Devil's claw

HISTORICAL NOTE The botanical name *Harpagophytum* means 'hook plant' in Greek, after the hook-covered fruits of the plant. Devil's claw is native to southern Africa and has been used traditionally as a bitter tonic for digestive disturbances, febrile illnesses and allergic reactions, and to relieve pain (Mills & Bone 2000). It has been used in Europe for the treatment of rheumatic conditions for over 50 years, and was first cited in the literature by Zorn at the University of Jena, Germany, who described his observations on the antiphlogistic and anti-arthritic effects after administration of oral aqueous extracts prepared from the secondary roots of *H. procumbens* in patients suffering from arthritides (Chrubasik et al 2006).

COMMON NAMES
Devil's claw root, grapple plant, harpagophytum, wood spider

BOTANICAL NAME/FAMILY
Harpagophytum procumbens (family Pedaliaceae)

PLANT PART USED
Dried tuber/roots

CHEMICAL COMPONENTS
The major active constituent is considered to be the bitter iridoid glucoside, harpagoside, which should constitute not less than 1.2% of the dried herb. Other iridoid glycosides include harpagide, procumbide, 8-O-(p-coumaroyl)-harpagide and verbascoside. About 50% of the herb consists of sugars. There are also triterpenes, phytosterols, plant phenolic acids, flavonol glycosides and phenolic glycosides. *Harpagophytum zeyheri*, which has a lower level of active compounds, may be partially substituted for *H. procumbens* in some commercial preparations (Stewart & Cole 2005). The extraction solvent (e.g. water, ethanol) has a major impact on the active principle of the products (Chrubasik 2004a). When administering *H. procumbens* extract topically it was found that higher penetration of all compounds occurred from an ethanol/water preparation (Abdelouahab & Heard 2008b).

MAIN ACTIONS

Anti-inflammatory/analgesic
There is good in vitro and in vivo pharmacological evidence of the anti-inflammatory and analgesic properties of devil's claw, although some negative findings have also been reported (McGregor et al 2005). Overall, greatest activity appears to be in semi-chronic rather than acute conditions.

Devil's claw exerted significant analgesic effects against thermally and chemically induced nociceptive pain stimuli in mice and significant dose-related reduction of experimentally induced acute inflammation in rats (Mahomed & Ojewole 2004), as well as reducing pain and inflammation in Freund's adjuvant-induced arthritis in rats (Andersen et al 2004). Results from a recent study in mice suggest that the opioid system is involved in the antinociceptive effects of *H. procumbens* extract (Uchida et al 2008).

The iridoids, particularly harpagoside, are thought to be the main active constituents responsible for the anti-inflammatory activity, although the mechanism of action is unknown and devil's claw is also rich in water-soluble antioxidants (Betancor-Fernandez et al 2003). More recent in vitro evidence suggests that the anti-inflammatory effect may in part be due to antioxidant activity (Denner 2007, Grant et al 2009, Langmead et al 2002). A study administering *H. procumbens* extract intraperitoneally to rats found that the anti-inflammatory response does not depend on the release of adrenal corticosteroids (Catelan et al 2006).

Contradictory evidence exists as to whether devil's claw affects prostaglandin (PG) synthesis. Early in vitro and in vivo studies suggest that it does not inhibit PG synthesis (Whitehouse et al 1983) and this is supported by studies of PG production in humans (Moussard et al 1992). However, more recent investigations have suggested that its anti-inflammatory and analgesic activities are due to suppression of PGE_2 synthesis and nitric oxide production and that the herb may suppress expressions of COX-2 and iNOS (Jang et al 2003). Harpagoside alone has been shown to suppress COX-2 and iNOS at both the mRNA and protein level in vitro due to a suppression of NF-kappaB activation (Huang et al 2006). Recent in vitro research shows that harpagoside and 8-O-(p-coumaroyl)-harpagide exhibit a greater reduction in COX-2 expression than verbascoside and that harpagide on the other hand causes a significant increase in COX-2 expression (Abdelouahab & Heard 2008a). Additionally, methanolic extracts of devil's claw have been shown to inhibit COX-2 in vivo (Kundu et al 2005, Na et al 2004).

Inhibition of leukotriene synthesis has been observed in vitro, which appears to relate to the amount of harpagoside present (Loew et al 2001). A study using subcritical and supercritical CO_2 extracts (15 to 30% harpagoside) showed almost total inhibition of 5-lipoxygenase biosynthesis at 51.8 mg/mL of extract, whereas the conventional extract (2.3% harpagoside) did not inhibit the enzyme significantly (Gunther et al 2006).

In vivo experiments have determined that the method of administration of devil's claw affects its anti-inflammatory properties. Intraperitoneal and intraduodenal administration was shown to reduce carrageenan-induced oedema, whereas oral administration had no effect, suggesting that exposure to stomach acid may reduce its anti-inflammatory activity (Soulimani et al 1994). This is supported by a study that found a loss of anti-inflammatory activity after acid treatment (Bone & Walker 1997).

In vitro studies on rat mesangial cells suggest that devil's claw may be used as an anti-inflammatory agent in the treatment of glomerular inflammatory diseases (Kaszkin et al 2004a). Devil's claw extract produced a concentration-dependent suppression of nitrite formation in rat mesangial cells in vitro due to an inhibition of iNOS expression through interference with the transcriptional activation of iNOS. It was found that this activity was due to harpagoside, together with other constituents that possibly have strong anti-oxidant activity (Kaszkin et al 2004b).

It has been suggested that the suppression of inflammatory cytokine synthesis, demonstrated in vitro and vivo (Fiebich et al 2001, Spelman et al 2006), could explain its therapeutic effect in arthritic inflammation (Kundu et al 2005). Fiebich and co-workers found that a 60% ethanolic extract decreases the expression of IL-1-beta, IL-6, and TNF-alpha (Fiebich et al 2001).

Chondroprotective

In vitro data suggest that the active principles of *H. procumbens* inhibit not only inflammatory mediators but also mediators of cartilage destruction, such as matrix metalloproteinases, NO and elastase (Boje et al 2003, Schulze-Tanzil et al 2004). A study using an animal model confirmed a chondroprotective effect in which the tissue inhibitor of metalloproteinase-2 is involved (Chrubasik et al 2006).

Hypoglycaemic

Devil's claw extract produced a dose-dependent, significant reduction in the blood glucose concentrations of both fasted normal and fasted diabetic rats (Mahomed & Ojewole 2004).

OTHER ACTIONS

In vitro and in vivo evidence suggests that harpagoside may exhibit cardiac affects and lower blood pressure, heart rate and reduce arrhythmias (Fetrow & Avila 1999). As an extremely bitter herb, devil's claw is thought to increase appetite and bile production. Diterpenes extracted from the roots and seeds of devil's claw exhibited selective antiplasmodial (Clarkson et al 2003) and antibacterial activity (Weckesser et al 2007) in vitro, which may have future relevance in view of the increasing resistance to conventional antimalarials and antibiotics. One study showed that aqueous devil's claw extract can markedly delay the onset, as well as reduce the average duration, of convulsion in mice. Although not conclusive, it seems that the extract produces its anticonvulsant activity by enhancing GABAergic neurotransmission and/or facilitating GABAergic action in the brain (Mahomed & Ojewole 2006).

CLINICAL USE

Arthritis

Overall, evidence from clinical trials suggests that devil's claw is effective in the treatment of arthritis.

An observational study of 6 months' use of 3–9 g/day of an aqueous extract of devil's claw root reported significant benefit in 42–85% of the 630 people suffering from various arthritic complaints (Bone & Walker 1997). In a 12-week uncontrolled multicentre study of 75 patients with arthrosis of the hip or knee, a strong reduction in pain and the symptoms of osteoarthritis were observed in patients taking 2400 mg of devil's claw extract daily, corresponding to 50 mg harpagoside (Wegener & Lupke 2003). Similar results were reported in a 2-month observational study of 227 people with osteoarthritic knee and hip pain and non-specific low back pain (Chrubasik et al 2002) and a double-blind study of 89 subjects with rheumatic complaints using powdered devil's claw root (2 g/day) for 2 months, which also provided significant pain relief, whereas another double-blind study of 100 people reported benefit after 1 month (Bone & Walker 1997). A case report suggests that devil's claw relieved strong joint pain in a patient with Crohn's disease (Kaszkin et al 2004b). A single group open study of 8 weeks duration involving 259 patients showed statistically significant improvements in patient assessment of global pain, stiffness and function, and significant reductions in mean pain scores for hand, wrist, elbow, shoulder, hip, knee and back pain. Moreover, quality of life scores significantly increased and 60% of patients either reduced or stopped concomitant pain medication (Warnock et al 2007).

Comparisons with standard treatment have also been investigated. In 2000, encouraging results of a randomised double-blind study comparing the effects of treatment with devil's claw 2610 mg/day with diacerhein 100 mg/day were published (Leblan et al 2000). The study involved 122 people with osteoarthritis of the hip and/or knee and was conducted over 4 months. It found that both treatment groups showed similar considerable improvements in symptoms of osteoarthritis; however, those receiving devil's claw required fewer rescue analgesics.

One double-blind, randomised, multicentre clinical study of 122 patients with osteoarthritis of the knee and hip found that treatment with Harpadol (6 capsules/day, each containing 435 mg of cryoground powder of *H. procumbens*) given over 4 months was as effective as diacerhein (an analgesic) 100 mg/day (Chantre et al 2000). However, at the end of the study, patients taking Harpadol were using significantly fewer NSAIDs and had a significantly lower frequency of adverse events. In a 6-week study of only 13 subjects, similar benefits for devil's claw and indomethacin were reported (Newall et al 1996). A preliminary study comparing the proprietary extract Doloteffin with the COX-2 inhibitor rofecoxib reported a benefit with the herbal treatment but suggested that larger studies are still required (Chrubasik et al 2003b).

Previously reviews have concluded that there is moderate evidence of the effectiveness of *H. procumbens* in the treatment of osteoarthritis of the spine, hip and knee; however it is suggested, as with many herbal medicines, that evidence of effectiveness is not transferable from product to product and that the evidence is more robust for products that contain at least 50 mg of harpagoside in the daily dosage (Chrubasik et al 2003a, Gagnier et al 2004, Long et al 2001).

