it start to work?

The effects on digestion should start rapidly; however, effects on blood glucose and lipid levels may take 1 month or more.

Are there any safety issues?

Cinnamon oil can cause allergic contact dermatitis when used topically and should be avoided by people with allergies to cinnamon or Peru balsam, pregnant women or those with active gastrointestinal ulcers.

Cloves

HISTORICAL NOTE Spices such as cloves have been used as food preservatives, disinfectants and antiseptics for centuries (De et al 1999). Modern research has confirmed that cloves are an effective preservative that inhibit the growth of many food-poisoning and food-spoiling bacteria.

COMMON NAME
Cloves

OTHER NAMES
Oil of cloves, Oleum caryophylli, *Eugenia caryophyllata*, *Eugenia aromatica*, *Caryophyllus aromaticus*, Myrtaceae

SCIENTIFIC NAME
Syzygium aromaticum (family Myrtaceae)

PLANT PART USED
Dried flower buds (clove oil is distilled from this plant part).

CHEMICAL COMPONENTS
The main constituent of clove oil is eugenol. Other components include beta-caryophyllene, acetyl eugenol, isoeugenol, eugenine, kaemferol, tannins, gallic acid, vitamin C, minerals (boron, calcium, chromium, iron, manganese, magnesium, potassium, phosphorus), flavonoids (Nassar 2006).

MAIN ACTIONS
Because of cloves' significant eugenol content, most pharmacological activity is based on studies involving eugenol.

Local analgesic, local anaesthetic and anti-inflammatory
The local analgesic and anti-inflammatory activity of clove oil is mainly due to the eugenol component. Eugenol acts on contact to depress nociceptors, the sensory receptors involved in pain perception (Brodin & Roed 1984). Eugenol also inhibits prostaglandin biosynthesis through potent cyclo-oxygenase-1 and -2 inhibitory activity (Huss et al 2002, Kelm et al 2000) and modulates inflammatory pathways by inhibiting

the release of leukotrienes (Raghavenra et al 2006). According to experiments with an animal model, daily doses of eugenol produce a cumulative effect after 5 days of continuous administration, producing a statistically significant reduction in neuropathic pain (Guénette et al 2007). Although eugenol is chiefly responsible for much of the pharmacological activity of cloves, other constituents are also involved (Ghelardini et al 2001a).

Beta-caryophyllene is another key component of clove oil, which exhibits significant anti-inflammatory and rapid local anaesthetic activity in several animal models (Ghelardini et al 2001b, Muruganandan et al 2001). Local anaesthetic effects develop within 5 minutes of application and diminish after about 15 minutes.

Antiseptic — fungicidal, antibacterial, antiviral, antiparasitic

Clove oil has an inhibitory effect against yeasts and fungi in vitro (Arora & Kaur 1999). Cloves are effective against species belonging to the *Eurotium*, *Aspergillus* and *Penicillium* genera in vitro (Guynot et al 2003) and clove essential oil has exhibited strong antifungal activity against *Aspergillus* and aflatoxigenic strains (Bluma et al 2008, Viuda-Martos et al 2007) and various other fungal species (Park et al 2007).

Experiments with animal models have identified significant activity against *Candida albicans*. Vaginal candidiasis responded to treatment of topical application of clove oil in animal models suggesting that further investigation is warranted to determine clinical relevance (Ahmad et al 2005). Another animal experiment found that oral intake of cloves reduced *Candida albicans* growth in the alimentary tract (Taguchi et al 2005). It is likely that the eugenol component is important for such effects, as in vitro experiments identified that eugenol displays anticandidal activity by affecting the envelope of the organism (Braga et al 2007, Fu et al 2007).

Antibacterial activity has also been demonstrated for cloves and several of its key constituents. Cloves has activity against gram-negative, anaerobic, periodontal oral pathogens, including *Porphyromonas gingivalis* and *Prevotella intermedia* (Cai & Wu 1996). Activity has also been demonstrated against *Bacillus subtilis*, *Listeria monocytogenes*, *Salmonella enterica*, *Escherichia coli* and *Saccharomyces cerevisiae* (Burt & Reinders 2003, Chami et al 2005, De et al 1999, Dorman & Deans 2000, Friedman et al 2002, Fu et al 2007) and *Staphylococcus epidermidis* (Fu et al 2007). Aqueous extract of cloves demonstrated a strong inhibitory action against six *Helicobacter pylori* strains in vitro (Yang et al 2005). Further research is required to determine the clinical relevance of these in vitro findings and establish whether cloves may be utilised as an effective treatment for common infections.

In vitro assays have identified inhibitory effects on hepatitis C virus protease (Hussein et al 2000) and human cytomegalovirus (Shiraki et al 1998, Yukawa et al 1996). An animal model confirmed significant activity against herpes simplex virus type 1 (Kurokawa et al 1998). An inhibitory effect against parasitic growth has been demonstrated in vitro for clove oil (Santoro et al 2007).

OTHER ACTIONS

Antihistamine

Clove bud extracts inhibit histamine release from mast cells in vivo and in vitro (Kim et al 1997, 1998, Shakila et al 1996).

Antioxidant

Several constituents within the flower have antioxidant activity, especially eugenol, which has been the focus of most antioxidant research (Duke 2002). Studies with cloves and eugenol have demonstrated protective effects against several agents, which cause damage to cells and tissues via an oxidative stress mechanism.

Cloves illustrated a protective effect against a cytotoxic agent (peroxynitrite) that causes damage to proteins, lipids and DNA (Ho et al 2008) and significantly reversed isoprenaline-induced cardiac hypertrophy in rats (Choudhary et al 2006). In other studies, eugenol was shown to reduce radiation-induced membrane damage (Pandey et al 2006), to prevent lipid peroxidation and increase glutathione (Kabuto et al 2007).

Antispasmodic

Both beta-caryophyllene and eugenol have antispasmodic activity (Duke 2002).

Antiplatelet

Eugenol inhibits platelet aggregation in vitro (Srivastava 1993, Srivastava & Malhotra 1991). It was more potent than aspirin in several experimental models and equivalent to indomethacin in one (Srivastava 1993).

Anticarcinogenic

Eugenol essential oil showed anticancer apoptosis activity on HL-60 human promyelocytic leukaemia cells in vitro (Yoo et al 2005). Further chemopreventive potential was explored in mice with induced lung carcinogenesis. A clove infusion, administered orally, was found to significantly reduce proliferating cells and increase apoptosis. The cloves down-regulated some growth-promoting proteins, while at the same time upregulating the expression of some pro-apoptotic proteins (Banerjee et al 2006). A later in vitro study confirmed apoptosis activity with eugenol (and its analogues) and suggested that it may have a chemotherapeutic role (Carrasco et al 2008). An aqueous infusion of cloves, administered orally, in a mouse experiment delayed the formation and reduced skin papilloma (Banerjee & Das 2005)

Antidiabetic

In vitro tests have identified hypoglycaemic activity for cloves. It appears that a phenolic compound in cloves may be the key constituent responsible and acts by repressing the expression of genes, which control hepatic gluconeogenesis (Prasad et al 2005). Commercially sold culinary cloves were also shown

to be potent inhibitors of fructose-mediated protein glycation and so may have antidiabetic potential (Dearlove et al 2008). Further research is required with in vivo models of diabetes to determine whether these effects may have clinical significance.

Cognitive effects

An animal study found that intraperitoneally administered clove extract (200 mg/kg) improved short-term memory recall but caused some impairment in learning ability (Morshedi et al 2006).

CLINICAL USE

The clinical effects of cloves and clove oil have not been significantly investigated; however, an understanding of the herb's pharmacological activity suggests a role in the treatment of several conditions.

Toothache and relief of dry socket pain

Clove oil and dried clove buds are used in dentistry to relieve dental pain and reduce infection. Based on the evidence available, Commission E has approved cloves for use as a local anaesthetic and antiseptic (Blumenthal et al 2000). In one study, clove oil was found to be as effective as benzocaine as a topical anaesthetic before needle insertion in dentistry (Alqareer et al 2006).

Oral hygiene

Used as an antiseptic and antibacterial agent for the oral mucosa, clove is used as an ingredient in mouth rinses and gargles. Its established antiseptic activity provides a theoretical basis for efficacy.

Herpes simplex virus type 1

One study using a combination of acyclovir and cloves administered orally found this to be superior to acyclovir alone in the treatment of herpes simplex virus type 1 infection (Kurokawa et al 1995). The combination significantly reduced the development of skin lesions and/or prolonged survival times of infected mice and reduced viral loads.

Headache (as part of a combination)

Tiger balm is a popular OTC preparation that contains clove oil, menthol, cassia oil, camphor, cajuput oil and sometimes peppermint oil. It is generally used to relieve the symptoms of sore muscles, but a randomised, double-blind study found that it is also as effective as paracetamol in reducing headache severity (Schattner & Randerson 1996). Although encouraging, the role of cloves in this combination is difficult to assess from the study.

Type 2 diabetes

In a small study, 36 people with type 2 diabetes were given 0, 1, 2 or 3 g capsules of cloves for 30 days. All the groups administered with cloves had significantly lowered serum glucose, triglycerides, total and LDL cholesterol and there was no change to HDL cholesterol. After 10 days washout period all these parameters were still significantly lower than at the start of the trial (Khan et al 2006). Further research is warranted to confirm clinical use for type 2 diabetes and to assess any side effects with oral ingestion of cloves.

OTHER USES

Cloves have been investigated as an agent to protect harvests from fungal contamination (Ranasinghe et al 2002).

DOSAGE RANGE

- Powder: 120–300 mg as a single dose.
- Oil: 0.05–0.2 mL as a single dose.
- Toothache or gum inflammation: oil of clove is applied directly to the site.
- Dry socket: the area is packed with dried flower buds steeped in oil.
- Headache: one drop of oil massaged into each temple or area of pain.

ADVERSE REACTIONS

According to one review, contact dermatitis has been reported, and local application may cause irritation to mucous membranes in sensitive individuals. Oral use of the oil can cause nervous system depression, seizures, hepatic dysfunction and irritation to mucosal tissues.

SIGNIFICANT INTERACTIONS

Cloves have been found in vitro to strongly inhibit metabolism mediated by CYP3A4 and CYP2D6. In vivo studies are currently under progress and clinical relevance has yet to be established (Usia et al 2006). If cloves are only used topically, these interactions are unlikely to be relevant.

CONTRAINDICATIONS AND PRECAUTIONS

None known.

PREGNANCY USE

Safety unknown.

PRACTICE POINTS

- Clove flower buds and clove oil has antiseptic, analgesic, anti-inflammatory and local anaesthetic properties.
- It is directly applied to relieve the symptoms of toothache and dry socket.
- Clove oil is also used in mouth rinses and gargles to improve oral hygiene.
- Massaging one drop of oil into the temples has been used to treat headache.
- This herb and its essential oil should not be taken internally.

PATIENTS' FAQs

What will this herb do for me?

Clove flower buds and clove oil have antiseptic, anti-inflammatory, analgesic and local anaesthetic properties that are useful in the treatment of toothache, dry socket and common mouth infections. Massaging one drop of the oil into the temples may relieve the symptoms of headache.

When will it start to work?

Research suggests that effects are almost immediate, although short lasting.

Are there any safety issues?

Clove buds and clove oil should not be taken internally, and only applied externally, although using cloves as a spice in cooking may give you some of the antioxidant benefits.

Cocoa

HISTORICAL NOTE Cocoa originates from Mexico where the Mayas, Incas and Aztecs considered it the food of the gods. Chocolate, mixed with vanilla and sugar, was first introduced as a beverage in Europe by Columbus and was considered an aphrodisiac and a symbol of wealth and power. The phenolics in chocolate prevent the fat becoming rancid, decreasing the need for added preservatives. This quality was exploited during World War II when at times US troops were rationed three chocolate bars per day during heavy combat as their sole source of nourishment (Waterhouse et al 1996).

COMMON NAME

Chocolate, cocoa, cocoa liquor, cocoa mass, baking chocolate, Cocoapro™, Acticoa™

BOTANICAL NAME/FAMILY

Theobroma cacao (family Sterculiaceae)

PLANT PARTS USED

Cocoa is produced through a process of fermenting the seeds from the pods of the cacao tree, *Theobroma cacao*. The beans are dried, roasted and crushed to produce high-fat, unsweetened chocolate, which is also called baking chocolate. This intermediate is pressed and alkalised to form cocoa powder, which is then homogenised with sugar and cocoa butter, and sometimes milk, to ultimately form chocolate. Dark chocolate generally contains more than 50% cocoa, whereas mass-produced milk chocolate contains only around 10% cocoa. White chocolate is based on cocoa butter (or theobroma oil) without the cocoa solids.

Although many different types of cocoa beans grow throughout the world, three varieties of cocoa beans are mainly used to make chocolate products: (a) criollo (meaning 'native'), distributed to the north and west of the Andes, (b) forastero (meaning 'foreign'), found mainly in the Amazon basin, and (c) trinitario (meaning 'sent from heaven') (Bruinsma & Taren 1999).

Cocoa beans from different countries along with postharvesting and processing procedures can have a striking influence on the flavanol content of chocolate and cocoa (Hollenberg et al 2004). As flavanols impart a bitter, astringent flavour, chocolate often undergoes extensive processing, dilution and the addition of flavour modifiers to improve its palatability despite these processes having the potential to negatively impact on cocoa's nutritional and clinical value (McShea et al 2008). While a study that examined the total phenolic content of chocolate found that the antioxidant properties of the artisan-made chocolate were significantly better than those of the factory-produced chocolate (Cervellati et al 2008), recent attention to flavonoid content has led to the development of commercial processes that protect and preserve the naturally occurring flavonoids with Cocoapro™ being developed by Mars Inc and Acticoa™ by the Swiss-based Barry Callebaut.

CHEMICAL COMPONENTS

Cocoa is among the most concentrated sources of the flavanols, catechin and epicatechin, with four times the catechin content of tea (Arts et al 1999). Chocolate also contains additional flavonoids not found in tea, with high concentrations of oligomeric procyanidins (Lazarus et al 1999). Dark chocolate has the highest total catechin content with approximately 53.5 mg/100 g, whereas milk chocolate contains approximately 15.9 mg/100 g (Arts et al 1999). White chocolate primarily contains cocoa butter with minimal levels of polyphenols.

In addition to flavanols, cocoa also contains the methylxanthines, caffeine and theobromine, the biogenic amines phenylethylamine, phenylalanine and tyrosine (Bruinsma & Taren 1999) and the cannabinoid-like fatty acid anandanine analogues, *N*-oleoylethanolamine and *N*-linoleoylethanolamine (Di Tomaso et al 1996). Chocolate is also a rich source of minerals, including magnesium, calcium, iron, copper, phosphorus, potassium and zinc (Steinberg et al 2003) and it is suggested that the presence of methylxanthines, peptides and minerals could synergistically enhance or reduce cocoa's antioxidant properties (Jalil & Ismail 2008).

MAIN ACTIONS

Both in vitro and in vivo studies indicate that cocoa flavanols have antioxidant effects, decrease LDL cholesterol oxidation, reduce platelet aggregation and enhance endothelial function. There is, however, tremendous variability in cocoa processing, flavonoid content and measurement of flavonoids,

and questions remain around bioavailability and dosing frequency (Fisher & Hollenberg 2006). A feeding study demonstrated that procyanidins were remarkably stable in the stomach environment and thus most ingested procyanidins reach the small intestine intact and are available for absorption or metabolism (Rios et al 2002). Epicatechin and its metabolites reach maximal levels 2 hours after either chocolate or cocoa intake, with rapid excretion in the urine (Baba et al 2000) and dimeric procyanidins have been detected in human plasma as early as 30–60 min after the consumption of flavanol-rich beverages providing 0.25–0.50 g/kg cocoa/kg body weight (Holt et al 2002, Zhu et al 2005).

Cocoa powder dissolved in milk as one of the most common ways of cocoa powder consumption seems to have a negative effect on the absorption of polyphenols; however, statistical analyses have shown that milk does not impair the bioavailability of flavonoids (Keogh et al 2007, Roura et al 2007). High-flavonoid cocoa products may lead to greatly enhanced flavonoid bioavailability in humans (Tomas-Barberan et al 2007).

Antioxidant

Cocoa has been found to have much higher levels of total phenolics and flavonoids, with a corresponding higher antioxidant capacity per serving, than black tea, green tea or red wine (Lee et al 2003). It has been suggested that the antioxidant capacity of cocoa polyphenols is greater than synthetic antioxidants and that they have the potential to complement or replace synthetic antioxidants in aqueous and oil-based food applications (Osman et al 2004).

Human studies have confirmed that the polyphenols in chocolate are indeed bioavailable and able to increase the antioxidant capacity of plasma, with one study reporting that ingestion of 80 g of procyanidin-rich chocolate increased plasma epicatechin concentrations 12-fold, significantly increased plasma total antioxidant capacity by 31% and significantly decreased 2-thiobarbituric acid reactive substances by 40% after 2 hours, with levels returning to normal within 6 hours (Rein et al 2000a).

Cocoa has been consistently shown to confer significant protection against oxidation both in vitro (Martin et al 2008, Sies et al 2005, Waterhouse et al 1996) and in vivo (Kondo et al 1996). In addition to reducing lipid oxidation, consumption of a flavanol-rich cocoa beverage has been shown to reduce susceptibility of erythrocytes to haemolysis and to increase their ability to buffer free radicals (Zhu et al 2005).

There is evidence that the polyphenols are not the only antioxidants in chocolate, as suggested by a study that found that consumption of chocolate containing 200 mg of polyphenols, as well as chocolate with less than 10 mg of polyphenols, reduced faecal free radical production (Record et al 2003). Furthermore, similar reductions in markers of lipid peroxidation have been observed after daily consumption of 75 g of dark chocolate and dark chocolate enriched with cocoa polyphenols, as well as with white chocolate, which contains very little polyphenols (Mursu et al 2004).

In a crossover study in 23 healthy subjects, cocoa powder and dark chocolate was seen to modestly reduce LDL oxidation susceptibility while increasing serum total antioxidant capacity and HDL cholesterol concentrations (Wan et al 2001), and another crossover trial of 25 healthy subjects found that supplementation with 36.9 g of dark chocolate (30 g of cocoa powder drink) for 6 weeks reduced LDL oxidisability (Mathur et al 2002). Similar results were seen in a randomised, double-blind crossover trial that found that a high-flavanol cocoa drink providing 187 mg flavan-3-ols/100 mL significantly reduced lipid peroxidation, compared with a low-flavanol cocoa drink providing only 14 mg/100 mL (Wiswedel et al 2004).

In contrast to these studies a further randomised, double-blind, placebo-controlled study of 21 healthy adults, however, found that intake of high-flavonoid (213 mg procyanidins, 46 mg epicatechin) dark chocolate bars for 2 weeks did not alter resistance to LDL oxidation, total antioxidant capacity, 8-isoprostanes, blood pressure, lipid parameters, body weight or BMI, despite increasing plasma epicatechin concentrations and improving endothelium-dependent flow-mediated dilation of the brachial artery (Engler et al 2004).

Effects on microcirculation and nitric oxide

Flavanols have been shown in several in vitro or ex vivo studies to modify the production of proinflammatory cytokines, the synthesis of eicosanoids, the activation of platelets and nitric oxide-mediated mechanisms (Selmi et al 2008). A double-blind, dose-finding study found that flavanol-rich cocoa increased circulating NO species in the plasma of male smokers, with maximal effects seen with ingestion of 176–185 mg flavanols (Heiss et al 2005). Another double-blind trial found that ingestion of a high-flavanol cocoa drink, but not a low-flavanol one, enhanced NO bioactivity and increased plasma concentrations of nitroso compounds and flow-mediated dilation of the brachial artery (Sies et al 2005). Similarly, ingestion of flavanol-rich cocoa is associated with acute elevations in levels of circulating NO species, enhanced flow-mediated dilatation response of conduit arteries, and an augmented microcirculation, with these effects being mimicked by ingestion of chemically pure epicatechin. Moreover, chronic consumption of a cocoa–flavanol-rich diet has been associated with augmented urinary excretion of NO metabolites (Schroeter et al 2006).

Double-blind, crossover intervention studies in both humans and rats suggest that an increase in the circulating NO pool following flavanol consumption is correlated with decreased arginase activity as the availability of L-arginine can be a rate-limiting factor for cellular NO production by nitric oxide synthase (NOS) (Schnorr et al 2008).

Lipid-lowering

A 3-week clinical supplementation trial of 45 non-smoking, healthy volunteers consuming high-polyphenol chocolate found a significant increase

in serum HDL cholesterol with dark and high-polyphenol chocolate (11.4% and 13.7%, respectively), whereas white chocolate consumption resulted in a small decrease in HDL. Markers of lipid peroxidation decreased 11.9% in all three study groups with no changes occurring in the total antioxidant capacity of plasma, in the oxidation susceptibility of serum lipids or VLDL and LDL, or in the concentration of plasma F2-isoprostanes or hydroxy fatty acids. This suggests that while cocoa polyphenols may increase the concentration of HDL cholesterol, chocolate fatty acids may modify the fatty acid composition of LDL, making it more resistant to oxidative damage (Mursu et al 2004).