Recently two reviews have concluded that 'data from higher quality studies suggest that Devil's claw appeared effective in the reduction of the main clinical symptom of pain' (Brien et al 2006) and that the evidence of effectiveness was 'strong' for at least 50 mg of harpagoside as the daily dose (Chrubasik JE et al 2007). Nevertheless, 2 other recent reviews concluded that there was only 'limited evidence' (Ameye & Chee 2006) and 'insufficient reliable evidence' regarding the long term effectiveness of devil's claw (Gregory et al 2008).

The herb is Commission E approved as supportive therapy for degenerative musculoskeletal disorders (Blumenthal et al 2000) and ESCOP approved for painful osteoarthritis (ESCOP 2003).

Back pain

Several double-blind studies have reported benefit with devil's claw in people with back pain. A double-blind study of 117 people with back pain reported decreased pain and improved mobility after 8 weeks' treatment with devil's claw extract LI 174, known commercially as Rivoltan (Laudahn & Walper 2001). Use of the same extract provided significant pain relief after 4 weeks in another randomised, double-blind placebo-controlled study of 63 subjects with muscle stiffness (Gobel et al 2001). Similar results were reported in two double-blind studies of 118 people (Chrubasik et al 1996) and 197 people (Chrubasik et al 1999) with chronic lower back pain.

Devil's claw appears to compare favourably to conventional treatments. A 6-week double-blind study of 88 subjects comparing devil's claw to rofecoxib found equal improvements in both groups (Chrubasik et al 2003b) A follow-up of the subjects from that study who were all given devil's claw for 1 year found that it was well tolerated and improvements were sustained (Chrubasik et al 2005). In an open, prospective study, an unspecific lower back pain treatment with *Harpagophytum* extract and conventional therapy were found to be equally effective (Schmidt et al 2005).

Three recent reviews looking at the treatment of low back pain concluded that there is strong evidence for short-term improvements in pain and rescue medication for devil's claw products standardised to 50 and 100 mg harpagoside as daily doses (Chrubasik JE et al 2007, Gagnier et al 2006, 2007).

Devil's claw root is approved for relief of low back pain by ESCOP (ESCOP 2003).

Dyspepsia

Traditionally, devil's claw has also been used to treat dyspepsia and to stimulate appetite (Fisher & Painter 1996). The bitter principles in the herb provide a theoretical basis for its use in these conditions, although controlled studies are not available to determine effectiveness. The herb is Commission E (Blumenthal et al 2000) and ESCOP (2003) approved for dyspepsia and loss of appetite.

OTHER USES

Traditionally, the herb is also used internally to treat febrile illnesses, allergic reactions and to induce sedation, and topically for wounds, ulcers, boils and pain relief (Fisher & Painter 1996, Mills & Bone 2000), as well as for diabetes, hypertension, indigestion and anorexia (Van Wyk 2000).

DOSAGE RANGE

Musculoskeletal conditions

- Dried root or equivalent aqueous or hydroalcoholic extracts: 2–6 g daily for painful arthritis; 4.5–9 g daily for lower back pain.
- Liquid extract (1:2): 6–12 mL/day.
- Tincture (1:5): 2–4 mL three times daily.

It is suggested that devil's claw extracts with at least 50 mg harpagoside in the daily dosage should be recommended for the treatment of pain (Chrubasik 2004a, 2004b).

Digestive conditions (e.g. dyspepsia)

- Dosages equivalent to 1.5 g/day dried herb are used (Blumenthal et al 2000). It is suggested that devil's claw preparations be administered between meals, when gastric activity is reduced.

TOXICITY

The acute LD_{50} of devil's claw was more than 13.5 g/kg according to one study (Bone & Walker 1997). In a recent review of 28 clinical trials only a few reports on acute toxicity were found, whereas no reports on chronic toxicity had been reported. The review concluded that more studies for long-term treatment are needed (Vlachojannis et al 2008). An earlier review looking at 14 clinical trials had come to the same conclusion (Brien et al 2006).

ADVERSE REACTIONS

Devil's claw is a well tolerated treatment. In a recent review of 28 clinical trials it was found that only minor adverse events, mainly mild gastrointestinal symptoms (e.g. diarrhoea), occur in 3% of the patients. The incidence of adverse effects in the treatment groups was never higher than in the placebo groups for all 28 trials (Vlachojannis et al 2008).

SIGNIFICANT INTERACTIONS

Devil's claw has been found to moderately inhibit cytochrome P450 enzymes (CYP2C9, 2C19, 3A4) in vitro (Unger & Frank 2004), however, the clinical relevance of this is yet to be determined. In contrast to NSAIDs, devil's claw does not affect platelet function (Izzo et al 2005).

Warfarin

Rare case reports suggest that devil's claw may potentiate the effects of warfarin, but the reports are mostly inconclusive (Argento et al 2000, Heck et al 2000, Izzo et al 2005). Clinical testing would be required to confirm a possible interaction.

Anti-arrythmic drugs

Theoretical interaction exists when the herb is used in high doses; however, clinical testing is required to determine significance — observe patients taking concurrent antiarrythmics (Fetrow & Avila 1999).

CONTRAINDICATIONS AND PRECAUTIONS

Use cautiously in patients with gastric and duodenal ulcers, gallstones or acute diarrhoea, as devil's claw may cause gastric irritation (Blumenthal et al 2000).

PREGNANCY USE

Devil's claw is not recommended in pregnancy, as it has exhibited oxytocic activity in animals.

PRACTICE POINTS/PATIENT COUNSELLING

- Devil's claw reduces pain and inflammation and is a useful treatment in arthritis and back pain, according to controlled studies.
- The anti-inflammatory action appears to be different to that of NSAIDs and has not been fully elucidated. There is also preliminary evidence of a chondroprotective effect.
- Preliminary research suggests that it is best to take devil's claw between meals, on an empty stomach.
- Devil's claw appears to be relatively safe but should not be used in pregnancy and should be used with caution in people with ulcers or gallstones or in those taking warfarin.

PATIENTS' FAQs

What will this herb do for me?

Devil's claw is a useful treatment for arthritis and back pain. It may also increase appetite and improve digestion and dyspepsia.

When will it start to work?

Results from studies suggest that pain-relieving effects will start within 4–12 weeks reaching maximum pain relief after 3–4 months (Chrubasik S et al 2007, Thanner et al 2008).

Are there any safety issues?

Devil's claw should be used cautiously by people with gallstones, diarrhoea, stomach ulcers and those taking the drug warfarin. It is also not recommended in pregnancy.

Dong quai

HISTORICAL NOTE Dong quai is an aromatic herb commonly used in Traditional Chinese Medicine (TCM). Its reputation is second to that of ginseng and is regarded as a 'female' remedy, or 'women's ginseng'. Used in combination with other herbs, dong quai is used to treat numerous menstrual disorders and menopausal symptoms, as well as abdominal pain, migraine headache, rheumatism and anaemia (Murray 1995). Dong quai (*Angelica sinensis*) is closely related to the European *Angelica archangelica*, a common garden herb and the flavouring in Benedictine and Chartreuse liqueurs.

COMMON NAME
Dong quai

OTHER NAMES
Chinese angelica, dang gui, women's ginseng, tang kuei

BOTANICAL NAME/FAMILY
Angelica sinensis (synonym: *Angelica polymorpha* var. *sinensis*) (family Apiaceae [Umbelliferae] — carrot family)

PLANT PART USED
Root

CHEMICAL COMPONENTS
Dong quai contains essential oil (0.4–0.7%) consisting of 45% ligustilide, n-butylphthalide, cadinene, carvacrol, safrole and isosafrol. The root also contains sucrose (40%) and various lactones and vitamins, together with phytosterols, ferulic acid and coumarins, including osthole, psoralen and bergapten (Micromedex 2003). Ferulic acid and ligustilide are considered to be the main active components (Dong et al 2005) and it has been suggested that assessment of total ferulic acid content provides a good measure of herbal quality (Lu et al 2005). High Performance Liquid Chromatography (HPLC) fingerprinting studies further suggest that active components are maintained better with whole roots than with prepared slices (Wu et al 2008). It is further suggested that the phenolic acids are the important contributors for antioxidant activity and that to maximise retention of volatile components, extracts should be prepared with 20% ethanol with extraction time less than 30 min (Huang et al 2008a).

MAIN ACTIONS
Nearly all studies investigating the pharmacological effects of dong quai have been conducted in vitro or in animals, so it is difficult to predict whether the observed effects are clinically significant.

Hormone modulation and uterine effects
Studies on the uterine effects of dong quai have produced variable results. A uterine relaxant effect has been attributed to the volatile oil, whereas a uterine stimulant effect has been attributed to an aqueous extract (Mills & Bone 2000). Animal experiments report that dong quai produces increased uterine excitability, with initial irregular, fast contractions, later slowing and becoming more regular (Zhu 1987).

Studies of dong quai's oestrogenic activity have also produced contradictory results. In vitro reports suggest that dong quai has weak oestrogen receptor-binding activity, producing up-regulation of progesterone receptor mRNA (Liu et al 2001), and stimulating oestrogen-dependent breast cancer cells independent of oestrogenic activity (Amato et al 2002). An aqueous extract of dong quai was found to stimulate the growth of both oestrogen receptor-positive and -negative breast cancer cells in vitro, suggesting both a weak oestrogen-agonistic activity and activity independent of oestrogen receptor-mediated pathways (Lau et al 2005). An in vivo study in ovariectomised rats found that dong quai had oestrogenic effects with stimulation of the uterine histoarchitecture with significant cornification in the vaginal epithelium and a reduction of serum LH concentration (Circosta et al 2006).

These findings are contrasted by a study using several different in vitro bioassays that found that dong quai did not have oestrogenic activity (Klein et al 2003), oestrogen receptor-binding activity or stimulate the growth of oestrogen-positive breast cancer cells and that it had neutral progestin activity (Zava et al 1998). Dong quai has also been reported to exhibit antioestrogenic and antiandrogenic activities in vitro (Rosenberg et al 2001).

Immunostimulant effect
It is reported that dong quai can counter the immunosuppressive effects of hydrocortisone in vivo (Mills & Bone 2000). Immunostimulation is further suggested by in vitro studies demonstrating enhanced cell-mediated immunity (Yang et al 2005) and up-regulation of IL-2 and IFN-gamma (Yang et al 2005), as well as non-specific lymphoproliferation (Wilasrusmee et al 2002). A polysaccharide from dong quai has also been found to enhance non-specific immunity while suppressing humoral immunity (Yang et al 2003).