A new soluble cocoa fibre product rich in soluble dietary fibre and antioxidant polyphenols diminished the negative impact of the cholesterol-rich diet in an animal model of dietary-induced hypercholesterolaemia (Ramos et al 2008). Similarly, in an animal model of hypercholesterolaemia a cholesterol- and triglyceride-lowering effect along with a reduction of biomarkers of oxidative stress and increasing faecal bulking was seen after 3 weeks of consuming a fibre-rich cocoa product (Bravo et al 2008).

Inhibits platelet function

Numerous dietary intervention studies in humans and animals indicate that flavanol-rich foods and beverages might exert cardioprotective effects with respect to vascular function and platelet reactivity (Keen et al 2005). Acute doses of flavanols and oligomeric procyanidins from cocoa have been observed to inhibit platelet activation (Pearson et al 2002, Rein et al 2000b) and have an aspirin-like effect on primary haemostasis 2 and 6 hours after consumption (Hermann et al 2006, Pearson et al 2002, Rein et al 2000b), with the effects being similar to, but less profound than, aspirin (Pearson et al 2002). Similar results have been observed in longer studies with lower doses of cocoa flavanols, with a double-blind, controlled trial demonstrating significantly lower platelet aggregation and significantly higher plasma ascorbic acid concentrations after supplementation with cocoa flavanols (234 mg cocoa flavanols and procyanidins/day) over 28 days (Murphy et al 2003).

In another randomised trial of 30 healthy volunteers, 100 mg of dark chocolate, but not white or milk chocolate, were found to significantly inhibit collagen-induced platelet aggregation (Innes et al 2003). The alteration of eicosanoid synthesis has been suggested as a plausible mechanism by which procyanidins can decrease platelet activation, and this has been observed in an in vitro study of the effect of procyanidin on aortic endothelial cells, as well as in a randomised, blinded, crossover study of high procyanidin chocolate (4.0 mg/g) (Schramm et al 2001).

Antidiabetic

Pretreatment with a cocoa extract high in polyphenols was seen to normalise body weight, plasma glucose levels, total cholesterol, triglycerides and high-density lipoprotein levels in streptozotocin-diabetic rats (Ruzaidi et al 2008). In humans, short-term administration of flavonoid-rich dark chocolate significantly improved insulin sensitivity and endothelial function in healthy and hypertensive subjects (Grassi et al 2008b), while a double-blind, placebo-controlled crossover study found that flavanol-rich dark chocolate but not flavanol-free white chocolate ameliorated insulin sensitivity and beta-cell function, decreased blood pressure and increased flow-mediated dilation in hypertensive patients with impaired glucose tolerance (Grassi et al 2008a). Similar results were obtained from another small, randomised controlled trial that found that high-flavanol cocoa reversed vascular dysfunction in diabetic patients (Balzer et al 2008). In contrast to these findings, a double-blind, crossover study found that daily consumption of flavanol-rich cocoa for 2 weeks was not sufficient to reduce blood pressure or improve insulin resistance in human subjects with essential hypertension (Muniyappa et al 2008).

Psychological effects

Chocolate is purported to have a range of psychological effects, including enhanced arousal and cognitive function, stimulation of feelings of wellbeing and euphoria, as well as initiating cravings. The orosensory aspects of chocolate, including its taste, smell and texture, certainly contribute to chocolate's positive appeal. Chocolate contains large amounts of fat in the form of cocoa butter, which melts at body temperature producing a pleasurable melt-in-the-mouth experience. Chocolate also often contains large amounts of sugar and thus satisfies the seemingly innate preference for sweet, high-fat, foods (Bruinsma & Taren 1999).

In addition to unique sensory properties, chocolate also contains many pharmacologically active substances. Several endogenous biogenic amines with sympathomimetic properties are found in chocolate, most notably tyramine and phenylethylamine (Hurst 1982). Phenylethylamine is an amphetamine analogue structurally related to methylenedioxy–methamphetamine that may act to potentiate dopaminergic and noradrenergic neurotransmission and modulate mood (Bruinsma & Taren 1999).

Cocoa is also known to contain methylxanthines, including caffeine and theobromine, both of which are stimulants. Although the stimulatory and sympathomimetic effects of caffeine are well documented, the psychological effects of theobromine are less certain.

A group of biologically active constituents, including *N*-oleoylethanolamine and *N*-linoleoylethanolamine, have been identified in chocolate and appear to be related to anandamide, the 'internal bliss' chemical, which is the endogenous lipoprotein that binds cannabinoid receptors within the brain (Di Tomaso 1996). Although it has been suggested that these compounds may elicit heightened sensitivity and euphoria by directly activating cannabinoid receptors or by increasing anandamide levels (Bruinsma & Taren 1999), measurements have suggested that their amounts in cocoa is several orders of magnitude below those required to

reach the blood and cause observable central effects (Di Marzo et al 1998).

Chocolate craving, which is reported to be the most common food craving (Weingarten & Elston 1991), is more common in women, with fluctuations occurring with hormonal changes just before and during the menses (Rozin et al 1991). The basis for chocolate craving, however, remains undetermined, but it is suggested that aroma, sweetness, texture and calorie content are likely to play a more important role in chocolate cravings than pharmacological factors (Bruinsma & Taren 1999, Michener & Rozin 1994, Rozin et al 1991, Smit et al 2004).

Modulation of immune function and inflammation

The procyanidin fraction from cocoa demonstrates immunomodulatory function in vitro, with stimulation of TNF-alpha (Mao et al 2002) and modulation of the secretion of the cytokine transforming growth factor (TGF-beta-1) (Mao et al 2003), as well as inhibiting induced nuclear transcription of human IL-1B (Mao et al 2000a), phytohaemagglutinin-induced stimulation of IL-2 (Mao et al 1999) and mitogen-stimulated secretion of IL-4 (Mao et al 2000b) in peripheral blood mononuclear cells in vitro. In vivo cocoa intake has been shown to modulate intestinal immune responses in young rats (Ramiro-Puig et al 2008), while cocoa polyphenols have been shown to reduce leukotriene synthesis through inhibition of human 5-lipoxygenase in humans (Sies et al 2005).

Anti-inflammatory

While flavanols are known to modify the production of proinflammatory cytokines, the synthesis of eicosanoids, the activation of platelets, and nitric oxide-mediated mechanisms (Selmi et al 2008), evidence for any beneficial effects of cocoa flavanols in providing a meaningful anti-inflammatory action has been gathered predominantly from in vitro experiments. Additional research in well-designed human clinical experiments is therefore required to determine if flavanol-rich cocoa could be used to treat or prevent chronic diseases linked to dysfunctional inflammatory responses (Selmi et al 2006).

Altered cellular signalling

Flavonoids have been shown to modulate tumour pathology in vitro and in animal models, and the pentameric procyanidin fraction isolated from cocoa is reported to slow the growth of cultured human aortic endothelial cells (Kenny et al 2004a), as well as inhibit the proliferation of human dermal microvascular endothelial cells in vitro through inhibition of tyrosine kinase ErbB2 expression. This has led to the suggestion that polyphenols may influence endothelial growth signalling in vitro, with potential beneficial effects for specific neoplasias in which cells over-express ErbB2 (Kenny et al 2004b).

Inhibition of dental caries

Cocoa contains substances that protect against dental caries (Palenik et al 1977, s'Gravenmade et al 1977) and in vitro experiments have shown that monomeric polyphenols and tannins from cocoa may interfere with glucosyltransferase activity of *Streptococcus mutans* and reduce plaque formation (Kashket et al 1985). Similar results were reported in hamsters, with a marked caries-inhibitive effect found with a water extract of cocoa (Stralfors 1966). Cocoa bean husk, while not used in cocoa or chocolate, demonstrates antibacterial properties attributed to its unsaturated fatty acids and antiglucosyltransferase activities attributed to epicatechin polymers, as well as being shown both in vitro and in vivo to possess significant antiplaque activity (Matsumoto et al 2004).

Antitussive

It has been suggested that theobromine, a methylxanthine derivative present in cocoa, may form the basis for a new class of antitussive drugs, as it has been shown to effectively inhibit citric acid-induced cough in guinea pigs in vivo, as well as suppress capsaicin-induced cough in a human double-blind trial. The observation that theobromine inhibits capsaicin-induced sensory nerve depolarisation of the guinea pig and human vagus nerve suggests that its antitussive action may be mediated peripherally through an inhibitory effect on afferent nerve activation (Usmani et al 2005).

Skin anti-ageing and photoprotecion

Long-term cocoa ingestion appears to lead to an increased resistance against UV-induced erythema and a lowered transepidermal water loss. In a crossover design study in 10 healthy women, a single dose of cocoa rich in flavanols (329 mg) was found to enhance dermal blood flow by 1.7-fold and elevate oxygen saturation of haemoglobin at 1 mm skin depth 1.8-fold 2 hours after consumption, while there was no effect seen after consumption of low-flavanol cocoa (27 mg) (Neukam et al 2007).

In a study using a model of ex vivo human skin explants, cocoa polyphenols were seen to exhibit a positive action on several indicators of skin elasticity and skin tonus, and an enhancing effect of cocoa butter on activity of cocoa polyphenol was observed (Gasser et al 2008).

There is evidence to suggest that dietary flavanols from cocoa contribute to endogenous photoprotection, improve dermal blood circulation, and affect cosmetically relevant skin surface and hydration variables in women. A 12-week randomised controlled trial, comparing high flavanol (326 mg/day containing epicatechin (61 mg/day) and catechin (20 mg/day) and low flavanol (27 mg/day containing 6.6 mg epicatechin and 1.6 mg catechin) cocoa consumption, found high flavanol consumption led to significantly reduced UV-induced erythema (by 15% and 25%, after 6 and 12 weeks of treatment). The high flavanol group also experienced increased skin density, skin hydration and skin thickness along with increased blood flow in cutaneous and subcutaneous tissues, and significantly decreased skin roughness and scaling compared with no change in the low-flavanol group (Heinrich et al 2006).

Antineurodegenerative

The major flavonoids of cocoa, epicatechin and catechin, protected cellular membrane from amyloid beta-protein-induced neurotoxicity in vitro, suggesting that cocoa may have antineurodegenerative effects (Heo & Lee 2005). This is supported by a study that found that 1-year administration of a cocoa polyphenolic extract (Acticoa powder), affects the onset of age-related cognitive deficits, urinary free dopamine levels and lifespan in old Wistar-Unilever rats (Bisson et al 2008a, 2008b). Daily oral administration of Acticoa powder was also seen to protect rats from cognitive impairments after heat exposure by counteracting the overproduction of free radicals (Rozan et al 2007).

OTHER ACTIONS

Acticoa powder has been observed to protect rats from prostate carcinogenesis (Bisson et al 2008a) and prostate hyperplasia as well as improve established prostate hyperplasia in an animal model (Bisson et al 2007). The clinical significance of these findings is yet to be determined.

CLINICAL USE

Cardiovascular disease

There is evidence to support that the flavanols in cocoa can be absorbed, are bioactive, and may be responsible for the cardiovascular benefits associated with regular cocoa consumption. Several mechanisms have been proposed to explain this positive influence, including metabolic, antihypertensive, anti-inflammatory and antioxidant effects along with decreased platelet activation and function, effects on serum lipids, insulin sensitivity, immune function and vascular endothelial function (Ding et al 2006, Eo 2008, Lippi et al 2008).

While there are no randomised controlled trials that studied effects on cardiovascular morbidity or mortality (Hooper et al 2008), there is accumulating evidence over the past decade demonstrating that moderate consumption of chocolate, especially dark chocolate, may exert protective effects against the development of cardiovascular disease. Epidemiologic studies have shown inverse associations between dietary polyphenols and mortality from coronary heart disease. Small, short-term, intervention studies have indicated that cocoa-containing foods may provide many cardiovascular benefits, including reducing blood pressure, inhibiting platelet function, preventing lipid oxidation, reducing LDL, increasing HDL, improving endothelial function, increasing insulin sensitivity, reducing insulin resistance and reducing inflammation.

A meta-analysis of 133 trials on flavonoid-rich foods and cardiovascular risk found that chocolate increased flow-mediated dilatation after acute (3.99%; 95% CI: 2.86, 5.12; 6 studies) and chronic (1.45%; 0.62, 2.28; 2 studies) intake and reduced systolic (−5.88 mmHg; −9.55, −2.21; 5 studies) and diastolic (−3.30 mmHg; −5.77, −0.83; 4 studies) blood pressure (Hooper et al 2008, Innes et al 2003). A 2006 systematic review of 136 experimental, observational and clinical studies on cocoa products and the risk of cardiovascular disease concluded that stearic acid may be neutral, while flavonoids are likely protective against cardiovascular mortality. The review found that multiple short-term, randomised feeding trials suggest cocoa and chocolate may exert beneficial effects on cardiovascular risk with a meta-analysis finding that flavonoids may lower risk of cardiovascular mortality, RR = 0.81 (95% CI: 0.71–0.92) comparing highest and lowest tertiles (Ding et al 2006).

While there are no published long-term, randomised controlled trials or prospective intervention studies of cocoa with hard clinical end points (Hooper et al 2008, Maron 2004), the cardiovascular benefits of cocoa are evident in a 15-year epidemiological study of 470 elderly men, which found that cocoa intake was inversely associated with blood pressure and 15-year cardiovascular and all-cause mortality. This study found a 50% reduction in cardiovascular-related death and all-cause mortality in men with the highest tertile of cocoa intake compared to the lowest tertile, suggesting that the pharmacological actions described for cocoa do, in fact, translate into reduced cardiovascular risk and other positive clinical outcomes (Buijsse et al 2006).

Hyperlipidaemia

While the lipid content of chocolate is relatively high, around one-third of the lipid in cocoa butter is composed of the fat, stearic acid, which exerts a neutral cholesterolaemic response in humans by an unknown mechanism (Kris-Etherton et al 1993, Steinberg et al 2003). Cocoa butter, however, is considered a high calorie fat because it has a high digestibility with a digestible energy value of 37 kJ/g in humans (Shahkhalili et al 2000). The results of a randomised, double-blind, cross-over design supplementation study suggest that the addition of calcium to chocolate can significantly reduce the absorption of cocoa butter, thus reducing the absorbable energy value of the chocolate by approximately 9% while at the same time reducing the plasma LDL cholesterol level and leaving the plasma HDL cholesterol level and taste of the chocolate unchanged (Shahkhalili et al 2001).

A double-blind study of 160 subjects that examined the effects of 13, 19.5 and 26 g/d of cocoa powder over 12 weeks found improved plasma lipid profiles in all groups with decreased plasma LDL, oxidised LDL and apo B and increased HDL concentrations in normocholesterolaemic and mildly hypercholesterolaemic human subjects (Baba et al 2007a, 2007b). Other short-term studies have demonstrated that cocoa flavanols can reduce serum LDL (Fraga et al 2005, Grassi et al 2005b) and increase HDL (Mursu et al 2004, Wan et al 2001) but long-term clinical trials are needed to determine its role in the clinical treatment of hypercholesterolaemia.

Cocoa bran may also have a use in hypercholesterolaemia, as well as constipation, because this low-fat, high-fibre material has been shown in a randomised, controlled, double-blind study to increase faecal bulk similarly to wheat bran and reduce the LDL/HDL cholesterol ratio, with

no effect on LDL cholesterol oxidation (Jenkins et al 2000).

Blood pressure

A meta-analysis of five randomised controlled studies involving a total of 173 subjects with a median duration of 2 weeks found significant reductions in both systolic and diastolic blood pressure in those consuming cocoa compared with cocoa-free controls (Taubert et al 2007). Clinical studies on flavanol-containing dark chocolate have demonstrated significant reductions in blood pressure in various populations, including normotensive people with mild hypercholesterolaemia (Erdman et al 2008), overweight adults (Davison et al 2008, Faridi et al 2008), patients with newly diagnosed essential hypertension (Grassi et al 2005b), patients with untreated upper-range prehypertension and stage 1 hypertension without concomitant risk factors (Taubert et al 2007) and healthy people (Grassi et al 2005a, Vlachopoulos et al 2007), including male soccer players (Fraga et al 2005).

While cocoa appears to have mild antihypertensive actions this is complemented by positive effects on other cardiovascular risk factors such as serum lipids, blood glucose and vascular function. These benefits are evident from the results of various clinical trials. For example, a randomised controlled trial using 100 g of dark chocolate containing approximately 500 mg of polyphenol consumed daily for 15 days found reductions in diastolic blood pressure by -11.9 ± 7.7 mmHg, decreases in serum LDL cholesterol from 3.4 to 3.0 mmol/L, improvements in flow-mediated dilation, and reductions in insulin resistance and increase insulin sensitivity in patients with newly diagnosed essential hypertension (Grassi et al 2005b). More recently, an 8-week double-blind, placebo-controlled, crossover study found that consumption of a cocoa flavanol-containing dark chocolate bar with added plant sterols lowered serum lipids and blood pressure in normotensive population with elevated cholesterol (Allen et al 2008). Yet another study found that 12 weeks of supplementation with high-flavanol cocoa led to reduced insulin resistance, diastolic BP and mean arterial BP and improved endothelial function independent of exercise in overweight and obese subjects (Davison et al 2008).

Vascular function

In a recent meta-analysis it was found that chocolate increases flow-mediated dilatation after acute and chronic intake (Hooper et al 2008).

A review of evidence from both animal and human studies suggests that human ingestion of the flavanol epicatechin is, at least in part, causally linked to the reported beneficial effects on vascular effects (Schroeter et al 2006) while results from a controlled trial suggest that formation of vasodilative nitric oxide contribute to beneficial vascular effects (Taubert et al 2007). A randomised, placebo-controlled, single-blind, crossover trial of 45 healthy adults further suggests that endothelial function improves significantly more with sugar-free than with regular cocoa and that sugar content may attenuate positive vascular effects while sugar-free preparations may augment them (Faridi et al 2008).

Improved vascular function after cocoa consumption has been demonstrated in a number of recent clinical trials involving hypercholesterolaemic postmenopausal women (Wang-Polagruto et al 2006), heart transplant recipients (Flammer et al 2007), and healthy subjects (Faridi et al 2008, Vlachopoulos et al 2007). It has also been found that flavanol-rich cocoa enhanced several measures of endothelial function to a greater degree among older than younger healthy subjects leading to the suggestion that the vascular effects of flavanol-rich cocoa may be greater among older people in whom endothelial function is more disturbed (Fisher & Hollenberg 2006).

There is evidence to suggest that the improved vascular function with flavanol-rich cocoa occurs acutely and in a sustained and dose-dependent manner with a maximal flow-mediated dilatation at 2 hours after a single-dose ingestion of flavanol-rich cocoa seen in a trial involving individuals with smoking-related endothelial dysfunction (Heiss et al 2007). Similar acute results were seen in a double-blind, randomised controlled trial involving 22 heart transplant recipients in which flavonoid-rich dark chocolate was seen to induce coronary vasodilation, improve coronary vascular function, decrease platelet adhesion and reduce serum oxidative stress 2 hours after consumption compared to cocoa-free control chocolate (Flammer et al 2007). Further evidence for acute effects comes from a study in which dark chocolate, but not white chocolate, was observed to significantly improve endothelial and platelet function in healthy smokers, with increased flow-mediated dilatation, increased total antioxidant status and reduced shear stress-dependent platelet function seen 2–8 hours after ingestion (Hermann et al 2006).

The above findings are contrasted by a 6-week double-blind, placebo-controlled, fixed-dose, parallel-group clinical trial of 101 healthy older adults that compared consumption of a 37 g dark chocolate bar or 237 mL of artificially sweetened cocoa beverage with placebo. This study failed to demonstrate the predicted beneficial effects of short-term dark chocolate and cocoa consumption on neuropsychological or cardiovascular health-related variables (Crews et al 2008).

Cardiac ischaemia

There is evidence suggesting that cocoa flavanols may help in reducing cardiac ischaemia with an animal study finding that epicatechin pretreatment confers cardioprotection in the setting of ischaemia reperfusion injury and that the effects are independent of changes in haemodynamics, sustained over time, and accompanied by reduced levels of indicators of tissue injury (Yamazaki et al 2008). Human studies suggest that cocoa consumption may have clinical benefits for cerebrovascular ischaemic syndromes, including dementias and stroke with dietary intake of flavanol-rich cocoa being associated with a significant increase in cerebral blood flow velocity in 34 healthy elderly humans (Sorond et al 2008). It

is further suggested that the prospect of increasing cerebral perfusion with cocoa flavanols is extremely promising with implications for stroke and dementia (Fisher et al 2006).

Premenstrual syndrome

Magnesium deficiency may contribute to PMS symptoms, which may be improved by chocolate or cocoa powder, which contain a high concentration of magnesium (≈ 100 mg/100 g in chocolate and 520 mg/100 g in cocoa powder). There is also some evidence to suggest that serotonin levels are low premenstrually, and it is possible that premenstrual chocolate cravings are the body's attempt to raise CNS concentrations of serotonin (Bruinsma & Taren 1999).

Enhanced cognitive function

The results of a double-blind, placebo-controlled study suggests that both milk and dark chocolate, but not white chocolate, improve cognitive function. A second double-blind study suggests that this improvement is due to the methylxanthin content of chocolate, with 11.6 g of cocoa powder producing identical improvements in cognitive function and the mood construct 'energetic arousal' as a mixture of caffeine (19 mg) and theobromine (250 mg) (Smit et al 2004).

Consumption of a 65 g chocolate bar was shown to significantly increase driving accuracy and reduce collisions compared to an equicaloric snack of cheese and biscuits or no snack in a controlled trial of 12 volunteers (Smith & Rich 1998).

Food source

Cocoa and chocolate are nutritious foods that contribute to caloric as well as trace mineral intake (Steinberg et al 2003). Milk chocolate has a relatively low glycaemic index of approximately 40 (Foster-Powell et al 2002) and this is attributed to the fat in chocolate slowing gastric emptying and thus the rate of subsequent digestion and absorption. The glycaemic effect of milk chocolate can be further reduced by replacing the sucrose with fructose or isomalt (Gee et al 1991). Foods containing cocoa have been shown to lead to a greater postprandial insulin secretion in healthy young adults than foods with alternative flavourings, despite having a similar glycaemic index. It is suggested that specific insulinogenic amino acids or greater cephalic phase insulin release may explain this finding, although the clinical implications are uncertain (Miller et al 1995).

Milk chocolate has also been shown to be a cheap, effective and palatable form of fatty meal for producing gall bladder contraction prior to cholecystography (Harvey 1977).

Colonic health and constipation

Cocoa mass has been suggested to have beneficial effects on metabolism of colonic microbiota (Mäkivuokko et al 2007) and cocoa husk rich in dietary fibre may assist paediatric patients with idiopathic chronic constipation. This is supported by an RCT that found that benefits seem to be more evident in paediatric constipated patients with slow colonic transit time (Castillejo et al 2006).

OTHER USES

Chocolate consumption 15 min before exercise has been shown to enhance exercise capacity, spare glycogen stores, delay fatigue and contribute to the recovery of glycogen repletion in healthy subjects (Chen et al 1996).

Cocoa may also be of use in lactose intolerance, with a feeding study of 35 subjects finding that the addition of cocoa significantly reduced breath hydrogen levels, as well as bloating and cramping, with the result being independent of the presence of sucrose and carrageenan (Lee & Hardy 1989).

Cocoa butter is used in the formation of suppositories and pessaries, as well as preparations for rough or chafed skin, chapped lips, sore nipples and various cosmetics (Raintree Nutrition 1996).

There is empiric evidence indicating successful treatment of copper deficiency by adding copper-rich cocoa powder to tube feeding formulas. It is suggested that although there are other high copper containing foods such as seaweed, oyster and beans, cocoa powder is advantageous due to the ease of adding it to feeding formulas (Tokuda et al 2006, Tokuda 2007).

DOSAGE RANGE

There is enormous variability in the polyphenol content of cocoa and chocolate and the flavanols in cocoa exist in a multitude of different stereochemical configurations, thus giving rise to a unique and complex mixture of compounds. Given this complexity, the quantitative analysis of cocoa flavanols can be challenging. It is only through the use of methods that can accurately quantify these flavanols that it will be possible to make meaningful dietary recommendations regarding the consumption of cocoa flavanol-containing foods (Kwik-Uribe & Bektash 2008).

Trials suggest that effective doses are approximately 40–100 g dark chocolate or 15–30 g cocoa powder, providing approximately 200–500 mg polyphenols.

TOXICITY

Cocoa contains caffeine, which is a mild CNS stimulant that can be profoundly toxic in large doses, resulting in arrhythmia, tachycardia, vomiting, convulsions, coma and death. The caffeine content of cocoa is variable, being approximately 0.009% by weight (Kondo et al 1996), with a typical milk chocolate bar containing approximately 10 mg of caffeine, compared to a cup of coffee, which contains approximately 100 mg (Bruinsma & Taren 1999). Fatal caffeine overdoses in adults have been reported, but are rare and typically require ingestion of more than 5 g of caffeine which would require consumption of more than 50 kg of chocolate (Kerrigan & Lindsey 2005).

ADVERSE REACTIONS

It is believed that chocolate is a trigger for migraine, yet there is inconsistent support for this. In one

small double-blind, parallel-group study of 12 patients who believed that chocolate could provoke their attacks, chocolate ingestion was more likely than placebo to trigger a typical migraine episode, with the median time until the onset of the attack of 22 h (Gibb et al 1991). Three other double-blind, placebo-controlled trials suggest that chocolate on its own rarely precipitates migraine (Marcus et al 1997, Moffett et al 1974), with the results of one trial suggesting that chocolate was no more likely to provoke headache than was carob in typical migraine, tension-type or combined headache sufferers (Marcus et al 1997).

Allergy to cocoa has been documented (Taibjee et al 2004) and it has been suggested that workers employed in the processing of cocoa and flour may be at a high risk for the development of allergic sensitisation and respiratory impairment (Zuskin et al 1998). One case report of cocoa aspiration causing severe aspiration pneumonitis in a 4-year-old has been documented (Lopatka et al 2004).

There is no evidence that chocolate contributes to acne (Ravenscroft 2005).

SIGNIFICANT INTERACTIONS

Polyphenols may reduce iron absorption, with a cocoa beverage containing 100–400 mg total polyphenols per serving having been shown to reduce iron absorption by approximately 70% (Hurrell et al 1999).

PREGNANCY USE

Cocoa and chocolate can be considered safe to use in pregnancy.

PRACTICE POINTS/PATIENT COUNSELLING

- Cocoa has many potential benefits for the cardiovascular system and may reduce blood pressure, inhibit platelet function, and improve the serum cholesterol profile, as well as having beneficial effects on insulin sensitivity. However, further research is required to confirm the benefits.
- Cocoa may act to enhance cognitive function in a similar way to coffee albeit with one-tenth the caffeine content.
- The most active agents in cocoa are the polyphenols, which are present in high amounts in dark chocolate, with lesser amounts in milk chocolate and minimal amounts in white chocolate.
- Cocoa powder contains minimal fat while dark chocolate contains less fat and sugar than milk or white chocolate. Beneficial effects are more likely to result from the use of cocoa powder or dark chocolate containing more than 50–60% cocoa mass.

PATIENTS' FAQs

What will this herb do for me?

Cocoa is a nutritious food that appears to have beneficial effects on blood pressure, cholesterol, blood clotting and psychological wellbeing.

When will it start to work?

Psychological effects of chocolate consumption may be evident immediately, whereas beneficial effects on blood pressure and cholesterol may be evident after 2–4 weeks.

Are there any safety issues?

Cocoa powder and dark chocolate are extremely safe and are unlikely to precipitate migraine, acne or dental caries or produce adverse effects from the caffeine content.

Coenzyme Q10

OTHER NAMES

Ubiquinone, ubidecarenone, ubiquinol

BACKGROUND AND RELEVANT PHARMACOKINETICS

Coenzyme Q10 (CoQ10) is an endogenous enzyme cofactor produced in humans from tyrosine through a cascade of reactions that itself requires eight vitamin coenzymes: tetrahydrobiopterin, vitamins B6, C, B2, B12, folic acid, niacin, and pantothenic acid (Folkers et al 1990). CoQ10 is also a fat-soluble antioxidant vitamin that plays an indispensable role in intracellular energy production.

Absorption occurs in the small intestine and tends to be poor, and is influenced by the presence of food and drink. CoQ10 is better absorbed in the presence of a fatty meal and is primarily bound to VLDL and LDL cholesterol. As such, serum levels of CoQ10 depend mostly on the amount of CoQ10-containing lipoproteins in circulation.

After incorporation into lipoproteins in the liver, CoQ10 is subsequently concentrated in various tissues, including the adrenals, spleen, kidneys, lungs and myocardium. Physical activity markedly reduces muscle tissue levels of CoQ10, which do not correlate to serum levels, suggesting that they are independently regulated (Laaksonen et al 1995a, Overvad et al 1999).

CHEMICAL COMPONENTS

The basic structure of ubiquinones is a benzoquinone head and terpinoid tail. The number of isoprenoid units in the tail portion varies among coenzymes. CoQ10 contains one quinine group and 10 isoprenyl units (Overvad et al 1999). Ubiquinones have been found in microorganisms, plants and animals but the CoQ10 form is the most common type found in mammals and humans.

FOOD SOURCES

Meat and fish products are the most concentrated sources of CoQ10, although lesser quantities are found in boiled broccoli, cauliflower, nuts, spinach and soy.

DEFICIENCY SIGNS AND SYMPTOMS

No recommended daily intake (RDI) levels have been established but there has been some speculation as to possible deficiency signs and symptoms. These include fatigue, muscle aches and pains and chronic gum disease.

Based on biopsy and/or serum samples, it has been observed that relative CoQ10 deficiency is associated with:

- congestive heart failure (Sole & Jeejeebhoy 2002, Spigset 1994a, Molyneux et al 2008)
- cardiomyopathy (Mortensen et al 1990)
- hypertension (Karlsson et al 1991)
- ischaemic heart disease (Karlsson et al 1991)
- hyperthyroidism (Bianchi et al 1999)
- breast cancer (Folkers et al 1997)
- cystic fibrosis (Laguna et al 2008)
- pancreatic insufficiency (Laguna et al 2008).

At this stage, it is still unclear whether an observation of relative deficiency in a particular disease state can be interpreted as part of the aetiology of that disease or whether lowered levels are a consequence of disease. In heart failure the situation is somewhat clearer, as patients with more advanced heart failure have significantly lower CoQ10 levels than those with less advanced conditions (Mortensen 1993).

A deficiency state may result from:

- impaired or reduced synthesis due to nutritional deficiencies, advancing age or medication use.
- interactions with drugs — there is clinical evidence that lovastatin, pravastatin and simvastatin reduce CoQ10 status in humans, which may, in part, explain the incidence of side effects, particularly myopathy, associated with their use (Bargossi et al 1994a, 1994b, Folkers et al 1990, Mortensen et al 1997). Clinical evidence also suggests that use of gemfibrozil and other fibric acid derivatives reduce CoQ10 levels (Aberg et al 1998). In vitro evidence suggests that other drugs, such as clonidine, hydralazine, hydrochlorothiazide, methyldopa, metoprolol and propranolol, may also decrease endogenous production of CoQ10 (Kishi et al 1975). Other sources cite tricyclic antidepressants as further medicines that can reduce CoQ10 status (Pelton et al 1999).
- inadequate intake or biosynthesis to meet increased requirements resulting from illness or excess physical exertion.
- genetic defects — deficiencies of CoQ10 have been associated with four major clinical phenotypes: (1) encephalomyopathy characterised by a triad of recurrent myoglobinuria, brain involvement, and ragged-red fibres; (2) infantile multisystemic disease typically with prominent nephropathy and encephalopathy; (3) cerebellar ataxia with marked cerebellar atrophy; and (4) pure myopathy (Quinzii et al 2008).

MAIN ACTIONS

Antioxidant

CoQ10 is a powerful antioxidant that buffers the potential adverse consequences of free radicals produced during oxidative phosphorylation in the inner mitochondrial membrane (Young et al 2007). It also binds to a site in the inner mitochondrial membrane that inhibits the mitochondrial permeability transition pore (MPTP).

Being a vital electron and proton carrier, CoQ10 supports adenosine triphosphate (ATP) synthesis in the mitochondrial inner membrane and stabilises cell membranes, preserving cellular integrity and function. It also reconstitutes vitamin E back into its antioxidant form by transforming vitamin E radicals to their reduced (active) form (Kaikkonen et al 2002).

Clinical note — Improving bioavailability

Absorption of compounds from the gastrointestinal tract is one of the important determinants of oral bioavailability. The absorption of oral CoQ10 is slow and limited due to its hydrophobicity and large molecular weight (Ochiai et al 2007). Research indicates that intestinal absorption of CoQ10 is enhanced when taken with food. To further improve bioavailability, specialty formulations have been produced by various manufacturers. Ochiai et al report that an emulsified form of CoQ10 had superior intestinal absorption and achieved a higher peak concentration than for a suspension formulation. Zmitek et al found that the water solubility and bioavailability of CoQ10 was increased significantly with the use of an inclusion complex with beta-cyclodextrin (Zmitek et al 2008). This complex is widely used as Q10Vital in the food industry. PureSorb-Q40 (water-soluble type CoQ10 powder) is reported in single-dose human and rat studies to have a greater absorption rate and absorbed volume of CoQ10, even taken postprandially, than those of regular CoQ10, which is lipid-soluble and generally taken in the form of soft gel capsules (Nuku et al 2007). Ullmann et al tested the bioavailability of DSM Nutritional Products Ltd (Kaiseraugst, Switzerland). CoQ10 10% TG/P (all-Q), a new tablet-grade formulation, with CoQ10 Q-Gel Softsules based on the Bio-Solv technology (Tishcon Corp., Salisbury, MD; marketed by Epic4Health, Smithtown, NY) and Q-SorB (Nature's Bounty, Bohemia, NY) (Ullmann et al 2005). They conducted a crossover study, which showed a bioequivalence between Q-Gel and all-Q, and both preparations were found to have better bioavailability properties than Q-SorB.

Recently, CoQ10 producers have synthesised ubiquinol (the reduced form of CoQ10) in an attempt to achieve better bioavailability and higher plasma concentrations with lower oral doses. Single-blind, placebo-controlled studies with healthy subjects testing single oral doses of 150 or 300 mg/day and longer term (4 weeks) oral administration of 90, 150, or 300 mg/day confirmed significant absorption of ubiquinol from the gastrointestinal tract (Hosoe et al 2007). Additionally, no safety concerns were noted on standard laboratory tests for safety or on assessment of adverse events for doses of up to 300 mg for up to 2 weeks after treatment completion.

Cardioprotective

CoQ10 supplementation offers myocardial protection during cardiac surgery, as indicated by clinical trials that observed improved postoperative cardiac function and reduced myocardial structural damage with presurgery administration of CoQ10. Studies with animal models have found that CoQ10 improves preservation of mitochondrial ATP-generating capacity after ischaemia and reperfusion (Pepe et al 2007). Treated animals demonstrate improved myocardial contractile function, increased coronary flow, reduced release of creatine kinase and malondialdehyde in the cardiac effluent.

Doxorubicin — induced cardiotoxicity

Irreversible oxidative damage to cardiac mitochondria is believed to account for the dose-related cardiomyopathy induced by anthracyclines. Tests in animal models have demonstrated that CoQ10 protects against doxorubicin cardiotoxicity, possibly via antioxidant activity and protection of mitochondrial function (Combs et al 1977, Folkers et al 1978). Clinical studies provide some support for the use of oral CoQ10 and indicate that adjunctive treatment provides protection against cardiotoxicity or liver toxicity during cancer therapy; however, further studies are required to prove this association conclusively (Roffe et al 2004).

Antihypertensive

In the 1970s, Yamagami et al observed a deficiency in CoQ10 in patients with hypertension (Yamagami et al 1975, 1976) and suggested that correction of the deficiency could result in hypertensive effects. Small studies were initially conducted with hypertensive patients identified as CoQ10 deficient.

Since then, numerous studies have been conducted. In 2007, a meta-analysis was published which evaluated 12 clinical trials (n = 362) and found that oral CoQ10 has the potential in hypertensive patients to lower systolic blood pressure by up to 17 mmHg and diastolic blood pressure by up to 10 mmHg without significant side effects (Rosenfeldt et al 2007). Interestingly, most trials fail to identify the subjects' baseline CoQ10 plasma levels and determine whether oral administration restored levels to within the normal range. It has been suggested that CoQ10 supplementation is associated with a decrease in total peripheral resistance, possibly because of action as an antagonist of vascular superoxide, either scavenging or suppressing its synthesis (McCarty 1999).

Immunostimulant activity

Several models of immune function have demonstrated the immunostimulant activity of CoQ10 (Folkers & Wolaniuk 1985).

Endothelial function

A randomised study involving 40 dyslipidaemic patients with type 2 diabetes mellitus found that oral CoQ10 (200 mg daily) taken over 12 weeks improved the endothelial function of conduit arteries of the peripheral circulation (Watts et al 2002). Another study of 80 subjects using the same dose for the same treatment period failed to improve endothelial forearm vasodilator function when given alone, although when combined with fenofibrate, the effectiveness was significant (Playford

et al 2003). Both research groups suggested that the effect may be due to an increase in the bioactivity of and/or responses to endothelium-derived relaxing factors, including nitric oxide.

Neuroprotective

Oxidative stress, resulting in glutathione loss and oxidative DNA and protein damage, has been implicated in many neurodegenerative disorders, including Alzheimer's disease, Parkinson's disease and Huntington's disease (Young et al 2007). Experimental studies in animal models suggest that CoQ10 may protect against neuronal damage that is produced by ischaemia, atherosclerosis and toxic injury. Though most have tended to be pilot studies, there are published preliminary clinical trials showing that CoQ10 may offer promise in many brain disorders.

Regulates genomic expression

CoQ10 targets the expression of multiple genes, especially those involved in cell signalling and intermediary metabolism (Pepe et al 2007).

OTHER ACTIONS

Recent research has identified that CoQ10 affects the expression of genes involved in human cell signalling, metabolism and transport (Groneberg et al 2005). This mechanism may account for some of the pharmacological effects observed with CoQ10 supplementation. Additionally, CoQ10 inhibits the formation of beta-amyloid protein in vitro (Ono et al 2005). CoQ10 affects the transport activity of P-gp, although the clinical significance of this remains to be established (Itagaki et al 2008).

CLINICAL USE

Cardiovascular diseases

In 1972, Folkers and Littaru from Italy documented a deficiency of CoQ10 in human heart disease (Ernster & Dallner 1995).

Since those early reports, a steady stream of research articles has been published and clinical experience in its use as an adjunct to conventional treatment in various forms of heart disease has accumulated. Data from laboratory studies have also accumulated and generally provide a supportive basis for its use.

A review by Langsjoen and Langsjoen of over 34 controlled studies and additional open studies concluded that CoQ10 supplementation goes beyond the correction of a simple deficiency state with strong evidence to show that it has the potential to reduce the risk of cardiovascular disease by the maintenance of optimal cellular and mitochondrial function in cardiomyocytes.

Although investigation into specific cardiovascular diseases has been undertaken, the results of an open study of 424 patients suggested that CoQ10 may have widespread benefits. The study found that CoQ10 supplementation produced clinically significant improvements in cardiac function and reduced medication requirements in patients with a range of cardiovascular disorders, including ischaemic cardiomyopathy, dilated cardiomyopathy, primary diastolic dysfunction, hypertension, mitral valve prolapse and valvular heart disease (Langsjoen et al 1994a).

A recent review by Langsjoen & Langsjoen (1999) of more than 34 controlled studies and additional open studies concluded that CoQ10 supplementation goes beyond the correction of a simple deficiency state, with strong evidence to show that it has the potential to reduce the risk of cardiovascular disease by the maintenance of optimal cellular and mitochondrial function in cardiomyocytes.

Congestive heart failure

CoQ10 has been reported to improve symptoms of congestive heart failure (CHF) and quality of life (QOL), and to reduce hospitalisation, and is used as standard therapy for CHF in some parts of Europe, Russia and Japan.

At the cellular level, oxidative stress, mitochondrial dysfunction and energy starvation are believed to play important roles in the aetiology of CHF (Overvad et al 1999). As such, it has been suggested that low CoQ10 levels identified in patients with CHF may play a role in disease development (Jeejeebhoy et al 2002) and that restoring myocyte nutrition with vitamin supplementation, including CoQ10, produces significant improvement (Sole & Jeejeebhoy 2002). Furthermore, an inverse relationship has been found between the severity of CHF and CoQ10 levels in blood from endocardial biopsies.

Clinical studies

CoQ10 improves systolic function in patients with heart failure as shown by a statistically significant change in ejection fraction (EF), cardiac output and stroke index compared to placebo according to the most recent meta-analysis (Sander et al 2006). The primary outcome measure was EF and secondary outcome measures were cardiac output (CO), cardiac index (CI), stroke volume (SV) and stroke index (SI). The analyses used data from 11 eligible trials (randomised, double-blind, placebo-controlled) and CoQ10 doses ranged from 60 to 200 mg/day with treatment periods ranging from 1 to 6 months. Overall, there was a significant 3.7% net improvement in EF ($P < 0.00001$). Interestingly, more profound effects on EF were observed for patients not receiving angiotensin-converting enzyme inhibitors (6.74% net improvement). To put the degree of EF improvement into perspective, the beta-blocker drug, metoprolol, is associated with an average increase in EF of 7.4% (range 3%–16%), whereas carvedilol is associated with an increase of 5% (3%–11%). CoQ10 also significantly increased the cardiac output by an average of 0.28 L/min. When a less conservative meta-analysis model was used, cardiac index, stroke volume and stroke index were also significantly improved. Sander et al (2006) used data from clinical trials by Hofman-Bang et al 1995, Khatta et al 2000, Langsjoen et al 1985, Morisco et al 1994, Munkholm et al 1999, Permanetter et al 1992, Watson et al 1999, Keogh et al 2003, Serra et al 1991, Pogessi et al 1991, Judy et al 1986.

This adds weight to the previous findings of a meta-analysis of eight RCTs which showed that adjunctive therapy with CoQ10 leads to significant improvements in total work capacity, cardiac index, cardiac output and stroke volume (Soja & Mortensen 1997). The subjects had cardiomyopathy and CHF of varying aetiologies (idiopathic, dilated, ischaemia, hypertension, valvular heart disease and congenital heart disease).

The largest controlled trial in adult cardiomyopathy and CHF was reported in 1993 (Morisco et al 1993) and involved 641 patients with New York Heart Association (NYHA) classes III and IV. The double-blind, placebo-controlled study used a dose of 2 mg CoQ10 per kg daily over 1 year and found that active treatment significantly improved arrhythmias and episodes of pulmonary oedema, as well as reducing the number of hospitalisations and overall mortality rate. The same researchers conducted a smaller double-blind, crossover study that again produced positive results. Oral CoQ10 (150 mg/day) taken for 4 weeks significantly improved EF, stroke volume and cardiac output in chronic heart failure patients (Morisco et al 1994).