Hepatoprotection
Dong quai is said to improve abnormal protein metabolism in people with chronic hepatitis or hepatic cirrhosis. Evidence comes from an in vivo study in which 5% dong quai was added to the daily diet of rats, resulting in enhanced metabolism, increased hepatic oxygen utilisation and increased glutamic acid and cysteine oxidation (Micromedex 2003). Dong quai has been found to have antioxidant activity (Wu et al 2004), as well as antiproliferative and proapoptotic activities in hepatic stellate cells in vitro, suggesting a potential antifibrotic action (Chor et al 2005).

Cardiac protection
Dong quai is reported to have a quinidine-like action, prolonging the cardiac refractory period and correcting atrial fibrillation (Fetrow & Avila 1999). An in vitro study of dong quai in conjunction with *Astragalus membranaceus* demonstrated protection against myocardial ischaemia-reperfusion injury (Yim et al 2000), while in vivo studies report prevention of atherosclerosis, dilation of coronary vessels and increased coronary blood flow (Mills & Bone 2000). In vivo and in vitro studies have also shown angiogenic effects (Lam et al 2008, Meng et al 2008) with enhanced expression of vascular endothelial growth factor (Shi et al 2007). A combined extract of dong quai and *Ligusticum chuanxiong* has been found to inhibit vascular smooth muscle cell proliferation in vitro (Hou et al 2005). In vivo studies in mice suggest that dong quai may protect against doxorubicin-induced chronic cardiotoxicity without compromising doxorubicin's antitumour activity (Xin et al 2007).

Anticoagulant and antiplatelet effects

Dong quai has been shown to have potent anticoagulant effects, as well as haemostatic effect related to promoting platelet aggregation (Yang et al 2002b). In a controlled trial, an IV preparation of dong quai was found to prolong prothrombin times significantly more than IV dextran in a group of 96 patients admitted with ischaemic stroke (Micromedex 2003). Dong quai has also been shown to significantly inhibit platelet activation, relieve vascular endothelial cell injury and improve microcirculation in patients with ulcerative colitis (Dong et al 2004). Ferulic acid, found in dong quai, has been reported to inhibit the aggregation of platelets in blood and retard platelet release of serotonin and adenosine diphosphate. *Angelica sinensis* has a lower coumarin content than other *Angelica* species.

Anticarcinogenic

Polysaccharides from dong quai have been shown to possess antitumour effects in experimental in vivo tumour models and inhibitory effects on invasion and metastasis of in vitro hepatocellular carcinoma cells (Shang et al 2003). An acetone extract of dong quai was found to inhibit proliferation of human cancer cells in vitro via induction of cell cycle arrest and apoptosis (Cheng et al 2004). There is evidence to suggest that a chloroform extract of dong quai suppresses growth of malignant brain tumour cells in vitro, as well as suppressing growths of malignant brain tumours of rat and human origin and shrinking the volumes of in situ glioblastoma multiforme, significantly prolonging survivals in vivo (Tsai et al 2005). An in vitro study suggests that the three main phthalides might have anticancer potential and that they may work in synergy with other compounds to produce an even stronger antitumour effect (Kan et al 2008).

Dong quai has been shown to protect against the cytotoxicity of cyclophosphamide on haematopoietic and gastrointestinal tissues in mice studies which further suggest that this may occur in part through the down regulation of vascular endothelial growth factor (Hui et al 2006). In vitro and in vivo studies in mice have also found that lipid soluble extracts of dong quai inhibit tumour growth through a similar mechanism (Lee et al 2006).

Neuroprotection

Dong quai has been found to be effective in treating acute cerebral infarction. In a case series of 1404 patients with acute cerebral infarction, of whom 692 were treated with dong quai injection, 390 with compound salvia and 322 with low-molecular-weight dextran injection, the group treated with dong quai were found to have significantly better neurological function and a larger reduction of infarcted area than the other groups (Liu Y-M et al 2004).

Bak Foong Pills, a combination Chinese herbal formula that contains dong quai and other herbs such as *Panax ginseng* and *Glycyrrhiza uralensis*, has been found to have a neuroprotective action, suggesting that these herbs may be used in the treatment of neurodegenerative diseases, such as Parkinson's disease (Jia et al 2005, Rui et al 2005). A multiherbal formula (Guibi-tang) containing dong quai has also been shown to improve learning and memory, and to increase the proliferation of hippocampal cells in rats (Oh et al 2005). An aqueous extract of three herbs, including dong quai, has been found to have a neuroprotective action and improve cognitive function in an animal model of vascular dementia (Lin et al 2005), and a multiherbal combination (Danggui-Shaoyao-san) has been found to improve memory and modulate monoamine neurotransmitter metabolism suggesting a possible use for treating senile dementia and Alzheimer's disease (Kou et al 2005). This is supported by in vitro studies, which found that dong quai extract prevented the neurotoxicity induced by Amyloid beta (A-beta) associated oxidative stress (Huang et al 2008b).

Gastroprotection

Polysaccharides derived from dong quai have been found to have a protective effect on colon injury in animal models through promotion of growth factors, decreasing oxygen free radicals and some anti-inflammatory effects (Liu S-P et al 2004, Wong et al 2008), as well as relieving the inflammation reaction and colon injury in immunological colitis in rats (Liu et al 2003a, 2003b). A polysaccharide containing extract of dong quai was also shown to promote migration and proliferation of normal gastric epithelial cells and enhance gastric ulcer healing in animal models (Ye et al 2003).

Anti-inflammatory

Dong quai is reported to be used to treat radiation pneumonitis in humans receiving treatment for thoracic cancer. In vivo mouse studies suggest that this action may be due to dong quai effectively down-regulating TNF-alpha and TGF-beta1 in irradiated lung tissue (Xie et al 2006). An aqueous extract of dong quai has also been found to protect against lethal endotoxaemia and experimental sepsis in part by attenuating systemic accumulation of late proinflammatory cytokines (Wang et al 2006).

OTHER ACTIONS

A preparation containing polysaccharides extracted from dong quai has been shown to have a radioprotective effect in mice (Mei 1988, Sun et al 2005), as well as an analgesic action in rats (Yue et al 2002).

An in vivo study has shown that dong quai in conjunction with astragalus reduced the deterioration of renal function and histologic damage in an animal model of nephrotic syndrome (Wang et al 2004). Dong quai has also been found to alleviate bleomycin-induded pulmonary fibrosis in rats (Chai et al 2003).

Dong quai promotes melanocytic proliferation, melanin synthesis and tyrosinase activity, suggesting a use in the treatment of skin pigmentation (Deng & Yang 2003).

An aqueous extract of dong quai has also been found to directly stimulate the proliferation and activity of human osteoprecursor cells in a dose-dependent manner in vitro (Yang et al 2002a).

The essential oil of dong quai has been found to have an anxiolytic action similar to diazepam in a mouse model of anxiety (Chen et al 2004).

In a rat model of iron deficiency anaemia, a dong quai polysaccharide–iron complex was found to be as effective as an iron-supplementing agent as well as supplementing blood and activating blood circulation (Wang et al 2007).

Various other in vitro and in vivo studies provide some evidence for antispasmodic, anti-allergic and antianaemic effects (Micromedex 2003).

CLINICAL USE

While dong quai has been used widely, in a clinical setting it is most often used in combination with multiple other Chinese herbs as part of traditional preparations and very little clinical research has been performed on it as a sole treatment making it difficult to assess its individual contribution to any clinical effects.

Gynaecological use

Orally, dong quai has been traditionally used in combination with other herbs for gynaecological ailments, including menstrual cramps, irregularity, retarded flow, weakness during the menstrual period and symptoms of menopause (Fisher & Painter 1996). Very little clinical research has been conducted to determine its effectiveness as sole treatment in these indications.

In a 12-week randomised, placebo-controlled trial in 55 postmenopausal women, a combination of dong quai and chamomile was found to significantly reduce hot flushes and improve sleep disturbances and fatigue. Another double-blind, randomised, placebo-controlled clinical trial of 71 women using dong quai as a single agent (4.5 g/day) found no differences between groups in the number of vasomotor flushes, endometrial thickness or vaginal cells over a 24-week period (Hirata et al 1997).

It is suggested that dong quai may have some efficacy for premenstrual syndrome when used in traditional Chinese multiherbal formulas (Hardy 2000), and an uncontrolled trial has suggested the possible benefit of uterine irrigation with dong quai extract for infertility due to tubal occlusion (Hardy 2000).

OTHER USES

In TCM, dong quai is used to strengthen the heart, lung and liver meridians and harmonise the blood. It is used to regulate menstruation, treat amenorrhoea, dysmenorrhoea, headache, constipation, abdominal pain and palpitations.

Traditionally, dong quai is considered a 'hot' herb and is not used in conditions associated with 'heat', according to these prescribing systems.

DOSAGE RANGE

- Decoction of dried root: 4.5–9 g/day.
- Liquid extract (1:2): 4.5–8.5 mL/day.

ADVERSE REACTIONS

Furanocoumarins, such as bergapten and psoralen, which are in dong quai have been widely studied for their phototoxicity; however, only *Angelica gigas* (Korean angelica) has been demonstrated to cause photodermatitis.

Safrole, found in the volatile oil, is a potential carcinogen; however, no specific cases of carcinogenesis have been reported (Micromedex 2003).

High doses of dong quai volatile oil have been reported to cause nephrosis in rats but there are no reports in humans (Zhu 1987).

SIGNIFICANT INTERACTIONS

An aqueous extract of dong quai has been found to increase CYP2D6 and 3A in vitro which may lead to potential drug interactions (Tang et al 2006).

Warfarin

Case reports suggest that the elevations in prothrombin and INR may occur when dong quai is used with warfarin (Heck et al 2000, Page & Lawrence 1999) — use caution if used concurrently with warfarin.

CONTRAINDICATIONS AND PRECAUTIONS

Because dong quai may have oestrogenic effects, women with hormone-sensitive tumours, endometriosis and uterine fibroids should avoid using dong quai.

Traditional contraindications include diarrhoea due to weak digestion, haemorrhagic disease, heavy periods, first trimester of pregnancy and acute infections such as cold or flu (Zhu 1987).

PREGNANCY USE

Dong quai may stimulate uterine contractions and is therefore contraindicated in pregnancy (Mills & Bone 2000).

PRACTICE POINTS/PATIENT COUNSELLING

- Dong quai is a popular Chinese medicine used widely to relieve menopausal symptoms; however, controlled trials in humans are lacking. In practice, dong quai is prescribed together with other herbs and may be effective when used in this way.
- Evidence of oestrogenic activity is contradictory.
- Care is required in people using drugs that affect blood clotting.
- Dong quai is generally safe when used appropriately.

PATIENTS' FAQs

What will this herb do for me?

Dong quai has a long history of use as a women's tonic. Although conclusive evidence is lacking, dong quai is used in conjunction with other herbs to assist in menopausal and menstrual complaints, and may be effective when used in this way.

When will it start to work?

It is difficult to predict from the available scientific research.

Are there any safety issues?

Dong quai appears to be relatively safe but care should be taken in people using drugs that affect blood clotting or in pregnancy and conditions that are hormone sensitive.

Dunaliella salina

HISTORICAL NOTE Microalgae is a nutrient-dense natural food and medicine that has been used for thousands of years by the Aztecs, some African and Asian peoples and South Pacific islanders. It has been suggested that gram-for-gram microalgae is the most nutrient-dense food on earth (Passwater & Solomon 1997) with minimal indigestible structures in contrast to higher plants or animals, which typically have less than half their dry weight being nutritionally useful (Bruno 2001). Examples of edible algae include *Spirulina*, *Chlorella* and *Dunaliella salina*. The last may be the most nutrient dense of the three, primarily due to its extremely high concentration of carotenoid antioxidants. The high carotenoids content is believed to impart a pink colouring to salt lakes where the microalgae flourish. The colour is amplified through the food chain to give the pink colour to brine shrimp and flamingos (Skinner 2008).

COMMON NAME
Dunaliella salina

BOTANICAL NAME/FAMILY
Dunaliella salina and *Dunaliella bardawil* are considered to be the same species (Borowitzka & Borowitzka 1988).

OTHER NAMES
Red marine phytoplankton (microalgae)

PLANT PARTS USED
Dunaliella salina is a marine phytoplankton that is a unicellular, biflagellate, soft walled, green algae that lives in salt-water lakes and coastal waters. As a phytoplankton, *D. salina* can be considered a whole plant; yet, it has a soft cell membrane that makes it easily digestible, compared with other microalgae that have hard cell walls (Ben-Amotz & Avron 1983). *D. salina* is one of the most salt-tolerant life forms known and is found in hypersaline waters generally >20% (salt lakes and evaporation ponds of salt works). It has a wide tolerance to environmental extremes, especially salinity, pH (pH 1 to pH 11), temperature (>45°C) and high UV exposure (Borowitzka & Borowitzka 1988). To cope with these extreme environments, *D. salina* produces very high levels of carotenoids in the chloroplast (organelles that conduct photosynthesis) as well as maintaining a high mineral content.

CHEMICAL COMPONENTS
D. salina contains a range of macro- and micronutrients, including amino acids, lipids and fatty acids, carbohydrates, chlorophyll, vitamins and minerals along with very high levels of carotenoids. As a phytoplankton that grows in seawater, *D. salina* is rich in many trace minerals. *D. salina* is also extremely high in carotenoids and while it contains over 500 different carotenoids, including alpha-carotene, lutein, zeaxanthin and cryptoxanthum, it is the richest known natural source of beta-carotene (USDA 2005), which it can make up to 8% of its dry weight (Ben-Amotz & Avron 1983). *D. salina* is therefore commonly used as a source of natural beta-carotene or mixed carotenoids in nutritional supplements (see Beta-carotene monograph).

Unlike synthetic (all-*trans*) beta-carotene, the beta-carotene from *D. salina* is composed of near equal amounts of the all-*trans* and 9-*cis* stereoisomers, which differ in their physicochemical features and antioxidative activity. The 9-*cis* isomer is considered to be one of nature's most powerful antioxidants, thus *D. salina* provides much greater bioavailability and antioxidant activity than synthetic beta-carotene supplements (Ben-Amotz & Levy 1996, Ben-Amotz et al 1989, Stahl et al 1993) (see *Beta-carotene* monograph).

It is believed that exposure to reactive oxygen species (ROS) triggers extensive carotenoid accumulation in *D. salina* (Ye et al 2008) and there are a number of biotechnology processes aimed at extracting its natural beta-carotene content (Lamers et al 2008, Raja et al 2007a). As a supplement, *D. salina* can be produced in either the whole dried (unwashed) form that contains high levels of minerals or a washed (desalinated) form that has higher carotenoid levels and lower mineral levels. Recently, advances in production technology have allowed the whole dried

D. salina biomass with its full range of nutrients and minerals to become commercially available in supplement form (Tracton & Bobrov 2005).

MAIN ACTIONS

Antioxidant and anti-inflammatory

Animal studies suggest that natural beta-carotene from *D. salina* can protect rats against CNS oxygen toxicity (Bitterman et al 1994), whole body irradiation (Ben-Amotz et al 1996) and gastrointestinal inflammation (Lavy et al 2003, Takenaka et al 1993). It is suggested that the gastric cytoprotective effect may depend on the amount of beta-carotene accumulated. A study that fed rats with diets containing up to 0.1% beta-carotene for 2 weeks using either dry *D. salina*, purified natural beta-carotene from *D. salina* or synthetic beta-carotene found that the rats showed higher accumulations of the algal beta-carotene than of the synthetic all-*trans* beta-carotene and that the *D. salina* and algal beta-carotene supplementation both significantly decreased the gastric mucosal lesions after water immersion stress, while synthetic beta-carotene did not (Takenaka et al 1993).

Cytoprotection

Animal studies suggest that supplementation with *D. salina* has hepatoprotective effects and can protect rats against laboratory models of liver toxicity to a significantly greater degree than synthetic beta-carotene. This is most likely due to the presence of various isomeric forms of carotene and other oxygenated carotenoids (Chidambara Murthy et al 2005, Vanitha et al 2007). *D. salina* supplementation has also been found to protect rats against laboratory-induced fibrosarcoma (Raja et al 2007b). Further studies have shown that prefeeding rats with *D. salina* ameliorated acid-induced enteritis (Lavy et al 2003). A double-blind trial in humans found that a single dose of natural beta-carotene from *D. salina* reduced the severity, but not the incidence, of postprocedural pancreatitis after endoscopic retrograde cholangiopancreatography (ERCP) (Lavy et al 2004).

Anti-atherogenic

Supplementation with *D. salina* powder inhibited atherogenesis in animal models using high-fat diet-fed LDL receptor knockout mice. Reductions of plasma cholesterol of 40–63% and atherosclerotic lesions of 60–83% along with reduced liver fat accumulation, liver inflammation and mRNA levels of inflammatory genes were also observed. By administrating *D. salina* powder containing different levels of 9-*cis* and all-*trans* beta-carotene isomers, these effects were shown to be 9-*cis*-dependent (Harari et al 2008).

Photoprotection

The red, orange and yellow colours of *D. salina* preferentially absorb UV light, therefore, ingestion of the microalgae adds pigmentation to the skin which helps to absorb UV light and reduce the effects of UV-induced erythema (sunburn) (Heinrich et al 2003). The beta-carotene in *D. salina* demonstrates photoprotective activity in plant cells and recent studies show that it has a similar effect on human skin (Heinrich et al 2003, Stahl et al 2000).

OTHER ACTIONS

Detoxification

D. salina contains chlorophyll along with other vitamins and minerals such as selenium and magnesium that are believed to aid in detoxification (Murray 1997). A small cohort study recently found that 14 weeks of supplementation with 3 g/day of *D. salina* powder produced marked reductions in hair tissue levels of various heavy metals. These findings now await further confirmation in controlled trials (Bobrov et al 2008).

Antibacterial

A study on the antimicrobial activity of different pressurised liquid extracts obtained from *D. salina* found 15 different volatile compounds as well as several fatty acids (mainly palmitic, alpha-linolenic and oleic acids) may be responsible for the observed antibacterial activity (Herrero et al 2006).

Antiproliferative

An ethanol extract of *D. salina* has been found to have antiproliferative effects and induce cell cycle G0/G1 arrest and apoptosis of human lung cancer cells (Sheu et al 2008).

Chemoprevention

There has been considerable research into carotenoids and chemoprevention. Many studies have shown the correlation between high intakes of natural beta-carotene from food and a decreased risk in the carcinogenesis of stomach, prostate and breast cancers (see Beta-carotene monograph). It is likely that natural beta-carotene from *D. salina* has different biological activity from synthetic beta-carotene — while synthetic beta-carotene has been shown to increase the risk of lung cancer in some populations, this has not been demonstrated with natural beta-carotene. As such, it is possible that long-term usage of *D. salina* may also decrease the risk of various cancers; however, this has yet to be investigated.

CLINICAL USE

D. salina is nature's richest source of natural beta-carotene and as such has similar uses to beta-carotene. To date, most of the clinical research on *D. salina* has been conducted with beta-carotene-containing extracts rather than the whole organism. This research suggests that potential benefits of supplementation with *D. salina* include prevention of cancer and cardiovascular disease, protection against sun damage and photosensitivity, supporting healthy eye, skin and immune function, providing benefits in asthma, macular degeneration and promotion of overall health and wellbeing (see *Beta-carotene* monograph).

Antioxidant protection

Human studies on *D. salina* extracts suggest many positive clinical effects, mainly due to its antioxidant activity. This is supported by the results of two

studies involving supplementation with a *D. salina* extract containing 60 mg/day of beta-carotene for 3 weeks in patients with non-insulin dependent diabetes mellitus (NIDDM). These studies found a reduction in oxidative injury (Levy et al 1999) along with normalisation of LDL oxidation (Levy et al 2000). Further support for the clinical benefits from the antioxidant properties of *D. salina* come from a study of 709 children with long-term exposure to radiation during and after the Chernobyl accident which found that 3-month supplementation with 40 mg of beta-carotene powder from *D. salina* reduced serum markers for oxidisation and acted as a lipophilic antioxidant and radioprotector (Ben-Amotz et al 1998).