Although CoQ10 is generally studied in heart failure patients (NYHA class II and III), a double-blind, placebo-controlled, randomised study published in 2004 (Berman et al) describes its effects in end-stage heart failure among patients awaiting heart transplantation. The study of 32 subjects compared Ultrasome CoQ10 (60 mg/day) to placebo over 3 months as an adjunct to conventional therapy. Significant improvements in functional status, clinical symptoms and QOL were reported for CoQ10; however, no significant changes in the echocardiography parameters (dimensions and contractility of cardiac chambers) or atrial natriuretic factor and tumour necrosis factor (ANF and TNF) blood levels were observed.

Whilst the overall body of evidence supports the use of CoQ10 in heart failure, not every trial has produced positive results. One theory proposes that the most profound effects on myocardial function occur when supplementation is given shortly after the diagnosis of CHF and before the development of irreversible myocyte loss and fibrosis. Some commentators have suggested that the sample sizes, severity and duration of disease, treatment dose and duration of treatment may have contributed to the neutral effects observed (Langsjoen 2000). An important issue that often fails to be considered is the measurement of plasma and myocyte CoQ10 concentrations and whether supplementation has achieved levels that are within the range likely to produce clinical results.

More recently, Langsjoen and Langsjoen (2008) reported that patients with CHF, NYHA class IV, often fail to achieve adequate plasma CoQ10 levels on supplemental ubiquinone at dosages up to 900 mg/day. These patients often have plasma total CoQ10 levels of less than 2.5 microgram/mL and limited clinical improvement. One theory proposed to explain this discrepancy is that critically ill patients have intestinal oedema, which may reduce oral CoQ10 absorption. To test this hypothesis, seven patients with advanced CHF were identified (mean EF 22%) with subtherapeutic plasma CoQ10 levels with mean level of 1.6 microgram/mL on an average dose of 450 mg of ubiquinone daily (150–600 mg/day) (Langsjoen & Langsjoen 2008). The doses of all patients were increased by an average of 580 mg/day of ubiquinol (450–900 mg/day) with follow-up plasma CoQ10 levels, clinical status and EF measurements by echocardiography. At these higher doses, mean plasma CoQ10 levels increased from 1.6 microgram/mL (0.9–2.0 microgram/mL) up to 6.5 microgram/mL (2.6–9.3 microgram/mL) with a subsequent mean improvement in EF from 22% (10–35%) to 39% (10–60%). Substantial clinical improvements were also reported with higher dosing as patients' NYHA class improving from a mean of IV to a mean of II (I–III).

Hypertension and cholesterol lowering

CoQ10 has been studied both as stand-alone and adjunctive treatment in hypertension. In 2007, a meta-analysis was published which evaluated 12 clinical trials (n = 362) consisting of 3 randomised controlled trials, 1 crossover study and 8 open label studies (Rosenfeldt et al 2007). In the randomised controlled trials (n = 120), systolic blood pressure in the treatment group decreased by 16.6 mmHg (12.6–20.6, $P < 0.001$), with no significant change in the placebo group. Diastolic blood pressure in the treatment group was also significantly reduced after treatment by 8.2 mmHg (6.2–10.2, $P < 0.001$), with no significant change in the placebo group. In the crossover study (n = 18), systolic blood pressure decreased by 11 mmHg and diastolic blood pressure by 8 mmHg with no significant change in the placebo group. In the open label studies (n = 214), mean systolic blood pressure decreased by 13.5 mmHg (9.8–17.1, $P < 0.001$) with active treatment and mean diastolic blood pressure significantly decreased by 10.3 mmHg (8.4–12.3, $P < 0.001$).

Previously, a review of eight studies concluded that supplemental CoQ10 results in a mean decrease in systolic blood pressure of 16 mmHg and in diastolic blood pressure of 10 mmHg (Rosenfeldt et al 2003). The effect on blood pressure has been reported within 10 weeks of treatment at doses usually starting at 100 mg daily. One small 10-week open study of 26 subjects with essential hypertension study found that an oral dose of 50 mg taken twice daily also reduced total serum cholesterol levels with a modest increase in serum HDL cholesterol (Digiesi et al 1994).

Cardiac surgery

The use of CoQ10 supplementation before cardiac surgery has been studied since the early 1980s. Since that time, growing evidence suggests that CoQ10 can reduce reperfusion injury after coronary artery bypass surgery, reduce surgical complications, accelerate recovery times and, possibly, shorten hospital stays (Chello et al 1996, Chen et al 1994, Judy et al 1993, Rosenfeldt et al 2002, Taggart et al 1996, Tanaka et al 1982, Zhou et al 1999). In general, the studies that achieved positive results had provided supplements for 1–2 weeks prior to surgery.

One study observed that continuing to administer CoQ10 for 30 days after surgery hastened the recovery course to 3–5 days without complications, compared with a 15–30-day recovery period for a control group, which did experience complications (Judy et al 1993, Rosenfeldt et al 2002).

The most recent randomised, double-blind trial investigated the effects of preoperative high-dose CoQ10 therapy (300 mg/day) in patients undergoing elective cardiac surgery (mainly coronary artery bypass graft surgery or valve replacement) (Rosenfeldt et al 2005). Approximately 2 weeks of active treatment resulted in significantly increased CoQ10 levels in the serum, atrial myocardium and mitochondria compared with placebo, but no significant change in the duration of hospital stay. Active treatment also improved subjective assessment of physical QOL (+13%) compared with placebo; however, the authors point out that physical QOL does not necessarily indicate improved cardiac pump function and further studies are required with larger sample sizes to clarify the role of CoQ10 in cardiac surgery.

The use of CoQ10 as preoperative treatment may hold special significance for older patients, who generally experience poorer recovery of cardiac function after cardiac surgery than their younger counterparts. One explanation gaining support is that the aged myocardium has less homeostatic reserve and so is more sensitive to both aerobic and physical stress and less well equipped to deal with cardiac surgery. Two studies have confirmed this theory, demonstrating an age-related deficit in myocardial performance after aerobic and ischaemic stress and the capacity of CoQ10 treatment to correct age-specific diminished recovery of function (Rosenfeldt et al 1999).

Besides improving cardiac resilience, CoQ10 has been found to reduce skeletal muscle reperfusion injury after clamping and declamping by reducing the degree of peroxidative damage (Chello et al 1996).

Angina pectoris

Based on the observation of relative CoQ10 deficiency in patients with ischaemic heart disease, and in animal models showing that it prevents reperfusion injury, several randomised clinical trials have been performed in angina pectoris. The doses used have varied from 60 mg to 600 mg daily, and the time frames for use varied from 4 days to 4 weeks. Overall, CoQ10 appears to delay signs of oxygen deficiency in the myocardium, increases patients' stamina on a treadmill or during exercise and delays the onset of angina (Overvad et al 1999), as well as reducing glyceryl trinitrate consumption (Kamikawa et al 1985).

Statin drug use

The mechanism of action of the statin group of drugs is inhibition of 3-hydroxy-3-methylglutaryl-coenzyme A (HMG-CoA) reductase, an enzyme involved in the biosynthesis of cholesterol from acetyl-CoA. Inhibition of this enzyme also adversely affects the intrinsic biosynthesis of CoQ10, as demonstrated in laboratory animals and humans and reduces plasma and myocardial levels of CoQ10 (Bargossi et al 1994b, Folkers et al 1990, Rosenfeldt et al 2005).

This fact, plus the role of CoQ10 in mitochondrial energy production, which is required in muscle function, has prompted the hypothesis that statin-induced CoQ10 deficiency is involved in the pathogenesis of statin myopathy and long-term statin use may actually impair cardiac function.

At least nine observational studies and six randomised controlled trials have demonstrated that statins reduce plasma/serum levels of CoQ10 by 16–54% (Marcoff & Thompson 2007). This could be related to the fact that statins lower plasma LDL levels, and CoQ10 is mainly transported in LDL; however, a decrease is also found in platelets and in lymphocytes of statin-treated patients and, therefore, it could truly depend on inhibition of CoQ10 synthesis (Littarru & Langsjoen 2007).

Reduced muscle CoQ10 concentrations are of greater concern because they may be associated with impaired cardiac function and, theoretically, increased risk of myopathy. The results obtained by Folkers et al (1990), Silver et al (2004) and Paiva et al (2005) provide support for an association between statin use and reduced intramuscular CoQ10 levels, whereas other studies find no change to intramuscular CoQ10 concentrations (Laaksonen et al 1994, 1995a, 1996), increased risk of cardiovascular disease or impaired left ventricular systolic or diastolic function in hypercholesterolaemic subjects (Colquhoun et al 2005, Stocker et al 2006). Further investigation is required to determine whether long-term reductions of CoQ10 as a result of chronic statin therapy increase the risk of myopathy and whether subpopulations at risk, such as patients with familial hypercholesterolaemia, heart failure, or who are over 65 years of age, may benefit from CoQ10 supplementation (Levy & Kohlhaas 2006).

Whilst myopathy is considered a relatively rare side effect of statin therapy, headache is more common. An association between headache and CoQ10 deficiency was identified in a recent study which found that CoQ10 supplementation significantly improved headache disability and headache frequency (Hershey et al 2007). Whether the observed headache side effect reported with statin use would respond to CoQ10 treatment is speculative and deserves further investigation.

Anecdotally, there are reports of fatigue and general malaise with statin use which respond to CoQ10 supplementation. Controlled trials are unavailable to determine the significance of these observations; however, a case study by Walravens et al (1989) illustrates the point.

A 48-year-old physician was taking lovastatin 20 mg/day for moderate hypercholesterolaemia and he also jogged three times a week, with occasional high-altitude cycling. After 2–3 weeks of lovastatin treatment, exercise became difficult because of muscle soreness and fatigue and at 7 weeks he had severe cramps while cycling. Soreness and weakness continued for 6 months, after which he began

taking CoQ10 (30 mg daily). After a few days' treatment, muscle fatigue after exercise ceased and the severe cramps did not recur. Restarting lovastatin 10 mg 5–6 times weekly did not result in muscle cramping while CoQ10 was taken.

Currently, it is still not clear whether CoQ10 supplementation should be considered a necessary adjunct to all patients taking statin drugs; however, there are no known risks to this supplement and there is some anecdotal and clinical trial evidence of its effectiveness (Marcoff & Thompson 2007). Consequently, CoQ10 can be tested in patients requiring statin treatment, who develop statin myalgia, and who cannot be satisfactorily treated with other agents and also in those patients considered at risk of deficiency, in particular, patients with a family history of heart failure, elevated cholesterol levels and who are over 65 years of age and taking statin drugs long-term (Levy & Kohlhaas 2006). A trial of therapy may also be worthwhile in patients reporting fatigue, malaise and headaches as side effects to statin treatment.

Arrhythmias

A small open study of 27 volunteers showed that CoQ10 exerts antiarrhythmic effects in some individuals (Fujioka et al 1983).

Sports supplement/ergogenic aid

Because CoQ10 is essential for energy metabolism, researchers have speculated that it may improve athletic performance. Nine clinical studies investigating the effects of CoQ10 supplementation on physical capacity were located, generally showing negative results (Bonetti et al 2000, Braun et al 1991, Laaksonen et al 1995b, Malm et al 1997, Mizuno et al 2008, Nielsen et al 1999, Porter et al 1995, Snider et al 1992, Weston et al 1997, Ylikoski et al 1997). Test doses of CoQ10 varied from 60 mg to 150 mg daily over time periods of 28 days to 8 weeks. Of these eight studies, only two studies produced positive results. One was a double-blind, crossover trial which produced positive results on both objective and subjective parameters of physical performance (Ylikoski et al 1997). In that study 94% of athletes felt that CoQ10 had improved their performance and recovery times, compared with the 33% receiving placebo. Most recently, another double-blind, placebo-controlled, crossover study of healthy people found that oral CoQ10 (300 mg/day) taken for 8 days improved subjective fatigue sensation and physical performance during fatigue-inducing workload trials (Mizuno et al 2008).

Of the others, one study found that 150 mg CoQ10 taken over 2 months had no effect on maximal oxygen consumption, lactate thresholds or forearm blood flow, although it did improve the subjective perceived level of vigour (Porter et al 1995). Another study demonstrated that CoQ10 did not alter physiological or metabolic parameters measured as part of cardiopulmonary exercise testing; however, it did extend the time and the workload required to reach muscular exhaustion (Bonetti et al 2000). Five further clinical trials produced negative results.

One retrospective study found that muscle CoQ10 levels were positively related to exercise capacity and/or marathon performance, suggesting that runners with the highest levels performed better than those with lower levels (Karlsson et al 1996).

Postpolio syndrome

One randomised, double-blind study tested whether adding oral CoQ10 to resistance training would further improve muscle strength and endurance as well as functional capacity and health-related quality of life (Skough et al 2008). All 14 patients (8 women and 6 men) with postpolio syndrome in the 12-week study undertook muscular resistance training 3 days/week and were randomised to receive either CoQ10, 200 mg/day, or placebo. For all patients, muscle strength, muscle endurance and quality of life regarding mental health increased statistically significantly but there was no significant difference between the CoQ10 and placebo groups.

Chronic obstructive pulmonary disease (COPD)

At least two clinical trials have investigated the use of CoQ10 supplementation in COPD (Fujimoto et al 1993, Satta et al 1991). In one study, 20 patients with COPD were randomly assigned CoQ10 (50 mg) or placebo as part of their pulmonary rehabilitation program (Satta et al 1991). Treatment resulted in a 13% increase in maximum oxygen consumption and a 10% increase in maximum expired volume — both significant improvements. A dose of CoQ10 (90 mg) daily over 8 weeks was studied in a smaller trial of patients with COPD (Fujimoto et al 1993). Significantly elevated serum CoQ10 levels were associated with improved hypoxaemia at rest, but pulmonary function was unchanged.

Cystic fibrosis

Pancreatic insufficiency and a diminished bile acid pool cause malabsorption of important essential nutrients and other dietary components in cystic fibrosis (CF) (Papas et al 2008). Of particular significance is the malabsorption of fat-soluble antioxidants such as carotenoids, tocopherols and CoQ10. Despite supplementation, CF patients are often deficient in these compounds, resulting in increased oxidative stress, which may contribute to adverse health effects. Papas et al conducted a pilot study to evaluate the safety of a novel micellar formulation (CF-1) of fat-soluble nutrients and antioxidants, which included CoQ10 (30 mg/10 mL), alpha-tocopherol (200 IU), beta-carotene (30 mg), gamma tocopherol (94 mg), vitamin D3 (400 IU) and other tocopherols (31 mg). Ten CF subjects aged 8–45 years were given 10 mL of the formulation orally daily for 56 days after a 21-day washout period in which subjects stopped supplemental vitamin use except for a standard multivitamin. No serious adverse effects, laboratory abnormalities or elevated nutrient levels (above normal) were identified for the treatment. Supplementation with CF-1 significantly increased CoQ10, beta-carotene and gamma tocopherol from baseline in all subjects and improvements in antioxidant plasma levels were associated with reductions in airway inflammation in CF patients.

Periodontal disease

CoQ10 is used both topically and internally for the treatment of chronic periodontal disease. Topical application has been shown to improve adult periodontitis (Hanioka et al 1994) and a small open study has shown that oral CoQ10 supplementation can produce dramatic results within 5–7 days, making location of baseline biopsy sites impossible (Wilkinson et al 1975).

Parkinson's disease

Parkinson's disease (PD) is a neurodegenerative disorder characterised by progressive loss of dopaminergic neurons within the substantia nigra pars compacta. The pathogenesis of PD remains obscure, but there is increasing experimental and clinical data which points to a defect of the mitochondrial respiratory chain, oxidative damage and inflammation as major pathogenetic factors in PD, inducing degeneration of nigrostriatal dopaminergic neurons (Beal 2003, Ebadi et al 2001, Gotz et al 2000, Storch 2007).

It has been theorised that restoration of mitochondrial respiration and reduction of oxidative stress by CoQ10 could induce neuroprotective effects against the dopaminergic cell death in PD and could also enhance dopaminergic dysfunction (Storch 2007). As a result, CoQ10 might exert both neuroprotective and symptomatic effects in PD. Current data from controlled clinical trials are not sufficient to answer conclusively whether CoQ10 is neuroprotective in PD or has significant symptomatic effects, as results are inconsistent. The data are presented here.

A number of preclinical studies using in vitro and in vivo models of PD have demonstrated that CoQ10 can protect the nigrostriatal dopaminergic system, and levels of CoQ10 have been reported to be decreased in blood and platelet mitochondria from subjects with PD (Shults 2005). As a result, a multicentre study was conducted to determine whether CoQ10 supplementation would exert beneficial effects in the disease.

The randomised, placebo-controlled, double-blind study compared three different doses of CoQ10 (300 mg, 600 mg or 1200 mg) with placebo in 80 subjects with early PD. After 9 months of treatment, subjects taking 1200 mg CoQ10 daily experienced significant improvements in disability compared with the placebo group. CoQ10 was also well tolerated at the dosages studied (Shults et al 2002). In 2003, results were published of a double-blind, placebo-controlled study, which showed that even a relatively low dose CoQ10 (360 mg/day) taken for a short period (4 weeks) produced a significant mild benefit on PD symptoms and significantly improved visual function compared with placebo (Muller et al 2003).

The safety and tolerability of high-dose CoQ10 in subjects with PD was investigated in an open study of 17 patients (Shults et al 2004). The study used an escalating dosage of 1200, 1800, 2400 and 3000 mg/day administered together with vitamin E (alpha-tocopherol) 1200 IU/d and failed to identify any serious adverse effects with CoQ10 administration. It also identified that plasma CoQ10 levels reached a plateau at 2400 mg/day, suggesting that higher treatment doses are not required.

In 2007, a multicentre, randomised, double-blind, placebo-controlled, stratified, parallel-group, single-dose trial was conducted which used nanoparticular CoQ10, as it has been shown to provide symptomatic effects in patients with mid-stage PD without motor fluctuations (Storch et al 2007). The study of 131 volunteers with PD without motor fluctuations and a stable antiparkinsonian treatment were randomly assigned to receive placebo or nanoparticular CoQ10 (100 mg 3 times a day) for a treatment period of 3 months. This form and dose of CoQ10 led to plasma levels similar to 1200 mg/d of standard formulations. No significant changes to the Unified Parkinson's Disease Rating Scale (UPDRS) were observed with CoQ10 after stratification for L-dopa dosing.

Alzheimer's dementia

Similar to Parkinson's disease, mitochondrial dysfunction and oxidative damage appear to play a role in the pathogenesis of Alzheimer's dementia and, therefore, CoQ10 supplementation has been investigated as a possible treatment. Currently, evidence is limited to test tube and animal studies and is far from definitive.

Recently, CoQ10 was shown to inhibit beta-amyloid formation in vitro (Ono et al 2005) and protect against brain mitochondrial dysfunction induced by a neurotoxic beta-peptide in a study using brain mitochondria isolated from diabetic rats (Moreira et al 2005). McDonald et al (2005) conducted two studies with test animals and found that supplemental CoQ10 (123 mg/kg/day) taken with alpha-tocopherol acetate (200 mg/kg/day) improved age-related learning deficits; however, supplementation of CoQ10 alone at this dose, or higher doses of 250 or 500 mg/kg/day, failed to produce comparable effects.

Haemodialysis

Increased oxidative stress is associated with various complications in haemodialysis (HD) patients (Sakata et al 2008). Due to its antioxidant activity, CoQ10 was administered for 6 months to 36 HD patients. Treatment was found to partially reduce oxidative stress as measured by a decrease of oxygen radical absorbing capacity (ORAC) and Trolox equivalent antioxidant capacity (TEAC).

Migraine

An open-labelled trial investigated the effects of oral CoQ10 supplementation (150 mg/day) over 3 months in 32 volunteers with a history of episodic migraine with or without aura. CoQ10 significantly reduced both the frequency of attacks and the number of days with migraine after 3 months' treatment (Rozen et al 2002). In 2005, Sandor et al investigated the effects of CoQ10 (300 mg/day) taken over 3 months in 42 migraine subjects in a double-blind, randomised, placebo-controlled study; 47.6% of CoQ10-treated patients responded to treatment compared with 14.4% for placebo, experiencing

a (50% or less) reduction in migraine frequency (number needed to treat, 3). Active treatment was superior to placebo for reducing attack frequency, headache days and days with nausea in the third treatment month and was well tolerated.

In 2007, Hershey et al assessed 1550 paediatric patients (mean age 13.3 ± 3.5, range 3–22 yrs) attending a tertiary care centre with frequent headaches for CoQ10 deficiency (Hershey et al 2007). Of these patients, 32.9% were below the reference range. Patients with low CoQ10 were recommended to start 1 to 3 mg/kg/day of CoQ10 in liquid gel capsule formulation as part of their multidisciplinary treatment plan. Those patients who returned for follow-up (mean, 97 days) demonstrated significantly increased total CoQ10 levels and significant improvements for headache disability and headache frequency (19.2 ± 10.0 to 12.5 ± 10.8).

OTHER USES

Cancer

Currently, controlled studies are not available to determine the clinical effectiveness of CoQ10 in cancer; however, there have been several case reports of CoQ10 (390 mg/day) successfully reducing metastases or eliminating tumours entirely (Lockwood et al 1994, 1995). An in vivo study found that CoQ10 enhances the effects of immunochemotherapy (Kokawa et al 1983).

Reducing cardiotoxic effects of anthracyclines

There is some evidence that CoQ10 supplementation protects the mitochondria of the heart from anthracycline-induced damage. A systematic review of six studies (three randomised), in which patients in five of the six studies received anthracyclines, concluded that CoQ10 provides some protection against cardiotoxicity or liver toxicity during cancer treatment; however, weaknesses in design and reporting made it difficult to reach a definitive conclusion (Roffe et al 2004). Despite the high level of heterogeneity, it appeared that CoQ10 had a stabilising effect on the heart. Importantly, CoQ10 was not shown to interfere with standard treatments in the clinical trials reviewed and no adverse effects were reported in any single study for CoQ10 administration.

Sample sizes in the studies ranged from 19 to 88 patients and one study included children. The methods researchers used to measure patient tolerance to anthracyclines and other cancer treatments were heart function and toxicity in five studies and hair loss and liver enzymes in one study. The dose of CoQ10 investigated in the trials ranged from 90 mg/day to 240 mg/day.

Mitochondrial myopathy

An open multicentre study involving 44 volunteers with mitochondrial myopathies showed that treatment with CoQ10 (2 mg/kg daily) over 6 months decreased postexercise lactate levels by at least 25% in 16 patients. Of those responding, a further 3 months' treatment with either CoQ10 or placebo produced no significant differences (Bresolin et al 1990).

Age-related macular degeneration (in combination)

Mitochondrial dysfunction is likely to play a role in the pathophysiology of age-related macular degeneration (Littarru & Tiano 2005). As a result, researchers are starting to investigate therapeutic agents, such as CoQ10, which affect mitochondrial function.

Metabolic therapy consisting of a combination of omega-3 fatty acids, CoQ10 and acetyl-L-carnitine may have potential benefits as a treatment for early age-related macular degeneration by improving mitochondrial dysfunction, specifically improving lipid metabolism and ATP production in the retinal pigment epithelium, improving photoreceptor turnover and reducing generation of reactive oxygen species (Feher et al 2007). According to a pilot study and a randomised, placebo-controlled, double-blind clinical trial, both central visual field and visual acuity slightly improved after 3–6 months of treatment with the metabolic combination; however, the difference was statistically significant as compared to the base line or to controls. Treatment produced an improvement in fundus alterations as the drusen-covered area decreased significantly compared to base line readings or controls, and was most marked in the less affected eyes. Interestingly, a prospective case study on long-term treatment confirmed these observations. Visual function remained stable and, generally, drusen regression continued for years and for some intermediate and advanced cases, significant regression of drusen was found with treatment.

Friedreich's ataxia

Decreased mitochondrial respiratory chain function and increased oxidative stress and iron accumulation play significant roles in the disease mechanism of Friedreich's ataxia (FRDA), raising the possibility that energy enhancement and antioxidant therapies may be an effective treatment (Cooper & Schapira 2007). Therapeutic avenues for patients with FRDA are beginning to be explored, in particular, targeting antioxidant protection, enhancement of mitochondrial oxidative phosphorylation and iron chelation. The use of quinone therapy (ubiquinone and idebenone) has been the most extensively studied to date with clear benefits demonstrated using evaluations of both disease biomarkers and clinical symptoms (Mariotti et al 2003).

A 4-year follow-up on 10 Friedreich's Ataxia patients treated with CoQ10 (400 mg/day) and vitamin E (2100 IU/d) showed a substantial improvement in cardiac and skeletal muscle bioenergetics and heart function which was maintained over the test period and some clinical feature of disease (Hart et al 2005). Comparison with cross-sectional data from 77 patients with FRDA indicated the changes in total International Cooperative Ataxia Rating Scale and kinetic scores over the trial period were better than predicted for seven patients, but the posture and gait and hand dexterity scores progressed as predicted.

Tinnitus
In patients with a low plasma CoQ10 concentration, CoQ10 supply may decrease the tinnitus expression in chronic tinnitus aurium according to a 16-week prospective, non-randomised clinical trial (n = 20) (Khan et al 2007). CoQ10 was tested in this population because of its antioxidant activity.

Myelodysplastic syndromes
The myelodysplastic syndromes (MDS) are a collection of haematopoietic disorders with varying degrees of mono- to trilineage cytopenias and bone marrow dysplasia. In recent years, much progress has been made in the treatment of MDS and there are now several therapeutic compounds used with varying levels of success; however, side effects make them unattractive for patients (Galili et al 2007).

Galili et al tested CoQ10 supplementation in MDS patients with low to intermediate-2 risk disease. A variety of responses were observed in seven of 29 patients. Sequencing mitochondrial DNA (mtDNA) from pretreatment bone marrows showed multiple mutations, some resulting in amino acid changes, in 3/5 non-responders, 1/4 responders and in two control samples. Based on these observations, it appears that CoQ10 may be of clinical benefit in a subset of MDS patients, but responders cannot be easily preselected on the basis of either the conventional clinical and pathologic characteristics or mtDNA mutations.

Huntington's chorea
A randomised, double-blind study involving 347 patients with early Huntington's chorea showed that a dose of CoQ10 (600 mg/day) taken over 30 months produced a trend towards slow decline as well as beneficial trends in some secondary measures; however, changes were not significant at this dosage level (Huntington's Study Group 2001).

DOSAGE RANGE

According to clinical studies
- Generally 100–150 mg/day has been used for conditions such as congestive cardiac failure (Mortensen et al 1990), hypertension, neurological disease, performance enhancement, periodontal disease (Wilkinson et al 1975).
- As preparation for cardiac surgery: 100–300 mg/day for 2 weeks before surgery followed by 100 mg/day for 1 month after surgery has been used (Judy et al 1993, Rosenfeldt et al 2002, 2005).
- Angina pectoris: 60–600 mg daily.
- Chronic obstructive pulmonary disease: 50–90 mg daily.
- Congestive heart failure: 60–200 mg/day.
- Huntington's chorea: 600 mg daily.
- Migraine: 150–300 mg daily.
- Parkinson's disease (< 1200 mg/day) (Shults et al 2002) (efficacy uncertain)
- Adjunct to chemotherapy (anthracyclines) 90–240 mg/day but evidence is not definitive.

ADVERSE REACTIONS
CoQ10 appears relatively safe and non-toxic and is extremely well tolerated. Dizziness, nausea, epigastric discomfort, anorexia, diarrhoea, photophobia, irritability and skin rash occur in less than 1% of patients. This tends to occur with higher doses (> 200 mg/day).

SIGNIFICANT INTERACTIONS
When controlled studies are not available, interactions are based on evidence of pharmacological activity, case reports and other evidence and are largely theoretical.

Beta-adrenergic antagonists
Induces CoQ10 depletion — beneficial interaction with co-administration (Stargrove et al 2008).

Doxorubicin
Tests in animal models have demonstrated that CoQ10 protects against doxorubicin cardiotoxicity (Combs et al 1977, Folkers et al 1978) and clinical studies provide some support for the use of oral CoQ10 and indicate that adjunctive treatment provides some protection against cardiotoxicity or liver toxicity during cancer therapy; however, further studies are required to prove this association conclusively (Roffe et al 2004); furthermore, in vivo results indicate that CoQ10 has no significant effect on the pharmacokinetics of doxorubicin and the formation of the cytotoxic metabolite, doxorubicinol (Combs et al 1977, Zhou & Chowbay 2002) — potentially beneficial interaction with co-administration under professional supervision.

Phenothiazines
CoQ10 reduces adverse effect this drug class has on CoQ10-related enzymes, NADH oxidase and succinoxidase — beneficial interaction with co-administration (Stargrove et al 2008).

Statin drugs
Currently, it is still not clear whether CoQ10 supplementation should be considered a necessary adjunct to all patients taking statin drugs; however, there are no known risks to this supplement and there is some anecdotal and clinical trial evidence of its effectiveness (Marcoff & Thompson 2007). Consequently, CoQ10 can be tested in patients requiring statin treatment, who develop statin myalgia, headache, fatigue or malaise as statin-induced side effects. It may also prove useful for patients considered at risk of deficiency, in particular, patients with a family history of heart failure, elevated cholesterol levels and who are older than 65 years and taking statin drugs long-term (Levy & Kohlhaas 2006) — possible beneficial interaction with co-administration.

Sulfonylureas
CoQ10 reduces adverse effect this drug class has on CoQ10-related enzymes, NADH oxidase and low CoQ10 levels have been observed in people with diabetes — beneficial interaction with co-administration (Stargrove et al 2008).

Timolol
Eye drops — oral CoQ10 reduced the vascular side effects of timolol without affecting eye pressure (Takahashi 1989) — beneficial interaction with co-administration.

Tricyclic antidepressants
CoQ10 reduces adverse effect this drug class has on CoQ10-related enzymes, NADH-oxidase and succinoxidase — beneficial interaction with co-administration (Stargrove et al 2008).

Warfarin
There are three case reports suggesting that CoQ10 may decrease the international normalised ratio (INR) in patients previously stabilised on anticoagulants (Spigset 1994b). However, a double-blind crossover study involving 24 outpatients on stable long-term warfarin found that oral CoQ10 (100 mg) daily had no significant effect on INR or warfarin levels (Engelson et al 2003). Observe patients using high CoQ10 doses and taking warfarin.

Vitamin E
Reconstitutes oxidised vitamin E to its unoxidised form — beneficial interaction with co-administration.

CONTRAINDICATIONS AND PRECAUTIONS
Insufficient reliable evidence — unknown.

PREGNANCY USE
Safety has not been scientifically established.

PRACTICE POINTS/PATIENT COUNSELLING
- CoQ10 is a safe antioxidant vitamin used in supplement form for a wide range of diseases.
  - Meta-analyses provide support for its use in congestive heart failure and hypertension.
  - Clinical evidence further supports the use of presurgical supplementation in cardiac surgery, as it improves recovery and has cardioprotective activity.
  - There is also some clinical evidence suggesting a role in migraine headache, Huntington's chorea, mitochondrial myopathy, COPD, periodontal disease, haemodialysis, Friedreich's ataxia, tinnitus, age-related macular degeneration, cystic fibrosis and reducing cardiotoxicity and liver toxicity associated with anthracyclines, although further research is required.
  - Whether CoQ10 may slow the progression of PD is unclear.
- Several common medicines, such as statins, have been found to reduce serum CoQ10 status. It is still unclear whether CoQ10 should be considered a necessary adjunct to statin drugs; however, there are no known risks to this supplement and there is some anecdotal and clinical trial evidence of its effectiveness. In particular, it may be useful in patients who develop statin myalgia, headache, fatigue or malaise and those considered at risk of deficiency.

PATIENTS' FAQs
What will this vitamin do for me?
CoQ10 is an antioxidant vitamin used in every cell of the body. It is necessary for healthy function and can improve heart function, lower blood pressure and reduce angina. Taken before cardiac surgery, it has been shown to reduce complications and hasten recovery in some studies. It may also provide benefits in migraine headache, Huntington's chorea, mitochondrial myopathy, COPD, periodontal disease, haemodialysis, Friedreich's ataxia, tinnitus, age-related macular degeneration, cystic fibrosis and reducing cardiotoxicity and liver toxicity associated with anthracyclines, although further research is required to definitively confirm effect. Whether it is helpful in PD is not clear. People taking statin drugs long term and experiencing side effects could take a trial of CoQ10 and see whether it helps them.

When will it start to work?
This depends on the indication. For heart conditions and to reduce migraine, 10–12 weeks may be required. To delay the progression of PD, one study found that effects started after 9 months' use.

Are there any safety issues?
Medical monitoring is required in patients taking warfarin and starting high-dose CoQ10 supplements; however, even high-dose supplements are well tolerated and considered safe.

Colostrum

BACKGROUND AND RELEVANT PHARMACOKINETICS

Colostrum is the milk produced by female mammals towards the end of pregnancy and secreted from the mammary gland in the first 2 days after giving birth. It is a very complex fluid, rich in nutrients, antibodies, growth factors, vitamins and minerals (Uruakpa et al 2002). The antibodies provide passive immunity to the newborn, and the growth factors stimulate development of the gastrointestinal tract.

CHEMICAL COMPONENTS

Colostrum contains macronutrients, such as protein and carbohydrate, micronutrients, such as vitamins and minerals, together with cytokines, including IL-1-beta, IL-6, trypsin inhibitors, protease inhibitors and oligosaccharides. It also contains growth factors such as insulin-like growth factor (IGF)-I and -II, transforming growth factor-alpha and -beta, lactoferrin, epidermal growth factor and others. Several different antimicrobial factors are also present, such as immunoglobulin (Ig) A, secretory IgA, IgG-1, IgG-2 and IgM, lactoferrin, lactoperoxidase and lysozyme, which produce both specific and non-specific bacteriostatic and bacteriocidal effects on many pathological microorganisms, including bacteria, viruses and fungi. IgG-1 is the principal immunoglobulin type in colostrums, and IgM, IgA and IgG-2 are present in lower amounts (Mach & Pahud 1971).

FOOD SOURCES

Bovine colostrums (BC) are derived from cows, and hyperimmune BC is derived from cows that have been exposed to organisms that can cause disease in humans.

Clinical note — Hyperimmune bovine colostrum

Bovine colostrum contains a variety of Ig, but the specific Ig present varies and is influenced by previous immune system challenges. Hyperimmune BC, in which the concentration of specific antibodies is raised, can be produced by immunising cows with either specific pathogens or their antigens. For example, BC from cows exposed to rotavirus might contain a relatively high neutralising Ig titre against the virus (as well as many other pathogenic microorganisms), whereas BC collected from cows never exposed to rotavirus is less likely to have specific neutralising Ig against rotavirus. This is an important distinction, because much of the research on BC as prophylaxis or treatment for infectious disease has focused on products that are, as a consequence of specific immune provocation, immunologically unique (Kelly 2003).

MAIN ACTIONS

Imparts passive immunity and stimulates growth of the neonatal gastrointestinal tract

Just as the immunoglobulins of human colostrum impart passive immunity to the newborn child, so too BC provides protection against microbial infections and confers passive immunity to the newborn calf until its own immune system matures (Korhonen et al 2000). Studies with targeted hyperimmune BC suggest that passive immunity may prevent or treat infectious diseases that affect the entire length of the gastrointestinal tract (Pacyna et al 2001).

Immunomodulatory activity

An animal study found that BC has a Th1 promoting activity, which may be helpful in treating

various infectious diseases, including influenza (Biswas et al 2007, Yoshioka et al 2005). When BC was administered to weaned piglets, this intervention increased total serum IgA levels, stimulated ileal Peyer's patch and both Th1 and Th2 cytokine production (Boudry et al 2007). Further research would be needed to assess if BC increases Th1 in already high Th1 profiles or simply modulates the immune function where there is dysfunction.

In contrast, a clinical study found no significant effect on immune parameters for healthy volunteers aged 40–80 years who received BC concentrate 1.2 g/d. The researchers suggested that improving immune function in people with healthy immune responses is difficult thereby explaining why no significant effect was observed (Wolvers et al 2006).

Antibacterial and antiviral effects

Targeted hyperimmune BCs have proven effective in prophylaxis against various human infectious diseases caused by organisms such as rotavirus, *Shigella flexneri*, *Escherichia coli*, *Clostridium difficile*, *Streptococcus mutans*, *Cryptosporidium parvum* and *Helicobacter pylori* (Korhonen et al 2000). Hyperimmune BC from cows previously immunised with a vaccine of 17 strains of pathogenic diarrhoea bacteria was shown to inhibit in vitro growth of the same pathogens by destroying cell walls and agglutinating with bacteria (Xu et al 2006).

It is suspected that colostrum may modulate the interaction of *H. pylori* and other adhesin-expressing pathogens with their target tissues, chiefly due to phosphatidylethanolamine and its derivatives rather than to an antibody response (Bitzan et al 1998).

Improves gut permeability

Studies with agents known to disrupt gut permeability indicate that BC has a preventive effect that is likely to be a result of more than one growth factor present in the colostrum.

Reduces NSAID-induced intestinal damage

Defatted BC had major beneficial effects in preventing non-steroidal anti-inflammatory drug (NSAID)-induced gut injury in a variety of well-validated in vivo and in vitro models (Kim et al 2005a, 2005b, Playford et al 1999). BC improves the integrity of intestinal villi and prevents NSAID-induced increases in small intestine permeability. More specifically, the studies indicate that it stimulates both cell migration and proliferation, thereby enhancing the natural repair mechanisms that occur during acute mucosal injury. One of the studies by Kim et al (2005a) identified that when BC is administered together with glutamine, gastrointestinal protection is greater than when either agent is used alone. The other study, further, found that the overgrowth of enteric aerobic bacteria seen with NSAID administration did not occur to the same extent with BC (Kim et al 2005b).

OTHER ACTIONS

The high nutritional content of BC makes it an excellent source of many macro- and micronutrients.

Antioxidant activity

Bovine colostrum given to intestinal ischaemia/reperfusion injured rats experienced reduced oxidative stress and reduced nitric oxide (NO) overproduction in the lungs, which reduced lung injury. Superoxide dismutase and glutathione peroxidase levels were significantly increased and myeloperoxidase and malondialdehyde were significantly reduced in lung tissue indicating an overall reduction in oxidative stress (Choi et al 2007). The same research team went on to show that BC may reduce damage in brain ischaemia/reperfusion-injured rats (Choi & Ko 2008).

CLINICAL USE

The use of BC as a dietary supplement has increased substantially over the past 2 decades. Unlike other dietary supplements, the composition of BC is not precisely defined and varies greatly according to the breed and health status of the cow, feeding practices, previous exposure to infectious organisms and time collected postparturition (Kelly 2003).

Prevention and treatment of infection

Targeted hyperimmune BC products have proven effective in prophylaxis against various infectious diseases in humans.

Infectious diarrhoea

Rotavirus infection

The clinical evidence available suggests that hyperimmune BC is a promising agent in the prophylaxis and treatment of infectious diarrhoea caused by rotavirus. One Australian study using BC containing

Clinical note — Ovine colostrum and colostrum proline-rich polypeptides

There is new research appearing in the literature regarding colostrum from ewes, mostly using a product called Colostrinin™ which is a proline-rich, polypeptide complex from mammalian colostrum. In-vitro, in-vivo and clinical trials using this product have gained attention as having possible therapeutic benefit in the treatment of mild or moderate Alzheimer's disease (AD) by improving cognitive symptoms and delaying the disease process. Two mechanisms have been proposed to explain these benefits — an antioxidant mechanism which reduces oxidative stress and prevention of beta-amyloid aggregation (Bilikiewicz & Gaus 2004, Boldogh & Kruzel 2008, Stewart 2008). The anti-inflammatory action of this substance may also have an effect on decreasing IgE/IgG1 production, which could prevent or reduce allergic responses (Boldogh et al 2008). It seems that bovine colostrum proline-rich polypeptides have also displayed some potential in this anti-allergenic arena. Ovine colostrum, Colostrinin™ and colostrum proline-rich polypeptides are products to watch and would benefit from broader clinical trials to confirm their potential therapeutic uses.

high titres of antibody to all four human rotavirus serotypes found that administration successfully prevented symptomatic infection in 100% of children treated with the preparation (Davidson et al 1989). It also reduced the duration of rotavirus excretion, which may have implications for preventing cross-infection. A double-blind study of 75 boys aged 6–24 months with rotavirus diarrhoea compared ordinary BC to hyperimmune BC (100 mL three times daily for 3 days) from cows immunised with four serotypes of human rotavirus (Mitra et al 1995). Diarrhoea ceased within 48 hours in 50% of children receiving hyperimmune BC, whereas 100% of children receiving ordinary BC continued to have diarrhoea. Total stool output (g/kg) between admission and cessation of diarrhoea was also reduced in the group receiving hyperimmune BC compared with ordinary BC. Another double-blind study also found that treatment with antirotavirus immunoglobulin of BC origin is effective in the management of children with acute rotavirus diarrhoea (Sarker et al 1998). A double-blind study of children aged 6–30 months found that treatment with hyperimmune BC (100 mL solution four times daily for 4 days) leads to improved weight gain, decreased duration of diarrhoea and resulted in fewer stools, although the differences were not statistically significant compared to ordinary colostrum or placebo (Ylitalo et al 1998).

Studies using hyperimmune BC in young children have identified rotavirus antibodies as early as 8 hours after ingestion and up to 72 hours after consumption has ceased, with a strong relation between the titre of rotavirus antibody administered and the level of antibody activity detected in the faeces (Pacyna et al 2001). This suggests that passive immunity is imparted to the entire length of the gastrointestinal tract.

Shigella infection

According to one small study, hyperimmune BC with a high titre of anti-*Shigella flexneri* 2a lipopolysaccharide prevented the incidence of shigella infection in 10 of 10 volunteers, whereas 5 of 11 volunteers administered a control substance went on to develop the infection (Tacket et al 1992).