Photoprotection

D. salina extracts protect the skin from sunburn and sun damage due to increased protective pigmentation of the skin along with reduced susceptibility to sunburn, according to a clinical study (Heinrich & Tronnier 1998, Stahl et al 1993). The placebo-controlled ($n = 24$) trial found 12 weeks of supplementation with 24 mg/day of *Dunaliella*-derived carotenoids significantly increased protection from sunburn (Heinrich et al 2003).

Exercise-induced asthma

A double-blind, placebo-controlled trial involving 38 subjects found that 1-week supplementation with *D. salina* provided a protective effect for patients with exercise-induced asthma (Neuman et al 1999).

DOSAGE RANGE

1–3 g of whole dried *D. salina* powder (which contains around 1–2% beta-carotene) when taken as a supplement.

ADVERSE REACTIONS

D. salina is classified as an edible species of microalgae. While no human toxicology studies have been carried out, there are no reported adverse effects from consumption of the whole microalgae or beta-carotene extract from *D. salina* in human clinical studies. An orange or yellow skin colouration (carotenodermia) may become evident after a few months of consumption but this is harmless and reversible on discontinuation (see *Beta-carotene* monograph).

SIGNIFICANT INTERACTIONS

No known interactions at this time.

PREGNANCY USE

While *D. salina* is considered safe, there is insufficient information to guide its use in pregnancy.

PATIENTS' FAQs

What will it do for me?

D. salina provides a source of natural beta-carotene and minerals that may promote energy and vitality, enhance skin health and appearance and assist in healthy ageing. As a rich source of beta-carotene, *D. salina* acts to supplement vitamin A levels without the risk of vitamin A toxicity. It may be used to assist in maintaining healthy skin, eyes and immune function, prevention of cancer and cardiovascular disease and reducing oxidative stress. *D. salina* may also provide photoprotection, detoxification of heavy metals and protective effect for patients with exercise-induced asthma.

When will it start to work?

Effects may be observable within 1 week but may take up to 3 months to obtain full benefits, while benefits of long-term supplementation on disease prevention may take many years to become evident. *D. salina* should be taken with meals or other dietary fats to increase the bioavailability of carotenoids.

Are there any safety issues?

D. salina is considered non-toxic. Large doses over long periods of time may produce carotenodermia, which is a harmless and reversible yellow-orange discolouration of the skin.

PRACTICE POINTS/PATIENT COUNSELLING

- *D. salina* is a marine phytoplankton that grows in extreme environments and is nature's richest source of natural beta-carotene.
- Dunaliella is a 'whole-food' supplement that provides a range of trace minerals and other nutrients that provide antioxidant, anti-inflammatory and photoprotection activity.
- Supplementation with *D. salina* may assist in prevention of a range of conditions including cardiovascular disease, some cancers and exercise-induced asthma.
- The antioxidants in *D. salina* may provide some protection against exposure to the sun and other sources of radiation.

STORAGE

D. salina should be stored in airtight containers or capsules away from direct sunlight, as carotenoids will oxidise on exposure to air and light.

Echinacea

HISTORICAL NOTE Echinacea was first used by Native American Sioux Indians centuries ago as a treatment for snakebite, colic, infection and external wounds, among other things. It was introduced into standard medical practice in the USA during the 1800s as a popular anti-infective medication, which was prescribed by eclectic and traditional doctors until the 20th century. Remaining on the national list of official plant drugs in the USA until the 1940s, it was produced by pharmaceutical companies during this period. With the arrival of antibiotics, echinacea fell out of favour and was no longer considered a 'real' medicine for infection. Its use has re-emerged, probably because we are now in a better position to understand the limitations of antibiotic therapy and because there is growing public interest in self-care. The dozens of clinical trials conducted overseas have also played a role in its renaissance.

COMMON NAME
Echinacea

OTHER NAMES
E. angustifolia — American coneflower, black sampson, black susans, coneflower, echinaceawurzel, Indian head, kansas snakeroot, purple coneflower, purpursonnenhutkraut, racine d'echinacea, *Rudbeckia angustifolia* L., scurvy root, snakeroot

E. purpurea — *Brauneria purpurea* (L.) Britt., combflower, purple cone flower, red sunflower

Rudbeckia purpurea L. — *E. pallida*, *Brauneria pallida* (Nutt.) Britt., pale coneflower, Rudbeckia pallida Nutt.

BOTANICAL NAME/FAMILY
Echinacea species (family Asteraceae [Compositae])

The name 'echinacea' generally refers to several different plants within the genus — *E. purpurea*, *E. pallida* and *E. angustifolia*.

PLANT PARTS USED
Root, leaf and aerial parts

CHEMICAL COMPONENTS
The most important constituents with regard to pharmacological activity are the polysaccharides, caffeic acid derivatives, alkylamides, essential oils and polyacetylenes, although there are other potentially active constituents, as well as a range of vitamins, minerals, fatty acids, resins, glycoproteins and sterols (Pizzorno & Murray 2006). Cynarin, a potential immunosuppressant and CD28 ligand, was also identified in *E. purpurea* (Dong et al 2006). Constituent concentrations vary depending on the species, plant part and growing conditions. With regard to the final chemical composition of an *Echinacea*-containing product, the drying and extraction processes further alter chemical composition.

Pharmacokinetics

The absorption of *E. purpurea* alkylamides from lozenges is rapid and linear (Guiotto et al 2008). A clinical study with healthy volunteers showed that following ingestion of tablets containing ethanolic echinacea extract, alkylamides were detectable in plasma 20 min after ingestion, whereas caffeic acid derivatives were not detectable in the plasma at any time after tablet ingestion (Matthias et al 2005a). A further study by the same authors showed that there was no significant difference in the bioavailability of alkylamides from a liquid and solid oral dosage form of an echinacea product (mixture of *E. purpurea* and *E. angustifolia*), with T_{max} reached at 20 and 30 min, respectively (Matthias et al 2007b). Two other studies reported that 30 to 45 min following administration of *E. purpurea* products (Echinaforce tincture, tablets, spray) containing milligram amounts of alkylamides, plasma concentrations of alkylamides of about 0.07–0.40 ng/mL were recorded (Woelkart et al 2006, 2008), and effects on the immune markers observed 23 h after oral administration (Woelkart et al 2006). Furthermore, tetraene alkylamides, present in *E. angustifolia* and *E. purpurea*, have been found to be metabolised by CYP450 enzymes (Matthias et al 2005b). In addition, the metabolism of tetraene alkylamides can be significantly decreased by monoene alkylamides that are only found in *E. angustifolia* (Matthias et al 2005b).

MAIN ACTIONS

Due to the wide assortment of chemical constituents found in echinacea, it has varied pharmacological effects.

Immunomodulator

Experimental results suggest that echinacea functions more as a modulator of the immune response rather than as a pure immune stimulant. It appears that in resting cells, an immune stimulus produces a faster response when the cells have been exposed to echinacea, whereas in overstimulated cells echinacea reduces the immune response. The immunomodulator activity of echinacea has been the subject of countless studies and appears to be the result of multiple mechanisms.

Overall, the fresh-pressed leaf juice of *E. purpurea* and alcoholic extracts of the roots of *E. pallida*, *E. angustifolia* and *E. purpurea* have been shown to act mainly on non-specific cellular immunity (Blumenthal et al 2000). It was reported that no one single constituent is responsible for the herb's immunomodulating action, with the most important elements being polysaccharides, glycoproteins, alkamides and flavonoids (Ernst 2002). A recent study suggests that water-soluble rather than lipophilic constituents are responsible for the immunostimulatory activity (Pillai et al 2007).

Macrophage activation has been well demonstrated, as has stimulation of phagocytosis (Barrett 2003, Bauer et al 1988, Groom et al 2007, Pugh et al 2008, Zhai et al 2009). Orally administered root extracts of echinacea have produced stronger effects on phagocytosis than aerial parts, with *E. purpurea* roots producing the greatest effect, followed by that of *E. angustifolia* and *E. pallida* (Pizzorno & Murray 2006).

The activation of polymorphonuclear leucocytes and natural killer (NK) cells and increased numbers of T-cell and B-cell leucocytes have been reported (Groom et al 2007, Zhai et al 2007a).

Echinacea stimulates cytokine (Altamirano-Dimas et al 2007, Brush et al 2006, Dong et al 2006, 2008, Farinacci et al 2008, Sharma et al 2006, Zhai et al 2007a, Zwickey et al 2007) and chemokine production (Wang et al 2006, 2008). Moreover, various echinacea species stimulate NO production in vitro (Classen et al 2006, Sullivan et al 2008).

Contradictory results were obtained for TNF-alpha production. In one study, echinacea significantly increased TNF-alpha production (Senchina et al 2006), whereas no effects on TNF-alpha were observed for all echinacea species in another study (McCann et al 2007), and in a third study, NFkappaB expression and TNF-alpha levels decreased in non-stimulated macrophages following echinacea treatment (Matthias et al 2007a).

In lipopolysaccharide-stimulated (LPS – endotoxin) cells, echinacea inhibited NFkappaB, TNF-alpha, NO and cytokine production, with different alkylamides exerting different effects (Matthias et al 2007a, 2008, Raduner et al 2006, Sasagawa et al 2006, Stevenson et al 2005, Woelkart et al 2006, Zhai et al 2007a).

Research in human subjects has produced conflicting results, with some studies showing that echinacea stimulates non-specific immunity and others showing no significant effect (Roesler et al 1991, Schwarz et al 2002).

Anti-inflammatory

Recent research has shown that alcohol extracts of all three echinacea species (*E. angustifolia*, *E. purpurea* and *E. pallida*) exert significant anti-inflammatory activity (Raso et al 2002, Zhai et al 2008). The result is due to multiple constituents acting with multiple mechanisms. The alkylamide fraction inhibits nitric oxide synthase (iNOS) and the caffeic acid fraction enhances arginase activity (Zhai et al 2008). In vivo tests further identify anti-inflammatory effects also for *E. angustifolia* and *E. pallida* when applied topically (Speroni et al 2002, Tragni et al 1985, Tubaro et al 1987).