HIV-induced diarrhoea

BC has also been investigated as a potential treatment in HIV-induced diarrhoea, a symptom that occurs in most patients infected with AIDS. A BC product (Lactobin, Biotest, Dreieich, Germany) containing high titres of antibodies against a wide range of bacterial, viral and protozoal pathogens, as well as against various bacterial toxins, was tested in a multicentre pilot study involving 29 HIV-infected patients (Rump et al 1992). An oral dose of 10 g/day produced a transient (10 days) or long-lasting (>4 weeks) normalisation of the stool frequency in 21 patients. Mean daily stool frequency decreased from 7.4 to 2.2 at the end of the treatment. Some success was also obtained 1 year later in a prospective, open, uncontrolled study of 25 HIV patients with chronic refractory diarrhoea and either confirmed cryptosporidiosis (n = 7) or absence of demonstrable pathogenic organisms (n = 18) (Plettenberg et al 1993). An oral dose of 10 g/day of an immunoglobulin preparation from BC over a period of 10 days led to complete remission of cryptosporidiosis infection in three of seven subjects and two had partial remission. Complete remission was also seen in seven of 18 patients with diarrhoea and negative stool culture and a further four had partial remission. Of those subjects not responding to treatment, doubling of the dose to 20 g/day led to partial remission in four more patients and complete remission in one.

A BC product designed for slow passage through the gastrointestinal tract (ColoPlus) was tested over 4 weeks in an open-label study of 30 people with HIV-associated diarrhoea (Floren et al 2006). Treatment resulted in a dramatic decrease in daily stool evacuations (from 7.0 ± 2.7 to 1.3 ± 0.5), a mean increase of 7.3 kg of body weight, a 125% increase in $CD4^+$ count and a substantial decrease in self-estimated fatigue.

Reducing incidence of upper respiratory tract infections (URTIs)

IgA is found in saliva and acts as a major barrier preventing pathogens entering the body via the oral route. As such, the level of secretory IgA has been found to correlate with resistance to some viral infections. According to two clinical studies, BC (20 g/day) increases salivary IgA levels, a factor that could feasibly increase the host's resistance to infection (Crooks et al 2006, Mero et al 2002). In the study by Crooks et al, secretory IgA levels were elevated by 79% after 12 weeks of BC administration in athletes. The presence of numerous immune factors in BC further provides a theoretical basis for its use; however, little clinical investigation has been conducted to confirm its preventive effects.

In 2003, results of a randomised, double-blind, placebo-controlled trial were published, providing some support for its use as a prophylactic agent (Brinkworth & Buckley 2003). The study of 174 physically active young males compared colostrum powder (60 g/day; intact™, Numico Research Australia Pty Ltd) to concentrated whey powder over 8 weeks. During the test period, a significantly fewer proportion of subjects taking BC reported URTI symptoms than the control group; however, BC did not alter the duration of URTI once infection was established. Due to the self-reporting method used in this study, results should be viewed as preliminary and require further confirmation. An open study with 605 children in India achieved exceptional results as a prophylactic in preventing recurrent episodes of upper respiratory tract infections and diarrhoea. The children received a BC (Pedimune®) for 12 weeks, which reduced the incidence of URTI by 91% and diarrhoea by 86% (Patel & Rana 2006). This was an open study and more rigorous clinical trials are needed to confirm these findings.

Influenza prophylactic

A recent trial compared a colostrum supplement, given over 2 months, with an influenza vaccination and a combination of the two, for the prevention of flu. Over the next 3 months, the group

receiving colostrum treatment only had the lowest number of flu episodes (13), with the next highest in the colostrum and vaccination group (14) and then the vaccination only (41) and highest in non-treated subjects (57). The study was repeated with 65 high-risk cardiovascular patients, which once again produced positive results, as the incidence of hospital admissions and complications was higher in those who received only the vaccination compared to people receiving colostrum. Overall, colostrum supplementation was considered at least three times more effective than vaccination for flu prevention (Cesarone et al 2007).

Improved physical performance and preservation of muscle mass

BC has been used by athletes mainly as a natural source of IGF-I because it has an anabolic effect and is involved in the regulatory feedback of growth hormone. It is taken with the belief that protein catabolism will be reduced during intense training periods and physical performance will improve.

A double-blind, crossover study of nine male athletes confirmed that ingestion of BC (125 mL/day; Bioenervie, Viable Bioproducts) resulted in elevated concentrations of IGF-I; however, no significant effects were reported for serum IgG or saliva IgA concentrations (Mero et al 1997). Several years later in a larger study of athletes, under double-blind study conditions, researchers confirmed that BC ingestion produced significant increases in serum IGF-I (Mero et al 2002). The dose of 20 g/day of BC (dynamic supplement) was used during a 2-week training period in this study, which further found that saliva IgA levels increased with this particular treatment.

In a more recent trial, 29 cyclists were randomly assigned to take either 10 g/day of a BC protein concentrate or a placebo consisting of 10 g/day of whey protein during normal training over 5 weeks. Performance tests showed that BC treatment improved results in a 40 km time trial during a high-intensity training regimen and also maintained ventilatory threshold (Shing et al 2006). The same researchers also found that the supplement modulated immunity before and after training and prevented postexercise reductions in serum IgG (2) at the end of the high-intensity training period. A trend towards fewer upper respiratory tract illnesses was also detected (Shing et al 2007).

Gastrointestinal protection against NSAID-induced damage

BC has also been investigated in a small, randomised, crossover study as prophylaxis against NSAID-induced gastrointestinal damage (Playford et al 2001). A spray-dried, defatted colostrum (125 mL three times daily) was co-administered with indomethacin (50 mg three times daily) for 5 days in the first phase, then the effect of 7 days treatment with the colostral solution on gut permeability was determined in subjects taking NSAID long-term. Indomethacin (150 mg/day) caused a threefold increase in gut permeability after 5 days, whereas no change was observed when colostrum was co-administered, suggesting a protective effect. In contrast, no protective effect was seen in subjects who had been using NSAIDs long-term and then administered colostrum for 1 week.

Antidiabetic

It has been suggested that BC may have an effect on blood glucose levels. A small, randomised study of 16 patients with type 2 diabetes tested the effects of BC (10 g/day) over 4 weeks. Total cholesterol and triglyceride levels decreased significantly with active treatment, and a reduction in blood glucose levels and ketones were observed, which suggests a potential role for BC in diabetes management (Kim et al in press). Larger clinical studies are warranted to confirm this finding.

OTHER USES

Due to its effects on gut permeability, BC is used in a variety of other conditions, such as inflammatory bowel disease, coeliac disease, food allergies, intestinal infection and inflammatory joint diseases. It has also been used to restore normal gut permeability in people using chemotherapy. In some instances, it is used with glutamine for these indications.

DOSAGE RANGE

According to clinical studies

- Diarrhoea due to rotavirus: 100 mL three times daily for 3 days of BC from cows immunised with the four serotypes of human rotavirus.
- HIV-induced diarrhoea: 10 g/day (Lactobin, Biotest, Dreieich, Germany).
- Prevention of URTI: 60 g/day (intact™, Numico Research Australia Pty Ltd).
- Increasing serum IGF-I levels: 125 mL/day (Bioenervie, Viable Bioproducts) or 20 g/day (Dynamic supplement).
- Prevention of NSAID-induced gastrointestinal damage: 125 mL three times daily of spray-dried, defatted BC.
- For improving performance in high-intensity training and reducing exercise-induced URTI: 10 g/day.

TOXICITY

Not known.

ADVERSE REACTIONS

Not known.

SIGNIFICANT INTERACTIONS

Not known.

CONTRAINDICATIONS AND PRECAUTIONS

Only BC products produced under strict quality control guidelines should be used. They typically contain lactose, so should be avoided by people with lactose intolerance.

PREGNANCY USE

Likely to be safe.

PRACTICE POINTS/PATIENT COUNSELLING

- Colostrum is a very complex fluid that is rich in nutrients, antibodies, growth factors, vitamins and minerals.
- Targeted hyperimmune BC products have proven effective in prophylaxis against various infectious diseases in humans, notably infectious diarrhoea.
- BC is a popular supplement among athletes and used mainly as a natural source of IGF-I because it has an anabolic effect and is involved in the regulatory feedback of growth hormone.
- Preliminary evidence suggests that BC may prevent NSAID-induced gastrointestinal damage and improve gut permeability.
- Most studies use hyperimmune BC in which the concentration of specific antibodies is raised.
- Preliminary evidence shows some potential for BC in flu prevention and upper respiratory tract infections.

PATIENTS' FAQs

What will this supplement do for me?

Bovine colostrum contains nutrients, antibodies, growth factors, vitamins and minerals, and has a variety of effects on the gastrointestinal tract, immune function and the ability to fight some infections, and may possibly reduce muscle catabolism.

When will it start to work?

Studies with infectious diarrhoea have reported benefits within 3–4 days, and improvement in gut permeability within 5 days.

Are there any safety issues?

Bovine colostrum produced under quality control guidelines is a safe substance; however, it should be avoided by people with lactose intolerance.

Cranberry

HISTORICAL NOTE Native American Indians used cranberries as both a food and a treatment for bladder and kidney diseases. In the mid 1800s, German scientists suggested that cranberry juice had antibacterial activity, supporting its use as a treatment for bladder infections. Recent investigation has confirmed its usefulness in the prevention of urinary tract infections.

COMMON NAME
Cranberry

OTHER NAMES
Kronsbeere, marsh apple, moosbeere, preisselbeere

BOTANICAL NAME/FAMILY
Vaccinium oxycoccus, *Vaccinium macrocarpon* (family Ericaceae)

PLANT PART USED
Fruit

CHEMICAL COMPONENTS
Catechin, flavone glycosides, fructose, organic acids, proanthocyanidins, vitamin C.

Cranberry has a high flavonol content (100–263 mg/kg) (Hakkinen et al 1999) — higher than commonly consumed fruits and vegetables.

MAIN ACTIONS

Bacteriostatic
The adhesion of pathogenic organisms to a tissue surface is required to initiate most infectious diseases (Sharon & Ofek 2002). The proanthocyanidins in cranberry are potent inhibitors of *Escherichia coli* adhesion, thereby influencing the initiation of disease without exerting bactericidal activity. One in vitro study found that cranberry juice inhibited adhesion of 46 different *E. coli* isolates by 75% (Sobota 1984): when administered to mice for 14 days, adherence of *E. coli* to uroepithelial cells was inhibited by 80%. Significant inhibition of adherence was also observed in samples of human urine 1–3 hours after subjects drank a cranberry drink.

The morphology of *E. coli* is changed when grown in the presence of cranberry juice or extract (Johnson et al 2008). It appears that the antiadhesion effects are a result of irreversible inhibition of the expression of P-fimbriae of *E. coli* (Ahuja et al 1998). Electron micrographic evidence suggests that cranberry juice acts either on the cell wall, preventing proper attachment of the fimbrial subunits, or as a genetic control preventing the expression of normal fimbrial subunits, or both (Gupta et al 2007). Furthermore, cranberry juice has been shown to disrupt bacterial ligand-uroepithelial cell receptor binding (Liu et al 2008). This inhibitory effect has been seen with *Staphylococcus aureus* (Magarinos et al 2008), *E. coli* and uroepithelial tissues, but also in the adhesion of *Helicobacter pylori* to human gastrointestinal cells (Burger et al 2002) and in the co-aggregation of oral bacteria and *Streptococcus mutans* counts in saliva (Sharon & Ofek 2002, Weiss et al 1998).

Antioxidant
Cranberries consistently rank highly among common fruits with antioxidant activity. In particular, the polyphenolic compounds in cranberry display substantial antioxidant capacity. In vitro tests with whole fruit and isolated flavonol glycosides found in cranberry showed free radical scavenging activity comparable or superior to that of vitamin E (Yan et al 2002). In vivo studies demonstrate that cranberry juice increases plasma antioxidant status (Villarreal et al 2007). A small human trial demonstrated that a single 240-mL serving of cranberry juice increased plasma antioxidant capacity significantly greater than controls receiving an equivalent amount of vitamin C in solution (Vinson et al 2008).

Increases excretion of oxalic acid and uric acid
According to an open study, a dose of 330 mL cranberry juice can increase the excretion of oxalic acid and uric acid (Kessler et al 2002).

Alterations to urinary pH
Earlier hypotheses that cranberry juice prevents UTI by acidification of urine or by its hippuric acid content have not been substantiated. Results from human studies are contradictory, but overall suggest no significant change to urinary pH at doses less than 330 mL daily. A crossover study of 27 patients with indwelling urinary catheters and chronic bacteriuria showed no change in urinary pH (Nahata et al 1982), as did a double-blind study of 153 women (Avorn et al 1994). One small, open study involving 12 healthy subjects found that 330 mL of cranberry juice reduced the urinary pH (Kessler et al 2002).

OTHER ACTIONS
In vitro tests using four different *Vaccinium* spp. found that the proanthocyanidin fraction of cranberry exhibits potential anticarcinogenic activity (Bomser et al 1996). A non-specific antiviral effect has been demonstrated in vitro for a commercially produced cranberry fruit juice drink (Lipson et al 2007).

CLINICAL USE

Prevention of UTI
Controlled clinical trials support the use of cranberry products (solid-dose form and juice) in the prevention of UTI in women experiencing recurrent infections.

A 2008 systematic review evaluated data from 10 randomised controlled trials (RCTs) or quasi-RCTs of cranberry products for the prevention of

UTIs in all populations (n = 1049) (Jepson & Craig 2008). The effects of cranberry/cranberry-lingonberry juice versus placebo, juice or water were evaluated in seven studies, and cranberry tablets versus placebo in four studies (one study evaluated both juice and tablets). Overall, cranberry products significantly reduced the incidence of UTIs at 12 months compared with placebo/control. Cranberry products were more effective in women with recurrent UTIs than in the elderly or people requiring catheterisation. Only one study reported a significant result for the outcome of symptomatic UTIs. Side effects were common in all studies, and dropouts/withdrawals in several of the studies were high (Jepson & Craig 2008).

Previously, a 2004 Cochrane systematic review considered results from seven randomised clinical trials ultimately using data from two good-quality studies to undertake a meta-analysis (Jepson et al 2004, Kontiokari et al 2001, Stothers 2002). Once again, cranberry products were found to significantly reduce the incidence of UTI at 12 months compared with placebo/control in women, and there was no significant difference in the incidence of UTI between cranberry juice and cranberry capsules. One trial used 7.5 g of cranberry concentrate daily (in 50 mL), whereas the other trial used a 1:30 concentrate given either in 250 mL juice or in tablet form. Additionally, Stothers showed that cranberry tablets provided the most cost-effective prevention for UTI when compared with organic cranberry juice (Stothers 2002).

Spinal cord injuries

Patients with spinal cord injuries are a high-risk group for catheter-associated UTIs, so cranberry products are popular in this group. One double-blind, factorial design, randomised controlled trial of 305 people with spinal cord injuries showed no significant UTI-free period compared to placebo when taking 800 mg of cranberry tablets twice daily (Lee et al 2007), whilst another randomised, double-blind, placebo-controlled, crossover trial in 47 patients with spinal cord injury demonstrated a significant reduction in the frequency of UTIs (Hess et al 2008). An open, pilot study involving 15 volunteers with spinal cord injuries showed that three glasses of cranberry juice daily significantly reduced the adhesion of gram-negative and gram-positive bacteria to uroepithelial cells (Reid 2002). Treatment using catheter device with proanthocyanidin solutions has also been shown to inhibit adhesion of bacteria to non-biological particles such as PVC (Eydelnant & Tufenkji 2008).

Children

Cranberry use is popular for children with renal disease. An anonymous survey of 117 parents of children seen in a hospital paediatric nephrology clinic identified that 29% gave cranberry products to their children, to treat as well as prevent diverse renal problems (Super et al 2005). Most parents felt that it was beneficial and only one reported a side effect (nausea).

Two studies conducted with children managed by clean intermittent catheterisation found no clinical or statistical difference in the number of symptomatic UTI observed in either the cranberry or placebo groups (Foda et al 1995, Schlager et al 1999). Foda et al used a dose of 5 mL/kg/day of cranberry cocktail for 6 months and the dose used by Schlager was 2 ounces (≈55 g) of cranberry concentrate.

Treatment of UTI

Although cranberry may be a viable adjunctive treatment in UTI when antibiotic resistance is encountered, there is no reliable evidence that it is an effective sole treatment in diagnosed UTI (Ulbricht & Basch 2005). One study of pregnant women demonstrated comparable effects of daily cranberry juice cocktail to those of placebo for asymptomatic bacteriuria and symptomatic UTIs; however, the results were not statistically significant and more than one-third of participants withdrew from the study because of gastrointestinal upset (Wing et al 2008). In another study, cranberry exhibited only weak antimicrobial activity in urine specimens of symptom-free subjects after ingestion of a single dose (Lee et al 2008b).

Nephroprotection

Cranberries have an anti-inflammatory effect through their antioxidant function and might prevent infection-induced oxidative renal damage. Animal studies suggest that cranberries might be used clinically as a beneficial adjuvant treatment to prevent damage due to pyelonephritis in children with vesico-ureteric reflux (Han et al 2007).

Urinary deodorising activity

Cranberry juice and solid-dose forms are popular in nursing homes as urinary deodorising agents in older adults with incontinence. Although no clinical study is available to confirm efficacy, numerous anecdotal reports suggest that it is useful when used on a regular basis.

OTHER USES

Gout

Cranberry juice has been used to treat gout. Evidence of increased uric acid excretion in humans provides a theoretical basis for the indication, although studies in patients with gout are not available to confirm effectiveness (Kessler et al 2002).

Oral hygiene

The antiadhesion effect of cranberry on oral microbial flora has been demonstrated in vitro (Bodet et al 2008, Koo et al 2006, Yamanaka et al 2007). More specifically, cranberry polyphenol fraction significantly decreased the hydrophobicity of oral streptococci in a dose-dependent manner suggesting that it may reduce bacterial adherence to the tooth surface (Yamanaka-Okada et al 2008).

Prevention and treatment of *Helicobacter* infection

Cranberry inhibits the adhesion of *H. pylori* to human gastrointestinal cells in vitro (Matsushima et al 2008); however, very little clinical evidences are

available to confirm significance in humans (Burger et al 2002). A multicentric, randomised controlled, double-blind trial found that regular intake of cranberry juice or a probiotic inhibited *H. pylori* in a trial of 295 children (Gotteland et al 2008). Another double-blind, randomised clinical study was carried out in 177 patients with *H. pylori* infection to investigate possible additive effect of cranberry juice to triple therapy with omeprazole, amoxicillin and clarithromycin (OAC). Overall, there was no statistically significant difference; however, analysis by gender showed that the eradication rate was higher in females taking cranberry, but not in males (Shmuely et al 2007).

Chemoprotection

Studies employing mainly in vitro tumour models show that cranberry extracts and compounds inhibit the growth and proliferation of several types of tumour, including lymphoma, bladder, breast, colon, prostate, ovaries, oesophageal, lung and oral squamous cell carcinoma (Chatelain et al 2008, Ferguson et al 2006, Hochman et al 2008, Kresty et al 2008, Prasain et al 2008, Singh et al 2009, Sun & Hai Liu 2006). The flavonoid components may act in a complementary fashion to limit carcinogenesis by inducing apoptosis in tumour cells (Neto et al 2008).

Cardioprotection

Consumption of 250 mL cranberry juice daily is associated with decreasing markers of oxidative stress (Ruel et al 2008) and a significant increase in plasma HDL cholesterol concentration (Ruel et al 2006). In addition, cranberry extract increases cholesterol uptake and the synthesis of LDL receptors (Chu & Liu 2005), suggesting that accelerated cholesterol excretion may occur in vivo (McKay & Blumberg 2007).

Type 2 diabetes

Some studies have suggested that consumption of a low-calorie cranberry juice is associated with a favourable glycaemic response (Wilson et al 2008a, 2008b); however, a randomised, placebo-controlled, double-blind study demonstrated that cranberry had a neutral effect on glycaemic control in type 2 diabetics. This same study found, however, that cranberry supplements are effective in reducing atherosclerotic cholesterol profiles, including LDL cholesterol and total cholesterol levels, as well as total:HDL cholesterol ratio in people with type 2 diabetes (Lee et al 2008a).

DOSAGE RANGE

Preventing UTI

- According to clinical studies:
  Adults: 30–300 mL daily or 400 mg capsule daily.
  Children: 15 mL/kg or up to 300 mL daily.

In practice, much higher doses are being used in an attempt to achieve quicker results (e.g. cranberry capsules or tablets 10,000 mg/day for prevention).

ADVERSE REACTIONS

At high doses (3 L or greater), gastrointestinal discomfort and diarrhoea can occur (Ulbricht & Basch 2005).

SIGNIFICANT INTERACTIONS

Proton pump inhibitors

The composition of bioactive components of cranberry juice can vary substantially and there is potential for drug interaction (Ngo et al 2009).

Cranberry juice increases the absorption of vitamin B12 when used concurrently with PPI medicines (Saltzman et al 1994) — beneficial interaction.

Warfarin

There are a number of case reports suggesting that cranberry juice may increase the INR in patients taking warfarin; however, two case reports did not clearly identify cranberry juice as the sole cause of INR elevation, whereas one case report appeared to show a correlation between the effects of cranberry juice and warfarin metabolism (Pham & Pham 2007). In contrast, results from two clinical pharmacokinetic studies indicate no clinically relevant pharmacokinetic interaction between cranberry juice and warfarin (Pham & Pham 2007). One clinical study found that cranberry juice did not change the anticoagulant effect of warfarin and daily ingestion of cranberry juice did not inhibit the activities of CYP2C9, CYP1A2 or CYP3A4 (Lilja et al 2007). A more recent study suggests that a pharmacodynamic interaction is more likely (Mohammed Abdul et al 2008).

Until the interaction can be better understood, patients taking warfarin with cranberry juice should be cautioned about a potential interaction and monitored closely for INR changes and signs and symptoms of bleeding.

CONTRAINDICATIONS AND PRECAUTIONS

People with diabetes should take care when using commercially prepared cranberry juices because of the high sugar content.

If symptoms of UTI become more severe while cranberry is being administered, other treatments may be required and medical advice is recommended.

People with a history of oxalate kidney stones should limit their intake of cranberry juice.

PREGNANCY USE

Women experience UTIs with greater frequency during pregnancy. A systematic review of the literature for evidence on the use, safety and pharmacology of cranberry, focusing on issues pertaining to pregnancy and lactation found that there is no direct evidence of safety or harm to the mother or fetus as a result of consuming cranberry during pregnancy. Indirectly, there is good scientific evidence that cranberry may be of minimal risk, where a survey of 400 pregnant women did not uncover any adverse events when cranberry was regularly consumed. In lactation, the safety or harm of cranberry is unknown. Given the evidence to support the use of cranberry for urinary tract infections and its safety profile, cranberry supplementation as fruit or fruit juice is an appropriate and valuable therapeutic choice in the treatment of UTIs during pregnancy (Dugoua et al 2008).

PRACTICE POINTS/PATIENT COUNSELLING

- Cranberry preparations are widely used to prevent and treat minor UTI.
- Overall, clinical testing suggests that the juice and solid-dose forms may have significant beneficial effects for UTI management.
- Cranberry exerts bacteriostatic effects by reducing bacterial adhesion to host tissues.
- Overall, evidence suggests no significant alteration to urinary pH at doses less than 330 mL daily.
- Cranberry products have also been used to treat gout and to deodorise urine in people with incontinence.
- Preliminary research suggests a possible role in preventing conditions such as *Helicobacter pylori* infection and dental plaque formation.
- Patients taking warfarin and regular cranberry intake should have their INR monitored.

PATIENTS' FAQs

What will this herb do for me?

Cranberry products appear to reduce the risk of developing UTI.

When will it start to work?

Studies using 1–2 glasses of cranberry juice suggest that 4–8 weeks' continual use is required; however, faster effects using concentrated tablets or capsules have been reported.

Are there any safety issues?

If fever or pain exists or symptoms of UTI become more severe, seek medical advice. People taking warfarin together with cranberry should monitor their INR for changes.

Creatine

HISTORICAL NOTE Creatine was first discovered in 1832 when it was identified in meat. The word creatine is derived from the Greek *kreas* for flesh, similar to the word 'creature'. About 15 years later, the meat from foxes killed in the wild were found to have 10-fold more creatine than meat from domesticated foxes, suggesting that physical exercise must influence the amount of creatine that accumulates in muscles. Early last century, orally consumed creatine was shown to be partly retained in the body and able to increase creatine content in muscles, leading some to suspect this could influence the performance of muscles. Nowadays, creatine monohydrate enjoys enormous popularity as a sports supplement and is being recommended to elite athletes by respected sporting bodies such as the Australian Institute of Sport (AIS 2009).

BACKGROUND AND RELEVANT PHARMACOKINETICS

Creatine is a naturally occurring nitrogenous compound produced in the human liver, pancreas and kidneys at a rate of 1–2 g daily. It is synthesised from the amino acids glycine, arginine and methionine and stored primarily in skeletal muscle, where it is in dynamic equilibrium with phosphocreatine and is a precursor to adenosine triphosphate (ATP), the main source of energy for muscle activity and many other biological functions. Orally ingested creatine is absorbed from the small intestine, then distributed via creatine transporters around the body to muscles and nerves (Persky et al 2003). These transporters also serve as a clearance mechanism because of creatine 'trapping' by skeletal muscle. It is ultimately converted to creatinine and excreted by the kidneys.

CHEMICAL COMPONENTS

Creatine is chemically known as *N*-(aminoiminomethyl)-*N*-methyl glycine.

FOOD SOURCES

Animal protein and fish. It has been estimated that approximately 1–2 g are ingested daily from the diet by non-vegetarians (Hendler 2001).

DEFICIENCY SIGNS AND SYMPTOMS

Several rare inborn errors of metabolism that result in a lack of creatine and phosphorylcreatine in the brain and severe mental retardation have been identified. Other symptoms and signs, such as involuntary extrapyramidal movements, speech disability, epilepsy, muscular hypotonia and weakness, and, in older patients, autism with

self-injurious behaviour have also been reported (Wyss & Schulze 2002).

People involved in intense physical activity, vegetarians and those with muscle diseases may have low creatine levels.

MAIN ACTIONS

Energy production

Although the exact mechanism is unknown, much is known about the biochemistry of endogenous creatine. In skeletal muscle tissue, it is used for the production of phosphocreatine, an important form of high-energy phosphate. Phosphocreatine is broken down into phosphate and creatine during high-intensity exercise lasting 15–30 s. During the process, energy is released and is used to regenerate ATP, the primary source of energy.

Supplemental creatine

Oral supplementation with creatine has been shown to increase phosphocreatine levels in muscles, and as such, has been described as 'fuelling up' natural energy stores. Increased creatine stores leads to faster regeneration of ATP, thereby making more energy immediately available to muscles. Theoretically, increased free creatine allows depleted stores to replenish more quickly, thus shortening recovery times during repeated bouts of intense exercise. Increased muscle creatine may also buffer the lactic acid produced during exercise, delaying muscle fatigue and soreness.

It has been estimated that short-term supplementation over 5–7 days with a daily dose of 20 g creatine increases total creatine content by 10–30% and phosphocreatine stores by 10–40% (Kreider 2003).

In clinical studies, the effect of creatine on performance, endurance, strength and recovery is variable.

Neuroprotective

Creatine supplementation has displayed neuroprotective effects in several animal models of neurological diseases, such as Huntington's disease, Parkinson's disease, or motor neuron disease (MND) (also known as amyotrophic lateral sclerosis) (Andreassen et al 2001, Dedeoglu et al 2003, Ferrante et al 2000, Wyss & Schulze 2002). The National Institute of Neurological Disorders and Stroke (NINDS) is currently conducting a large double-blind, placebo-controlled, phase III study involving 1720 people with early-stage Parkinson's disease to evaluate the effects of long-term creatine supplementation.

Creatine may exhibit antiageing benefits according to an in vivo study where creatine-fed mice lived longer and exhibited improvements in neurobehavioural tests. Further, creatine significantly lowered the amounts of ageing pigment, lipofuscin and upregulated various genes involved in neuroprotection and learning (Bender et al 2008). Preliminary data from a randomised, comparative, open study has shown a neuroprotective effect in cases of children with traumatic brain injury. Treatment with creatine improved a number of parameters, including duration of post-traumatic amnesia, length of recovery time, social/behaviour and cognitive function (Sakellaris et al 2006). A number of theories of a possible mechanism for neuroprotection have been put forward. One theory proposes that creatine exerts antioxidant activity and mitochondrial stabilising effects, two mechanisms of benefit in neurodegenerative diseases, which are characterised by mitochondrial dysfunction and oxidative damage (Shefner et al 2004). Recently, oral doses of creatine have been shown to pass the blood brain barrier (Andres et al 2008).

OTHER ACTIONS

A recent animal model demonstrated a 40% reduction in infarct volume after stroke. By using magnetic resonance imaging (MRI) the study found augmented cerebral blood flow after stroke in the mice treated with creatine (Prass et al 2006). Research in animal models has shown that it inhibits the growth of some solid tumours and also exhibits antioxidant activity (Lawler et al 2002). In a rat model, creatine monohydrate exhibited a positive influence on bone mineral density (Antolic et al 2007).

CLINICAL USE

Creatine monohydrate is the form generally used and tested. In practice, this is available in three different forms, which differ according to particle size (granular, powder and micronised), with the belief that smaller particles are more fully absorbed and cause less gastric distress.

Ergogenic aid

Creatine supplementation has become one of the most widely used supplements taken by athletes and is touted by some as the only truly effective ergogenic aid, besides carbohydrate loading. It is used by athletes engaged in sprint disciplines (e.g. 100 m run or 50 m swim), strength disciplines (e.g. weight lifting) or high-intensity, repetitive burst exercise (e.g. tennis, hockey, football, soccer) separated by short bouts of recovery. Its use is based on the assumption that supplementation at doses above dietary levels will increase energy and power output and also enhance recovery.

Hundreds of small studies have attempted to evaluate the effects of creatine supplementation on exercise capacity and muscle physiology in various populations.

A 2003 review of the literature concluded that approximately 300 studies have evaluated its potential as an ergogenic aid, with about 70% of studies reporting statistically significant positive results (Kreider 2003).

Who will respond?

The observation that not every athlete responds to creatine supplementation with improved strength, performance and recovery has prompted investigation to identify the key features of responders. One study identified that responders had the lowest initial levels of muscle creatine, greatest percentage of type 2 fibres, greatest preload muscle fibre

cross-sectional area and fat-free mass in comparison to non-responders (Syrotuik & Bell 2004). Other factors that are likely to influence an individual's response to creatine include training status, diet, age and the bioavailability of the creatine supplement being used. One review on the use of creatine in the elderly suggested that timing of creatine intake may be important, and if creatine is taken closely before or after the resistance training session it is likely to be more effective (Candow & Chilibeck 2008). Not taking these factors into account may partly explain the inconsistent results obtained in randomised studies.

Short duration, high-intensity exercise

Most, but not all, controlled studies have shown that supplementation improves performance and delays muscle fatigue (Balsom et al 1995, Becque et al 2000, Burke et al 1996, Cox et al 2002, Finn et al 2001, Gilliam et al 2000, Kreider et al 1998, Maganaris & Maughan 1998, Mujika & Padilla 1997, Mujika et al 2000, Tarnopolsky & MacLennan 2000, Williams & Branch 1998). One small study with 10 cyclists found improved sprint cycling in the heat with a dose of 5 g given four times a day for 6 days (Wright et al 2007). A recent trial with 18 players during an 8-week rugby season of Rugby Union football found that creatine, at a relatively low dose (0.1 g/kg/day) increased muscular endurance without detrimentally affecting body composition or aerobic endurance (Chilibeck et al 2007). Other trials, such as a placebo, RCT with 17 ice hockey players given 0.3 g/kg/day of creatine for 5 days (Cornish et al 2006), show no benefits. Also a recent double-blind study found no significant improvement on multiple sprint performance, fatigue or blood lactate concentration when testing creatine use with 42 physically active men who were given 5 g four times a day for 5 days (Glaister et al 2006). One recent study of 13 volunteers given creatine over 4 weeks found that creatine had no effect on metabolic adaptation in endurance training (Reardon et al 2006). In these recent studies, creatine monohydrate was used and the dosages were similar, but given that the studies were all small it may be that larger studies would produce more consistent findings. Another explanation for the differences in the results of these studies is that almost 30% of athletes are thought to be non-responders to creatine (possibly due to adequate creatine levels or a different make-up of their muscle fibres). It is possible that creatine use is beneficial in short-duration anaerobic exercise but not for endurance performance (Calfee & Fadale 2006).

Studies have been conducted in a variety of athletes, such as sprint cyclists, soccer players and sprint swimmers, and generally used a dose of 20 g daily. A recent study with tennis players found no significant benefits of creatine on repetitive sprint power or in muscular strength (Pluim et al 2006).

Lean body mass

Creatine increases exercise-related gains in lean body mass (Chrusch et al 2001, Jowko et al 2001, Stone et al 1999), although some of these apparent gains may actually represent water retention in the muscles.

Enhanced power

Many studies show that creatine supplementation in conjunction with resistance training augments muscle strength and size, although the effect is not consistent for everybody (Spriet & Gibala 2004, Volek & Rawson 2004). A 2003 review of 22 studies estimated that the average increase in muscle strength following creatine supplementation as an adjunct to resistance training was 8% greater than the placebo (20% vs 12%) (Rawson & Volek 2003). Similarly, the average increase in weightlifting performance (maximal repetitions at a given percentage of maximal strength) following creatine supplementation plus resistance training was 14% greater than the placebo (26% vs 12%).

Creatine supplementation increases muscle fibre hypertrophy, myosin heavy chain expression and swelling of myocytes, which may in turn affect carbohydrate and protein metabolism. Supplementation also increases acute weightlifting performance and training volume, which may allow for greater overload and adaptation to training. According to a double-blind, placebo study, creatine in combination with physical training increases fibre growth by increasing satellite cell number and myonuclei concentration. Researchers took muscle biopsies at various intervals during 16 weeks of heavy resistance training where participants were given 6 g of creatine monohydrate four times a day for the loading phase of 7 days and then once a day (Olsen et al 2006).

Some studies show no benefits of adding supplementation to a training protocol on either strength or lean body mass. In one study, creatine monohydrate was given at a dose of 0.3 g/kg for 7 days and then 0.03 g/kg for 9 weeks, and resistance training was carried out for 4 days a week. This study was of 26 females and it may be that the non-response was due to the gender (Ferguson & Syrotuik 2006). Another study of 42 elderly males found that creatine supplementation did not confer any extra benefits to isotonic exercise training and did not enhance muscle adaptability (Carter et al 2005). In this double-blind, randomised, placebo-controlled study, 7 g creatine per day were administered in the 1-week loading phase and then 5 g creatine a day for the remainder of the 16-week study, and the volunteers undertook resistance training for 3 days a week.

Reducing strength decline in the elderly

The effects of supplemental creatine in older adults have been investigated in a few studies, overall producing positive results (Brose et al 2003, Chrusch et al 2001, Kreider et al 1998). One randomised, double-blind study involving 30 older men (> 70 years) showed that resistance training combined with creatine supplementation produced significantly greater increases in lean tissue mass, leg strength, endurance and average power than placebo (Chrusch et al 2001). The dose regimen used was 0.3 g/kg for the first 5 days followed by 0.07 g/kg thereafter. Another double-blind study in 28 men and women aged

over 65 years showed that creatine supplementation (5 g daily) combined with resistance training enhanced the increase in total and fat-free mass, and gains in several indices of isometric muscle strength (Brose et al 2003). A recent double-blind, placebo, RCT with 14 days of creatine supplementation in elderly men and women confirmed significant increases in grip strength, muscle endurance and physical working capacity at fatigue threshold (Stout et al 2007). In contrast, a 7-day study of elderly women produced mixed results, as creatine supplementation (dosage 0.3 g/kg/day) did not show any benefits for endurance but did help volunteers to perform lower body function exercises that involved quick movements (Canete et al 2006).

Cervical level spinal cord injury

According to a randomised, double-blind, placebo-controlled crossover trial, creatine supplementation enhances upper extremity work capacity in subjects with complete cervical level spinal cord injury (Jacobs et al 2002).

Bone mineral density

According to a double-blind, placebo-controlled study with 29 older men, creatine (0.3 g/kg for 5 days and 0.07 g/kg thereafter) administered for 12 weeks while undergoing resistance training significantly increased bone density. Creatine supplementation had an additional benefit for regionalised bone mineral content where there was a change in lean tissue mass. It was suggested that the effect may be due to greater tension on the bone due to an increase in muscle mass in the creatine participants (Chilibeck et al 2005).

Muscular dystrophy

A number of muscle diseases are associated with a decrease in intracellular creatine concentration, which could theoretically contribute to muscle weakness and degeneration of muscle tissue (Wyss et al 1998).

One double-blind, crossover study of 36 patients with various muscle diseases found that creatine supplementation over 8 weeks produced a mild but significant improvement in muscle strength and daily-life activities on Medical Research Council scales and the Neuromuscular Symptom Score (Walter et al 2000). A single-blind, placebo-controlled trial of 21 volunteers with different neuromuscular disorders found that creatine supplementation (10 g daily for 5 days followed by 5 g daily for 5–7 days) produced significant improvements in body weight, handgrip, dorsiflexion and knee extensor strength (Tarnopolsky et al 1997). A recent review concluded that creatine has therapeutic potential in Duchenne muscular dystrophy due to its ability to increase fat-free mass and muscle strength. Further long-term studies were recommended to assess benefits and any side effects (Pearlman & Fielding 2006).

A recent systematic review of literature looking at creatine supplementation in muscle diseases evaluated 12 randomised trials and found the evidence demonstrated that both short- and medium-term creatine supplementation improved muscular strength in those with muscular dystrophies but no significant improvement in metabolic myopathies. However, people with glycogen storage disease type V should avoid high-dose creatine supplementation, as it caused a significant increase in pain in one study (Kley et al 2007).

Clinical note — The Australian Institute of Sport Supplement Program

The AIS is world renowned for its professionalism and high-quality training programs. In 2000, a project called the AIS Sports Supplement Program (AIS 2009) was developed to ensure that athletes use supplements correctly and confidently, and receive 'cutting edge' advice on nutritional practices. In order to streamline the information available, a panel of experts categorised some of the most popular sports supplements into various classes to clarify which are approved or recommended and which are directly banned by international doping rules. Some of the approved supplements recommended for use include creatine, antioxidants (vitamins C and E), multivitamins, iron, calcium supplements and sports drinks.

Congestive heart failure

Muscle fatigue due to loss of skeletal muscle mass and strength, decreased oxidative capacity and other abnormalities of muscle metabolism have been associated with congestive heart failure. As a result, creatine supplementation has been suggested as a possible therapeutic agent in this condition.

A dose of 10 g creatine daily for 7 days significantly increased exercise capacity and muscle strength compared to placebo in a double-blind study involving 17 men with congestive heart failure (Gordon et al 1995). However, creatine supplementation did not alter ejection fraction at rest or at work. Muscle endurance during handgrip exercises was also seen to improve in another double-blind, crossover study of 20 men given 5 g creatine four times daily for 5 days (Andrews et al 1998). Another study using the same dose of creatine, for 6 weeks, in a double-blind, placebo, crossover study with 20 congestive heart failure patients found an increase in body weight and muscular strength which occurred only during the supplementation period and not beyond. There was no significant change in peak oxygen uptake, walking distance or quality of life (Kuethe et al 2006).

Neurological degenerative diseases

Over the past few years, a considerable body of scientific evidence has given support to the idea that creatine supplementation may alleviate some of the clinical symptoms of neurological disease and delay disease progression (Wyss & Schulze 2002). Unfortunately, neuroprotective effects demonstrated in animal models have not been consistently demonstrated in clinical trials. This may be not only because the pathophysiological processes of

neurodegenerative disease are different in humans, but also due to differences in dosage and timing of creatine supplementation. Some animal studies have used doses 10 times higher than in clinical trials. Clearly, further investigation is warranted (Andres et al 2008).

Huntington's disease

A number of studies conducted with experimental animal models of Huntington's disease have identified a possible role for creatine supplementation (Andreassen et al 2001, Dedeoglu et al 2003, Ferrante et al 2000). Creatine was shown to increase survival, delay onset of symptoms and exert neuroprotective effects in vivo. A recent double-blind, placebo RCT with 64 Huntington's disease patients given creatine at a dose of 8 g/day for 16 weeks found that creatine concentrations in the brain and serum increased with supplementation and reduced oxidative injury to DNA (Hersch et al 2006).

Parkinson's disease

Decreased muscle mass and strength is a feature of Parkinson's disease. Creatine monohydrate combined with resistance training showed improved muscular endurance and improvements in upper body strength. This double-blind, placebo, RCT had 20 patients given 20 g/day of creatine for 5 days and then 5 g/day for 12 weeks (Hass et al 2007). Another recent placebo, RCT followed 60 patients for a 2-year period and found that creatine had no overall effect on Unified Parkinson's Disease Rating Scale scores (which covers behaviour and mood, daily living activities, motor skills and complications of therapy; patients taking creatine did experience elevated mood and required smaller increases in dopamine medication) (Bender et al 2006).

Motor neuron disease

A preliminary study demonstrated that creatine supplementation of 20 g daily for 7 days followed by 3 g daily for 3 and 6 months produced temporary increases in maximal isometric power in patients with MND (Mazzini et al 2001). Two randomised, double-blind, placebo-controlled studies have been conducted with MND patients, with both finding no change to disease progression with creatine monohydrate supplementation at doses of 5–10 g daily (Groeneveld et al 2003, Shefner et al 2004). Study periods varied from 6 to 12 months. The study by Shefner et al used creatine monohydrate at a loading dose of 20 g/day for 5 days, followed by 5 g/day. It must be noted that this study was powered only to detect a 50% or greater change, so the failure to show a significant positive effect of treatment might have limited clinical significance.

Charcot-Marie-Tooth Disease (CMT)

Muscle function improved when creatine and resistance training was undertaken by people with CMT according to a randomised, placebo-controlled trial of 18 people. Over the 12-week period, combined treatment also resulted in improved muscle myosin heavy chain composition (Smith et al 2006).

Reduces mental fatigue and improves cognitive function

Creatine supplement (8 g/day for 5 days) reduced mental fatigue when examined under double-blind, placebo-controlled conditions in 24 healthy volunteers (Watanabe et al 2002).

An RCT found that creatine significantly improved tasks requiring speed of processing both working memory and intelligence (Raven's Advanced Progressive Matrices). This trial involved 45 healthy young vegetarians who are more likely to have lower creatine levels than non-vegetarians and possibly be more responsive to treatment (Rae et al 2003). A placebo, RCT demonstrated that creatine improved cognitive function in elderly patients with various cognitive performance tasks showing significant improvement on baseline, apart from backward number recall where no improvement was found (McMorris et al 2007). Alternatively, a negative double-blind, placebo-controlled study of 22 individuals given 0.03 g/kg of body weight of creatine per day for 6 weeks found no significant difference in cognitive function (Rawson et al 2008).