COX-1/COX-2

Alkylamides from the roots of *E. purpurea* partially inhibit both COX-1 and COX-2 isoenzymes thus decreasing prostaglandin E2 levels (Clifford et al 2002, LaLone et al 2007, Raman et al 2008). Several alkylamides isolated from a CO_2 extract of the roots of *E. angustifolia* have been shown to inhibit COX-2-dependent prostaglandin E_2 formation although COX-2 mRNA and protein expression was not inhibited, but rather increased (Hinz et al 2007).

Cannabinoid & TRPV1 receptor interaction

It has been further identified that alkamides from echinacea modulate TNF-alpha mRNA expression in human monocytes/macrophages via the cannabinoid type 2 (CB2) receptor, thus

Clinical note — Echinacea and cannabinoid receptors

Alkylamides found in echinacea show a structural similarity with anandamide, an endogenous ligand of cannabinoid receptors. Cannabinoid type-1 (CB1) and CB2 receptors belong to G-protein coupled receptors. CB2 receptors are believed to play an important role in various processes, including metabolic dysregulation, inflammation, pain and bone loss. Compounds such as cannabinoids, which act on these receptors, are becoming more and more popular as they represent new targets for drug discovery. A well-known plant cannabinoid is delta-9-tetrahydrocannabinol, a constituent of *Cannabis sativa*.

identifying a possible mode of action for its immunomodulatory activity (Raduner et al 2006, Woelkart & Bauer 2007). Two alkylamides, which bind to the CB2 receptor more strongly than endogenous cannabinoids and activate it, have been classified as a new class of cannabinomimetics (Gertsch et al 2006). It was found that some of the alkylamides in echinacea self-assemble into micelles in aqueous solution which then determines their binding to the CB2 receptor (Raduner et al 2007). However, ketoalkenes from *E. pallida* did not interact with cannabinoid receptors (Egger et al 2008).

Ethanol extracts from echinacea roots showed potent agonist activity on TRPV1, a mammalian pain receptor. The compounds involved in the TRPV1 receptor activation differed from those involved in the inhibition of prostaglandin E2 production (Birt et al 2008).

Immunological adjuvants

In vitro studies in human lymphocytes activated with different lectins showed that using *E. purpurea* root extract in addition to individual lectins increased lymphoproliferation, which would suggest adjuvant activity (Chaves et al 2007). In mice, no adjuvant activity was detected for lipophilic, neutral and acidic extracts of echinacea (Gaia Herbs) (Ragupathi et al 2008).

Antiviral

Extracts of eight taxa of the genus *Echinacea* were found to have antiviral activity against herpes simplex virus (HSV)-1 in vitro when exposed to visible and ultraviolet A (UVA) light (Binns et al 2002). Antiviral activity was confirmed for *E. purpurea* extracts in 2008, with evidence suggesting that polyphenolic compounds other than the known HIV inhibitor, cichoric acid, may also be involved (Birt et al 2008).

Antifungal activity

Hexane extracts of echinacea have phototoxic antimicrobial activity against fungi (Binns et al 2000). The extracts inhibited growth of yeast strains of *Saccharomyces cerevisiae*, *Candida shehata*, *C. kefyr*, *C. albicans*, *C. steatulytica* and *C. tropicalis*.

OTHER ACTIONS

Traditional

Herbalists consider echinacea to have lymphatic, blood cleansing and wound healing actions.

Antioxidant

Free radical scavenging activity can be attributed to numerous antioxidant constituents found in echinacea, such as vitamin C, beta-carotene, flavonoids, selenium and zinc. One in vitro study reported that the antioxidant activity exerted by echinacea tincture was significantly greater than that observed for *Ginkgo biloba* (Masteikova et al 2007).

Anaesthetic

The alkylamides exert a mild anaesthetic activity, which is typically experienced as a tingling sensation on the tongue (Pizzorno & Murray 2006).

Apoptosis

Apoptosis, or programmed cell death, is a physiological, active cellular suicide process that can be modulated by various stimuli, including hormones, cytokines, growth factors and some chemotherapeutic agents. Research has been undertaken with the three clinically used *Echinacea* spp., several key constituents and different herbal fractions to investigate mechanisms of action, strength of activity and specificity of effect.

The *n*-hexane extracts of all three *Echinacea* spp. exert cytotoxic effects on human pancreatic and colon cancer cells in a concentration- and time-dependent manner, with *E. pallida* being the most active species (Aherne et al 2007). The effects were partially due to apoptosis by significantly increasing caspase-3/7 activity (Chicca et al 2007, 2008). Cytotoxic effects of the *n*-hexane extract of *E. angustifolia* on lung cancer cells have also been reported (Ramirez-Erosa et al 2007). However, in comparison to other herbal medicines such as wild yam and dichora root, echinacea exhibits only weak tumouricidal effects (Mazzio & Soliman 2008).

Isolated hydroxylated polyacetylenes and polyenes (more hydrophilic) from *E. pallida* are less cytotoxic than the more hydrophobic compounds (Pellati et al 2006).

It has been shown that the effects of isolated constituents on cell proliferation vary. In cervical and breast cancer cells treated with doxorubicin and *E. purpurea* extract or isolated echinacea constituents (i.e. cynarin, chicoric acid), the ethyl acetate fraction of echinacea extract and chicoric acid increased breast cancer cell growth and cynarin enhanced the growth of cervical cancer cells. However, cynarin showed antiproliferative effects on breast cancer cells (Huntimer et al 2006).

Chemoprevention

Several experimental studies with mice have found that treatment with echinacea reduces the incidence of tumour development (Brousseau & Miller 2005, Hayashi et al 2001, Miller 2005). Most research has been conducted with *E. purpurea*. In a study with gamma-irradiated mice, *E. purpurea* was able to

show radioprotection (use before radiation) as well as radio-recovery effectiveness (Abouelella et al 2007). One study reported that *E. angustifolia* can stimulate mammary epithelial cell differentiation (Starvaggi Cucuzza et al 2008).

Antiparasitic

Aqueous extracts of echinacea showed activity against gastrointestinal nematodes in goats and pigs (Lans et al 2007).

CLINICAL USE

Clinical trials using echinacea have used various preparations, such as topical applications, homeopathic preparations, injectable forms and oral dose forms, characteristics that should be noted when reviewing the data available. Overall, the majority of clinical studies performed in Europe have involved a commercial product known as Echinacin (Madaus, Germany), which contains the fresh-pressed leaf juice of *E. purpurea* stabilised in ethanol.

Upper respiratory tract infections

Overall, clinical studies support the use of echinacea in upper respiratory tract infections (URTIs), such as bacterial sinusitis, common cold, influenza-like viral infections and streptococcal throat. Evidence most strongly supports the use of echinacea in adults as an acute treatment, with some evidences showing that it is also useful as a means of reducing the natural incidence of the common cold. With regard to acute treatment, evidence is most consistent for the *E. purpurea* preparations (aerial parts and root) and for best clinical effects, treatment should be commenced at the first signs of infection (Linde et al 2006, Schoop et al 2006a, Woelkart et al 2008a). Preparations from *E. angustifolia* and *E. pallida* need further controlled clinical trials to provide better evidence for efficacy as acute treatments (Woelkart et al 2008b). As preventative treatment, *E. purpurea* (pressed juice) and *E. angustifolia* (alcoholic extract) show the most promise although further investigation is still required to confirm this (Schoop et al 2006b). Whilst various echinacea preparations appear useful in adults, clinical trials in childhood URTIs have produced disappointing results.

A 1999 review of 13 clinical trials consisting of 9 treatment studies and 4 prevention studies concluded that 8 of 9 treatment trials produced positive results, whereas 3 of four prevention trials suggested modest effects (Barrett et al 1999). In 2000, a Cochrane review was published that had assessed the evidence available from 16 clinical trials (8 treatment and 8 prevention) involving a total of 3396 subjects (Melchart et al 2000), and it concluded that some echinacea preparations may be better than placebo, with a majority of studies reporting favourable effects.

A more recent Cochrane systematic review (2006) evaluated data from 16 randomised, double-blind studies (Linde et al 2006), only five of which had been included in a previous Cochrane review. Whilst reviewers reported that evaluation was difficult because of the heterogeneity of preparations tested and variability of trial approaches, it was concluded that preparations based on the aerial parts of *E. purpurea* might be effective for the early treatment of colds in adults, although results are not completely consistent. Beneficial effects of other echinacea preparations and their use in prevention also exists but required further investigation. A 2006 meta-analysis by Schoop et al was more positive and concluded that the odds of experiencing a clinical cold were 55% higher with placebo than with pressed *Echinacea purpurea* juice or hydroethanolic *E. angustifolia* extract following inoculation with rhinovirus (Schoop et al 2006b). A 2007 meta-analysis published in *Lancet Infectious Diseases* was also positive and concluded that echinacea products from all species were beneficial in significantly decreasing the incidence (by 58%) and duration (by 1.4 days) of the common cold (Shah et al 2007b). Certain facets of quality of life improve with echinacea treatment during an URTI, according to a 2006 review, suggesting that treatment provides symptom relief and improved wellbeing (Gillespie & Coleman 2006).

Athletes

E. purpurea (Echinaforce Forte) was effective in the prophylaxis, as well as treatment, of the common cold in persons who actively participated in sport (Schoop et al 2006a). It is believed that echinacea attenuates mucosal immune suppression known to occur with intensive exercise and can reduce the duration of URTI that exercising people incur (Hall et al 2007).

There are many different confounding variables that make it difficult to definitively decide on the role of echinacea in the prevention and treatment of URTIs and, further, which echinacea preparations are best suited to the different uses. One key factor is the variability in chemical composition of echinacea test products and the lack of clear reporting by researchers about this factor. Additionally, there are methodological variations, different clinical settings, study populations and time of treatment initiation.

Future research should include a full disclosure of the chemical analysis of the echinacea preparation being tested so that systematic reviews will be able to use this information to separately assess the effects of each echinacea species, rather than combining them under the umbrella term of 'echinacea'. Moreover, larger prevention trials with appropriate outcome measures (e.g. the Wisconsin Upper respiratory Symptom Survey) should be conducted.

Paediatric studies

Four randomised studies published after 2000 were conducted with children and generally produced disappointing results (Cohen et al 2004, Spasov et al 2004, Taylor et al 2003, Weber et al 2005). A short review by Koenig and Roehr (2006) has also concluded that there is currently no evidence for the efficacy of *E. purpurea* in the treatment of URTI in children (Koenig & Roehr 2006). A 2008 clinical study with 60 children aged 12–60 months suggests that treating cold with *E. purpurea* in otitis-prone young children does not decrease the risk of acute otitis media, but is associated with a borderline

Clinical note — Common cold symptoms: What is usual?

The pathogenesis of the common cold involves a complex interplay between replicating viruses and the host's inflammatory response (Heikkinen & Jarvinen 2003). The onset of cold symptoms after viral incubation varies considerably and depends on the causative virus. In experimental rhinovirus infections, the onset of symptoms has been reported to occur as soon as 10–12 h after intranasal inoculation. Generally, the severity of the symptoms increases rapidly, peaks within 2–3 days after infection, and decreases soon after. The mean duration of the common cold is 7–10 days, but in a proportion of patients some symptoms can still be present after 3 weeks. Symptoms typically start with a sore throat, which is soon accompanied by nasal stuffiness and discharge, sneezing and cough. The soreness of the throat usually disappears quickly, whereas the initial watery rhinorrhoea becomes thicker and more purulent over time and can be accompanied by fever, most usually in children. Other symptoms associated with the cold syndrome include hoarseness, headache, malaise and lethargy.

increased risk of having at least one episode of acute otitis media during a 6-month follow-up compared to placebo (Wahl et al 2008).

Commission E approves the use of *E. purpurea* herb as an immune system support in cases of respiratory and lower urinary tract infection, and *E. pallida* root as supportive treatment in influenza-like infections (Blumenthal et al 2000).

Wound healing

Several uncontrolled clinical studies support the topical use of echinacea to enhance wound healing. A trial involving 4598 people investigated the effects of a preparation consisting of the juice of the aerial parts of *E. purpurea* on various wounds, burns, skin infections and inflammatory skin conditions (Kinkel et al 1984). Topical application of echinacea produced a 85% overall success rate, and the key constituent responsible for enhancing wound healing appears to be echinacoside (Speroni et al 2002).

Commission E approves the external use of *E. purpurea* herb for poorly healing wounds and chronic ulcerations (Blumenthal et al 2000).

Herpes infection

Based on the herb's antiviral activity against HSV-1 in vitro, it is also used in the treatment of herpes infections.

Genital herpes

A prospective, double-blind, placebo-controlled, crossover trial conducted over 1 year investigated the effects of an extract of the plant and root of *E. purpurea* (Echinaforce 800 mg twice daily) on the incidence and severity of genital herpes outbreaks in 50 patients (Vonau et al 2001). The study found no statistically significant benefit compared with placebo after 6 months of therapy.

Reducing chemotherapy side effects

Results from a small, open, prospective study of subjects with advanced gastric cancer suggest that intravenous administration of a polysaccharide fraction isolated from *E. purpurea* may be effective in reducing chemotherapy-induced leucopenia (Melchart et al 2002). Test subjects had advanced gastric cancer and were undergoing palliative chemotherapy with etoposide, leucovorin and 5-fluorouracil. The median number of leukocytes 14–16 days after chemotherapy was 3630/microlitre (range 1470–5770) in the patients receiving herbal treatment compared with 2370/microlitre (870–3950) in the patients of the historical control group ($P = 0.015$).

Radiation-associated leucopenia

Equivocal evidence exists for the use of echinacea in radiation-induced leucopenia, according to a small number of randomised studies (Ulbricht & Basch 2005). The product tested was Esberitox, which contains ethanolic extracts of three herbs, including root of echinacea.

Halitosis

A study with healthy volunteers suggests that a palatal adhesive tablet containing echinacea may serve as an effective means of treatment for patients complaining of oral malodour, because it resulted in a significant reduction in both oral malodour scores and volatile sulphide compound (VSC) levels. The reduction in VSC levels was significantly higher than with zinc and chlorhexidine (Sterer et al 2008).

Recurrent candidiasis

The herb is used to treat recurrent candidiasis, chiefly because of its antifungal and immunostimulant properties. Controlled studies are unavailable to determine effectiveness in this condition.

OTHER USES

Echinacea has also been used to treat UTI, allergies, acne and abscesses, and as adjunctive therapy in cancer (Mills & Bone 2000). It has also been used to prevent exercise-induced immunosuppression (Gleeson et al 2001). In practice, it is prescribed with other herbs to treat common infections and to prevent infections generally.

DOSAGE RANGE

General guide

- Dried herb: 3 g/day of either *E. angustifolia* or *E. purpurea*.
- Liquid extract (1:2): 3–6 mL/day of either *E. angustifolia* or *E. purpurea*. This dose may be increased to 10–20 mL/day in acute conditions. Treatment is usually started at the first sign of URTI and continued for 7–14 days.

Specific guide

- *E. angustifolia* dried root: 1–3 g/day.
- *E. purpurea* dried root: 1.5–4.5 g/day.

Clinical note — Safety of echinacea

The safety of echinacea has come into question in recent years due to two different articles that were poorly described in the press. One was a case report of suspected anaphylaxis reported in the *Medical Journal of Australia* (Mullins 1998). On closer inspection, the article describes an atopic woman who had taken nearly a dozen supplements at once, as well as double the recommended dose of a liquid echinacea product, before experiencing symptoms suggestive of anaphylaxis. Successful treatment consisted of oral promethazine and no other intervention. After the event, hypersensitivity was confirmed by skin prick and RAST testing, suggesting that an allergic response did occur.

In 2002, a second report described in detail five allergic reactions to different echinacea preparations and further stated that 51 adverse reactions involving echinacea had been reported to Adverse Drug Reactions Advisory Committee (ADRAC) (Mullins & Heddle 2002). Unfortunately, this time the media omitted the important fact that these cases were reported over a 21-year period. Once again, a closer look at the article finds approximately half of those reports were of suspected allergic responses and of those, only two could certainly be linked to echinacea use, with 10 classified as probable and 12 as possible. Considering an estimated 200 million doses of echinacea are used by Australians each year, the relative lack of adverse reports is impressive.

- *E. purpurea* dried aerial parts: 2.5–6.0 g/day.
- *E. purpurea* expressed juice of fresh plant: 6–9 mL/day.
- *E. pallida* ethanolic extract of root: 2–4 mL/day.

Although controversy still exists over which part of the plant and which particular plant has the strongest pharmacological activity, it appears that the cold-pressed juice and ethanolic extract of the aerial parts of *E. purpurea* and the hydroethanolic extracts from the roots of *E. angustifolia* are the most studied preparation for URTIs.

ADVERSE REACTIONS

Echinacea is well tolerated. Short-term use of echinacea is associated with a good safety profile, with a slight risk of transient, reversible and self-limiting gastrointestinal symptoms and rashes (Huntley et al 2005).

Overall, echinacea is safe for asthmatics and only in rare instances has been associated with allergic reactions or disease exacerbation (Huntley et al 2005).

It is unclear whether children are more prone to rashes with *E. purpurea* than adults. One study found that rash occurred in 7.1% of children using echinacea compared with 2.7% taking placebo (Taylor et al 2003), whereas a more recent study failed to identify allergic responses or adverse reactions in children with echinacea use (Saunders et al 2007).

There is no clear evidence from basic science or human studies to show that echinacea causes liver toxicity (Ulbricht & Basch 2005). Echinacea (8000 mg/day) taken over 28 days resulted in an increase in serum erythropoietin levels at days 7, 14 and 21, but did not significantly alter red blood cell, haemoglobin and haematocrit levels (Whitehead et al 2007). A single 350-mg dose of *E. purpurea* had no effect on electrocardiographic and blood pressure measurements (Shah et al 2007a).

One clinical study has reported that 1 g *E. purpurea* administered over 10 days altered the gastrointestinal microflora by significantly increasing total aerobic bacteria and bacteria belonging to the *Bacteroides* genus, but not significantly changing the number of enteric bacteria, enterococci, lactobacilli, bifidobacteria or total anaerobic bacteria (Hill et al 2006). Moreover, a review reported several ocular adverse effects due to *E. purpurea* (Santaella & Fraunfelder 2007). One case report exists where it is believed that an ethanolic extract of *E. pallida*, taken 10–20 days before, may have induced or exacerbated severe thrombotic thrombocytopenic purpura (TTP) in a healthy 32-year-old man (Liatsos et al 2006).

SIGNIFICANT INTERACTIONS

There are reports that urge to great caution when using echinacea with anticancer and antiretroviral agents (Meijerman et al 2006, van den Bout-van den Beukel et al 2006), due to possible effects on drug metabolising and transporting enzymes. However, most of the evidences are based on in vitro studies, of which some may not be of clinical relevance in vivo, but some should definitely be considered (Huntimer et al 2006). However, one recent review found only eight papers that contained primary data relating to drug interactions and concluded that there are no verifiable reports of herb–drug interactions with any echinacea product (Freeman & Spelman 2008).

CYP450 enzymes

Whilst in vitro studies have found evidence of weak inhibitory activity for *E. purpurea* on CYP1A2, CYP2D6, CYP2C19, CYP2D9 and CYP3A4 (Hansen & Nilsen 2008, Hellum et al 2007, Modarai et al 2007) further indicating that the alkylamide concentration was a chief determinant of activity on CYP 3A4 (Hansen & Nilsen 2008, Modarai et al 2007, Raner et al 2007); however, these findings have limited clinical relevance in vivo (Heinrich et al 2008). Two recent studies conducted with healthy volunteers showed again no effects on CYP2D6 (Gurley et al 2008, Hellum & Nilsen 2007). Previously, a study of healthy volunteers found that echinacea had no significant effect on CYP1A2, CYP2D6, CYP2E1 or CYP3A4 activity (Gurley et al 2004). In contrast, Gorski et al (2004) identified a complex effect on CYP3A4, which can be described as near self-cancelling inhibition of intestinal 3A4 with induction of hepatic CYP3A4 (Stargrove et al 2008). In other words, the net effect on availability of CYP3A4 substrates was essentially unchanged. This study used 400 mg of powdered dried root of *E. purpurea* taken four times daily for 8 days (Gorski et al 2004).