OTHER USES

Gyrate atrophy

Doses of 1.5 g/day for 1 year resulted in improvement of the skeletal muscle abnormality that accompanies gyrate atrophy, a genetically acquired form of blindness (Feldman 1999).

Diabetes

Creatine supplementation (10 g/day) for 3 months improved glucose tolerance but not insulin sensitivity when combined with aerobic training in a double-blind, randomised, placebo-controlled trial with 22 healthy sedentary males who consumed 10 g of creatine a day over 3 months (Gualano et al 2008).

DOSAGE RANGE

There are two common dosing regimens.

Loading

Creatine loading protocols have been well studied.

- *Rapid loading:* a dose of 5 g is taken four times daily for 5–7 days as a loading phase, followed by 2–10 g daily as maintenance for 1 week–6 months (Bemben & Lamont 2005). This is followed by a 4-week break and then restarted in a process known as 'cycling'.
- *Slower loading:* a similar effect can be achieved by taking 3 g daily over 28 days.

Concurrent ingestion of carbohydrate (50–100 g) may improve creatine uptake.

Once muscles have become saturated, it takes approximately 4 weeks to return to baseline levels.

Clinical note — Interview with Steve Brown, former Mr Australia and personal trainer

In practice, micronised forms of creatine monohydrate provide superior results to powders or granules and have less gastrointestinal side effects, particularly when taken with glucose or dark grape juice, according to Steve Brown (pers. commun. 2003). The loading regimen typically increases the ability to lift heavier weights for greater repetitions within 2–4 weeks and occurs quite suddenly. Also, creatine increases alertness and mental sharpness, effects that are obvious after the first week. Although there is a slight weight gain due to water retention, lean body mass also increases, because the body is able to work harder and for longer with creatine. Once supplementation stops, the physical effects on performance quickly reduce and are noticeable after the first week.

Non-loading

• Daily dose of 3 g.

In practice, creatine is often taken with simple carbohydrates, such as glucose or fruit juice, in order to increase creatine accumulation within muscle.

ADVERSE REACTIONS

Side effects include gastrointestinal distress with nausea and vomiting, diarrhoea, muscle fatigue, pain and cramping, dehydration and heat intolerance. The effects may be reduced when micronised forms of creatine are taken together with glucose or simple carbohydrates. Gastrointestinal disturbance may further be reduced if doses are divided (e.g. two doses of 5 g a day may be better tolerated than a single 10-g dose) (Ostojic & Ahmetovic 2008).

Fluid retention is commonly observed during the loading phase of supplementation and it can result in early weight gain of 1.6–2.4 kg.

SIGNIFICANT INTERACTIONS

Controlled studies are not available and there is insufficient reliable evidence to determine interaction potential.

CONTRAINDICATIONS AND PRECAUTIONS

Use of high-dose creatine is contraindicated in individuals with renal failure.

Caution in people with bipolar depression — two case reports suggest that creatine monohydrate supplementation may cause a manic episode (Roitman et al 2007).

A risk assessment report using data from clinical trials concluded that, overall, creatine has a good safety profile in healthy individuals with the main side effect being gastrointestinal upset when taken in large doses. Doses up to 5 g/day are generally considered safe but the long-term safety of larger doses is yet to be established (Shao & Hathcock 2006). Creatine supplementation for up to 8 weeks has not been associated with major health risks, but the safety of more prolonged creatine supplementation has not been established (Williams & Branch 1998).

PRACTICE POINTS/PATIENT COUNSELLING

- Creatine is a very popular sports supplement and is not a substance banned by the International Olympic Committee. Although scientific evidence supports its use in high-intensity, repetitive burst exercise, not every individual will respond. Investigation is underway to determine the key characteristics of athletes most likely to respond.
- Creatine is also used in the treatment of numerous conditions involving fatigue or muscle weakness, but little evidence is available yet to determine its effectiveness.
- Creatine is used in the production of ATP, the main source of energy for muscle activity and many other biological functions.
- Clinical studies suggest that creatine supplementation may improve cognitive function and mood.
  - Neuroprotective effects observed in animal studies and some clinical studies suggest a possible role in neurodegenerative diseases; however, further research is still required to clarify its role.
- In practice, creatine is often taken in high doses for 5–7 days, followed by lower maintenance doses for up to 8 weeks. This is called 'loading'.
- High-dose creatine is contraindicated in renal failure.

PREGNANCY USE

Insufficient reliable data are available, but it is generally not recommended in pregnancy.

PATIENTS' FAQs

What will this supplement do for me?

Creatine enhances physical power and recovery in most cases. It may also reduce mental fatigue, enhance mood and memory and have a protective effect on nerves. Research shows a possible role in neurodegenerative diseases, which remains to be confirmed.

When will it start to work?

The physical effects generally develop within 1–4 weeks of use.

Are there any safety issues?

It should not be taken in high doses by people with kidney disease and its long-term safety has not been established.

Damiana

HISTORICAL NOTE Damiana is a wild deciduous shrub found in the arid and semi-arid regions of South America, Mexico, United States and West Indies. It is believed that Mayan Indians used damiana to prevent giddiness, falling and loss of balance, and as an aphrodisiac. It has also been used during childbirth, and to treat colic, stop bedwetting and bring on suppressed menses. Today its leaves are used for flavouring in food and beverages, and infusions and other preparations are used for a variety of medicinal purposes.

COMMON NAME
Damiana

OTHER NAMES
Herba de la pastora, Mexican damiana, miziboc, old woman's broom, shepherd's herb, stag's herb

BOTANICAL NAME/FAMILY
Turnera diffusa, Damiana aphrodisiaca, Turnera aphrodisiaca (family Turneraceae)

PLANT PARTS USED
Dried leaves and stems

CHEMICAL COMPONENTS
Sesquiterpenes, alkaloids, essential oils containing caryophyllene, delta-cadinene, beta-elemene and 1,8-cineol and other lesser constituents, tetraphylin B (a cyanogenic glycoside, 0.26%), resin, tannins, gum, mucilage, starch, a bitter element and possibly caffeine. Damiana also contains a flavone and at least five flavonoids, including arbutin (Piacente et al 2002).

MAIN ACTIONS
The pharmacological actions of damiana have not been significantly investigated, so traditional use and in vitro and in vivo evidence is used.

Hormonal effects
One study that investigated the effects of over 150 herbs for their relative capacity to compete with oestradiol and progesterone binding to intracellular receptors identified damiana as a herb that binds to intracellular progesterone receptors, exerting a neutral effect and also exerting weak oestrogen agonist activity (Zava et al 1998). It has been reported that delta-cadinene is a testosterone inducer and 1,8-cineole is a testosterone hydroxylase inducer (Duke 2006). A study analysing the constituents of the essential oils found in various damiana samples identified that fresh and dry samples contained both compounds, but wild plants contained more delta-cadinene than cultivated plants (Alcaraz-Melendez et al 2004). The action of these constituents may support the common belief that damiana is useful as an aphrodisiac.

Anti-inflammatory activity
A significant anti-inflammatory activity was identified for the aqueous and ethanolic fractions of damiana in an experimental model (Antonio & Souza Brito 1998). Antiplatelet activity was not observed.

Hypoglycaemic agent
A decoction of dried damiana leaves caused a significant reduction of the hyperglycaemic peak, exerting a hypoglycaemic effect comparable to that of tolbutamide in an experimental model (Alarcon-Aguilara et al 1998).

CLINICAL USE
Damiana has not been significantly investigated under clinical trial conditions; therefore, evidence is derived from traditional use, in vitro and animal studies, and its clinical significance is unknown.

Sexual dysfunction or decreased libido

Damiana has been used traditionally for sexual dysfunction or as an aphrodisiac to enhance sexual activity. Scientific studies in experimental models provide preliminary support for its use in these conditions, but controlled trials are lacking. One in vivo study established that damiana fluid extract significantly improves the copulatory performance of sexually sluggish animals, but has no effect on normally functioning ones (Arletti et al 1999). The effect appears to be dose-dependent, as positive results were obtained only when the highest dose (1 mL/kg) was administered.

One clinical study of unknown design compared a herbal combination product consisting of ginseng, Ginkgo, damiana, L-arginine and a variety of vitamins and minerals with placebo in 77 female volunteers. After 4 weeks, 73.5% of the women in the treatment group reported an increase in sexual satisfaction compared with 37.2% receiving placebo (Ito et al 2001). Although promising, the role of damiana in achieving this result is unknown.

Diabetes

Although in vivo studies suggest significant hypoglycaemic activity, no clinical studies are available to determine whether the effects are clinically significant.

Weight loss

No controlled studies are available to determine the effectiveness of damiana as a stand-alone treatment in weight loss; however, one study that used a combination of herbs that included damiana has produced positive results. The randomised, double-blind study involving 47 overweight subjects tested a herbal combination product known as 'YGD' (*Yerbe mate*, *Paullinia cupana* and damiana) for weight loss activity. Treatment resulted in a prolonged gastric emptying time and a body weight reduction of 5.1 $\pm$ 0.5 kg compared with 0.3 $\pm$ 0.08 kg after placebo over 45 days. A 12-month follow-up revealed that weight loss was maintained in the active treatment group (Andersen & Fogh 2001). Until studies using damiana as sole therapy are conducted, the effectiveness of this herb in weight loss is still unknown.

OTHER USES

In practice, damiana is sometimes used to treat anxiety and depression associated with hormonal changes (e.g. menopause) or where there is a sexual factor involved. It is also used as a mild stimulant and aphrodisiac, to enhance stamina generally, and for nervous dyspepsia and constipation.

DOSAGE RANGE

- Dried leaf: 2–4 g taken three times daily.
- Infusion: pour a cup of boiling water onto one teaspoonful of the dried leaves and let infuse for 10–15 min. Drink three cups daily.
- Liquid extract (1:2) or solid dose equivalent: 20–40 mL/wk or 3–6 mL/day.

ADVERSE REACTIONS

There is insufficient reliable information available.

SIGNIFICANT INTERACTIONS

Controlled studies are not available; therefore, interactions are based on evidence of activity and are largely theoretical and speculative.

Hypoglycaemic agents

Additive effects are theoretically possible, with unknown clinical significance — observe patients.

CONTRAINDICATIONS AND PRECAUTIONS

Traditionally, the herb is not recommended for people with overactive sympathetic nervous system activity.

PREGNANCY USE

Safety in pregnancy has not been scientifically evaluated; however, no increase in fetal abnormalities has been observed from limited use in women (Mills & Bone 2005).

PRACTICE POINTS/PATIENT COUNSELLING

- Damiana is a herb with a traditional reputation as being an aphrodisiac, stimulant, mood enhancer and general tonic.
- Currently, evidence to support its use as an aphrodisiac is limited to research in animals, which has produced some positive results.
- In vivo studies have identified significant anti-inflammatory and hypoglycaemic activity, although human studies are still required to determine clinical significance.
- It is also suspected that the herb exerts some degree of hormonal activity.

PATIENTS' FAQs

What will this herb do for me?

Damiana has not been significantly tested in human studies, so much information is taken from traditional sources or preliminary research in animals. According to these sources, it may increase sexual function and libido in some cases of dysfunction, lower blood glucose levels and exert anti-inflammatory actions.

When will it start to work?

There is insufficient evidence to predict when effects may develop.

Are there any safety issues?

A long history of use suggests it is generally safe. However, scientific testing has not been conducted.

Dandelion

HISTORICAL NOTE Dandelion grows as a perennial native herb throughout the Northern Hemisphere and as a weed in other temperate zones. It has a long history of medicinal and culinary use. Dandelion leaves are added to salads, providing a good source of minerals, and the roasted root is used as a coffee substitute. Dandelion leaves are traditionally used as a diuretic, and the root as a liver tonic.

OTHER NAMES

Blowball, cankerwort, common dandelion, lion's tooth, priest's crown, puffball, swine snout, taraxacum, wild endive, white endive

BOTANICAL NAME/FAMILY

Taraxacum officinale; synonyms: *Leontodon taraxacum*, *Taraxacum vulgare* (family Compositae [Asteraceae])

PLANT PARTS USED

Leaf and root

CHEMICAL COMPONENTS

Dandelion leaf and root contain slightly different constituents.

Overall, dandelion is a rich source of minerals, particularly potassium (Hook et al 1993), as well as iron, magnesium, zinc, potassium, manganese, copper, choline, selenium, calcium, boron and silicon (Queralt et al 2005), and a rich source of vitamins A, C, D and B complex (US Department of Agriculture 2003). The relatively high protein, fibre and linoleic acid content of dandelion leaves has led to suggestions that dandelion is a nutritious and underutilised food source (Escudero et al 2003). Dandelion's constituents also include triterpenes, flavonoid glycosides and various phenolic acids, as well as phytosterols, sugars and mucilage (Blumenthal et al 2000). The phenolic acids and flavonoids include chicoric acid (dicaffeoyltartaric acid) and quercetin glycosides, respectively (Schutz et al 2005).

MAIN ACTIONS

Diuretic

Dandelion leaf has been found to have a greater diuretic effect than the roots, with activity comparable to that of frusemide, without causing potassium loss because of the leaves' high potassium content (Newell et al 1996). A study using an infusion of dandelion root found that dandelion did not significantly increase diuresis in rats (Grases et al 1994), and no secondary metabolites showing major diuretic activity were found (Hook et al 1993).

Choleretic

The bitter constituents in dandelion root are believed to be responsible for increasing bile production and flow, as well as contributing to the root's mild laxative effects.

Hepatic enzyme induction

In vivo studies have demonstrated decreased activity of CYP1A2 and CYP2E enzymes and dramatic increases in levels of the phase II detoxifying enzyme UDP-glucuronosyl transferase in liver microsomes of rats receiving dandelion tea (Maliakal & Wanwimolruk 2001). The same study found that dandelion tea had no effect on the activities of CYP2D and CYP3A.

Anti-inflammatory and antioxidant activity

Pharmacological tests demonstrate that ethanol extract of dandelion (part used not reported) has anti-angiogenic, anti-inflammatory and antinociceptive actions through its inhibition of nitric oxide production and COX-2 expression and/or its antioxidative activity. Dandelion extract was shown to exhibit a mild analgesic and anti-inflammatory effect in mice (Tito et al 1993), and an aqueous dandelion extract was found to prevent diabetic complications due to lipid peroxidation and free radicals in diabetic rats (Cho et al 2002). Dandelion extract has also been found to have a protective effect against induced acute pancreatitis in rats (Seo et al 2005) and dandelion flower extract demonstrated marked antioxidant activity that has been attributed to its phenolic content, with suppression of reactive oxygen species and nitric oxide (Hu & Kitts 2003, 2005, Kery et al 2004). Extracts of dandelion flowers, roots and stem have been found to have significant OH-radical scavenging activity (Kaurinovic et al 2003).

OTHER ACTIONS

Traditionally, dandelion root is understood to have laxative activity and to stimulate digestion, whereas dandelion leaf has antirheumatic effects. Dandelion root infusion, which contains oligofructans,

has been found to stimulate the growth of multiple strains of bifidobacteria, suggesting its use as a probiotic (Trojanova et al 2004).

Dandelion may have antidiabetic actions because ethanolic extracts of whole dandelion exhibited insulin secretagogue activity (Hussain et al 2004) and dandelion in conjunction with various other herbal extracts has been shown to have an antihyperglycaemic effect in mice (Petlevski et al 2003). Plants of the genus Taraxacum (dandelions) have a history of use in Chinese, Arabian and Native American traditional medicine, to treat a variety of diseases, including cancer. An extract of dandelion leaf (but not root or flowers) has been demonstrated to decrease the growth of MCF-7/AZ breast cancer cells in vitro suggesting that it may be of value as an anticancer agent. There is preliminary scientific evidence from animal and in vitro studies that suggest the roots of *Taraxacum japonicum* (Japanese dandelion) may have a cancer preventative effect. The extract has been shown to induce cytotoxicity through TNF-alpha and IL-1-alpha secretion in vitro.

CLINICAL USE

The therapeutic effectiveness of dandelion has not been significantly investigated under clinical trial conditions, so evidence is derived from traditional, in vitro and animal studies.

Diuretic

Dandelion has a long history of use as a diuretic in well-established systems of traditional medicines; however, the scientific and clinical evidence to support this use is limited to animal studies (see above). The high potassium content of dandelion is considered to be partly responsible for any diuretic activity (Hook et al 1993).

A double-blind, randomised study of 57 women with recurrent cystitis found that a commercial preparation known as Uva-E (a combination of bearberry leaves and dandelion root) significantly reduced the frequency of recurrence of cystitis compared with placebo. At the end of 12 months, none of the patients taking Uva-E had a recurrence of cystitis, compared with 23% recurrence in the control group ($P < 0.05$) (Larsson et al 1993). The role of dandelion in achieving this result is unknown; however, the researchers suggested that its diuretic effect was likely to have contributed to the positive results.

Liver tonic

Dandelion has a long history of use as a liver tonic (Macia et al 2005); however, the scientific and clinical evidence to support this use is limited. Preliminary studies suggest that dandelion root stimulates the flow of bile.

Commission E approves the use of dandelion root and herb for disturbances in bile flow, loss of appetite and dyspepsia (Blumenthal et al 2000).

European Scientific Co-Operative on Phytotherapy (ESCOP 2003) recommends dandelion root for 'restoration of hepatic and biliary function, dyspepsia, and loss of appetite'.

OTHER USES

Dandelion has been used traditionally as a source of minerals and for treating diabetes, rheumatic conditions, heartburn, bruises and for recurrent hives, urticaria and eczema. It has also been used to treat various digestive complaints such as dyspepsia, lack of appetite and constipation (Newell et al 1996), as well as for breast and uterine cancers (Koo et al 2004). The sap has been used topically on warts (Guarrera 2005).

DOSAGE RANGE

Leaf

- Infusion of dried herb: 4–10 g three times daily.
- Fluid extract (25%): 4–10 mL three times daily.
- Fresh juice: 10–20 mL three times daily.

Root

- Decoction of dried root: 2–8 g three times daily.
- Tincture (1:5): 5–10 mL three times daily.
- Fluid extract (30%): 2–8 mL three times daily.
- Juice of fresh root: 4–8 mL three times daily.

ADVERSE REACTIONS

Dandelion is generally considered safe when consumed in amounts commonly found in foods. Side effects are rare, and the likelihood of dandelion leaf preparations causing a contact allergy is low. However, cross-reactivity may exist between dandelion and other members of the Compositae (Asteraceae) family, such as ragweed, mugwort, sunflower, daisy and chamomile (Cohen et al 1979, Fernandez et al 1993, Jovanovic et al 2004). The most common type of allergy to dandelion is dermatitis following direct skin contact. Contact allergy to herbal teas derived from the plant family was investigated in patients allergic to sesquiterpene lactones (SLs). Ninety percent had positive test reactions to the Compositae teas, mainly to those based on dandelion, German chamomile and wormwood. Children with a family or personal history of atopy, summer-related or -exacerbated dermatitis of any kind, may be more sensitive to exposure to Compositae weeds, especially dandelions.

Avoid in patients with hypersensitivity/allergy to dandelion or other member of the Asteraceae family.

SIGNIFICANT INTERACTIONS

Controlled studies are not available; therefore, interactions are based on evidence of activity and are largely theoretical and speculative.

Diuretic agents

Dandelion leaf may theoretically interact with other diuretics, although the clinical significance of this is unknown — observe patient.

Quinolone antibiotics

The high mineral content of dandelion may result in the formation of chelate complexes with quinolone antibiotics and reduce their absorption and bioavailability. This has been demonstrated in rats with *Taraxacum mongolicum* (Chinese dandelion) (Zhu et al 1999). While the clinical significance of

this is unknown, it is recommended to avoid concomitant use of these substances or to separate their dosing.

CONTRAINDICATIONS AND PRECAUTIONS

It is recommended that dandelion not be used by people with obstruction of the bile ducts or other serious diseases of the gall bladder (Blumenthal et al 2000).

PREGNANCY USE

Based on a long history of use in traditional medicine, dandelion is generally considered safe in pregnancy and lactation (Blumenthal et al 2000, McGuffin et al 1997).

PRACTICE POINTS/PATIENT COUNSELLING

- Dandelion leaf and root have a long tradition of culinary and medicinal use.
- Dandelion has been traditionally used as a diuretic and liver tonic. It has also been used to treat various digestive complaints such as dyspepsia, lack of appetite and constipation.
- The therapeutic effectiveness of dandelion has not been significantly investigated under clinical trial conditions, so evidence is derived from traditional, in vitro and animal studies.
- Dandelion is generally considered to be safe and non-toxic, but may cause allergy in people allergic to ragweed and daisies.

PATIENTS' FAQs

What will this do for me?

In practice, dandelion is used to improve digestion and detoxification, as a diuretic and laxative and to treat diabetes, rheumatic conditions, heartburn, bruises and for recurrent hives, urticaria and eczema. Controlled studies are not available to determine its effectiveness in these conditions.

When will it work?

Stimulation of digestive processes is thought to occur rapidly after one dose.

Are there any safety issues?

Dandelion is generally considered to be safe and non-toxic but may cause allergy in people allergic to ragweed and daisies.