P-glycoprotein (P-gp)

Inconsistencies between in vitro and clinical results were also found among studies investigating effects on P-gp. In vitro tests revealed inhibition of P-gp for *E. purpurea* (Hansen & Nilsen 2009, Hellum & Nilsen 2008) which has been isolated to the *n*-hexane extracts (of all three echinacea species) and isolated polyacetylenes and polyenes from *E. pallida* (Romiti et al 2008). However, a clinical trial of 18 healthy volunteers failed to detect significant alteration to digoxin pharmacokinetics for *E. purpurea* indicating the effect on P-gp is not clinically significant (Hellum & Nilsen 2008).

Cyclophosphamide

Echinacea appears to increase the immunostimulatory effect of low-dose cyclophosphamide, which may be detrimental in autoimmune disease where low doses are used (Stargrove et al 2008) — the clinical significance of this observation is unknown — avoid until safety can be assured.

Immunosuppression agents (e.g. cyclosporin)

Theoretically, there may be an antagonistic pharmacodynamic interaction with immunosuppressive medication, but the clinical relevance is unclear. Exercise caution when using immunosuppressive agents and echinacea concurrently.

Myelosuppressive chemotherapeutic agents

Use of echinacea between treatment cycles may theoretically improve white cell counts, reduce dose-limiting toxicities on myelopoeisis and improve patient's quality of life — potentially beneficial interaction under professional supervision.

CONTRAINDICATIONS AND PRECAUTIONS

Contraindicated in people with allergies to the Asteraceae (Compositae) family of plants (e.g. chamomile, ragweed).

Commission E warns against using echinacea in cases of autoimmune disorders, such as multiple sclerosis, SLE and RA, as well as tuberculosis or leukocytosis (Blumenthal et al 2000) based on theoretical considerations and case reports with a questionable causal relationship; however, this warning does not appear to be warranted (Lee & Werth 2004). Boullata and Nace recommended the avoidance of echinacea use in patients with autoimmune disease (Boullata & Nace 2000), but this recommendation was only seen as the 'extrapolation from experimental observations of echinacea's effects on the immune system' by other authors (Logan & Ahmed 2003). Moreover, no adverse effects were reported when echinacea was consumed by mice afflicted with autoimmune (type 1) diabetes for up to 18 weeks. Instead, a consistent, long-lasting immunostimulation of only NK cells was observed, thus warranting further research (Delorme & Miller 2005). In addition, recent human studies reported safe and effective systemic echinacea treatment of low-grade autoimmune idiopathic uveitis resulting in longer steroid-free treatment periods for patients on echinacea treatment (Neri et al 2006).

In practice, echinacea has been successfully used by herbalists in autoimmune disease without mishap (Mills & Bone 2005).

Duration of use

Based on evidence that parenterally administered echinacea reversibly depresses immune parameters, Commission E has recommended that echinacea should not be used for more than 8 weeks. However, in a study in which it was taken orally for up to 6 months, no changes in immune parameters were detected (Vonau et al 2001). As such, no conclusive evidence demonstrates that long-term use is detrimental.

PREGNANCY USE

Oral use of echinacea has generally been considered safe in pregnancy when used in recommended doses (Mills & Bone 2005). This was substantiated by preliminary results from a prospective study of 206 women who had inadvertently taken echinacea during their pregnancy, which found that gestational use was not associated with an increased risk for major malformations (Gallo et al 2000). Moreover, a recent review concluded that echinacea is non-teratogenic when used during pregnancy, but that caution should prevail when using echinacea during lactation until further high-quality human studies can determine its safety (Perri et al 2006).

Studies in animal models have reported that echinacea preparations derived from *E. purpurea* produce unwanted effects in pregnant animals such as interference with embryonal angiogenesis (Barcz et al 2007), alteration of maternal haemopoiesis, fetal growth and a reduction in number of viable fetuses (Chow et al 2006). Due to the high rate of false positives obtained in such animal studies and problems with extrapolating data to humans from these models, the clinical significance of these findings remains unknown.

PRACTICE POINTS/PATIENT COUNSELLING

- Different types of echinacea have demonstrated immunomodulating, anti-inflammatory, antifungal, antiviral and antioxidant activity.
- Overall, clinical studies support the use of echinacea in URTIs, such as bacterial sinusitis, common cold, influenza-like viral infections and streptococcal throat. Current evidence is strongest for supporting its use as acute treatment in URTIs with some evidence supporting its use as prophylactic treatment.
- Several uncontrolled clinical studies support the topical use of echinacea to enhance wound healing.
- Echinacea is also used to treat UTI, allergies, acne and abscesses, as adjunctive therapy in cancer, herpes virus infections and candidiasis.
- Although controversy still exists over which part of the plant and which particular plant has the strongest pharmacological activity, it appears that the cold-pressed juice and ethanolic extracts of the *E. purpurea* plant and *E. angustifolia* root are the most studied preparations for URTIs.

PATIENTS' FAQs

What will this herb do for me?

Echinacea stimulates immune function and may also have antifungal, antiviral and anti-inflammatory activity. Scientific research generally supports its use as an acute treatment for URTIs in adults and possibly as prevention against URTIs. Applied to the skin, it may also enhance wound healing and be useful for chronic wounds. It also has anti-inflammatory actions.

When will it start to work?

As an acute treatment for URTI, echinacea should be started when the first signs and symptoms of infection appear.

Are there any safety issues?

Echinacea is well tolerated, although allergic reactions are possible in rare cases.

Elder

HISTORICAL NOTE The elder tree has enjoyed much popularity throughout the ages. Ancient Egyptians used elderflowers to heal burns and improve their complexion. Throughout England elder was termed 'the medicine chest of the country people', and Native Americans used elder for coughs, colds, infections and skin conditions. Elderflowers are a favorite ingredient in herb teas, cordials and some wines.

COMMON NAME
Elder

OTHER NAMES
Black elder, common elder

BOTANICAL NAME/FAMILY
Sambucus nigra/*Caprifoliaceae*

PLANT PART USED
Flower or ripe berry

CHEMICAL COMPONENTS

Flowers
Flavonoids, primarily quercertin, isoquercertin, rutin and astragaline (Dawidowicz et al 2006, Wach et al 2007). Elderflowers also contain essential oils.

Berries
Anthocyanins are abundant in the berries, including cyanidin 3-sambubioside-5-glucoside, cyanidin 3,5-diglucoside, cyanidin 3-sambubioside, cyanidin

3-glucoside and cyanidin 3-rutinoside. Cyanidin 3-sambubioside is the most abundant anthrocyanin and accounts for more than 50% of all anthocyanins found in the berries (Veberic et al 2009, Murkovic et al 2000). The berries also contain flavonoids including quercertin, quercertin 3-rutinoside and quercetin 3-glucoside, organic acids and sugars (Veberic et al 2009). The unripe berries contain cyanogenic glycosides (Dellagreca et al 2003).

MAIN ACTIONS

There is very little research evaluating the actions of elderflower, even though it is the flowers that are most commonly used. Recently there has been increasing interest in the berries and therefore much of the research reviewed below has focused on these extracts.

Antioxidant

Elderflowers contain flavonoids such as quercertin, isoquercertin and rutin which all possess potent antioxidant properties (Dawidowicz et al 2006). The berries also contain these flavonoids and additionally have appreciable amounts of anthocyanins, chiefly cyanidin 3-sambubioside and cyanidin 3-glucoside (Veberic et al 2009, Murkovic et al 2000).

The effects of dietary cyanidin-3-O-glucoside (2 g/kg) and a concentrate of elderberry (2 g/kg) on the plasma and tissue concentrations of tocopherol and cholesterol were investigated for a period of 4 weeks in vivo (Frank et al 2002). Cyanidin-3-O-glucoside increased the levels of vitamin E in the liver and lungs and appeared to have a sparing effect. Cholesterol levels were not affected but both cyanidin-3-O-glucoside and elderberry reduced the amount of saturated fatty acid in the liver. Higher temperatures (100 degrees C) during aqueous extraction appear to yield a higher flavonoid content (Dawidowicz et al 2006).

Antiviral

In vitro studies have shown that Sambucol® (contains 1.9 g of elderberry extract per 5 mL, other ingredients include raspberry extract, sucrose, citric acid and honey) is effective against ten strains of influenza virus (Zakay-Rones et al 1995).

Immunostimulating

The standardised black elderberry product Sambucol® has been shown to increase the production of certain inflammatory cytokines (IL-1 beta, TNF-alpha, IL-6, IL-8) in human monocytes (Barak et al 2001). It is proposed that this may be one of the mechanisms via which elderberry improves immune system activity. Another study confirmed these results and in addition showed that elderberry also increases the anti-inflammatory cytokine IL-10 (Barak et al 2002). An in vitro study using a lectin isolated from elderflower (*Sambucus nigra* agglutinin) found the extract increased the release of IL-4 from basophils (Haas et al 1999).

Anti-inflammatory

An extract of elderflower was found to reduce inflammatory mediators in monocytes, macrophages and neutrophils incubated with whole cells of the periodontal pathogens *Porphyromonas gingivalis* and *Actinobacillus actinomycetemcomitans* (Harokopakis et al 2006). The extract appeared to inhibit the activation of nuclear factor kappa B and phosphatidylinositol 3-kinase. Controlled trials are needed, however these preliminary studies suggest that elderflower may be useful to attenuate the inflammation in periodontitis.

Diuretic

Elderflower has traditionally been used as a diuretic agent. An in vivo study found that the extract possessed diuretic properties comparable to the reference product hydrochlorothiazide (Beaux et al 1999). The extract also increased sodium excretion.

Antidiabetic

An aqueous extract of elderflowers has been shown to increase insulin secretion and enhance muscle glucose uptake (70%), glucose oxidation (50%) and glycogenesis (70%) in pancreatic beta cells in vitro (Gray et al 2000). The insulinotropic effects of elder were slightly stronger with a hot preparation. An aqueous extract of elder failed to increase glucose diffusion in another in vitro study (Gallagher et al 2003). The authors theorise that the anti-diabetic effects of elder may not be related to intestinal absorption.

OTHER ACTIONS

Elderflowers are also commonly used as diaphoretic agents to increase sweating during temperatures or fevers. It is believed that the action is greatly improved by the use of a hot infusion. They are also employed as expectorants and decongestants for the sinuses.

CLINICAL USE

Influenza

The elderberry extract Sambucol® (contains 1.9 g of elderberry extract per 5 mL, other ingredients include raspberry extract, sucrose, citric acid and honey) was evaluated in a multi-centre, randomised, placebo controlled clinical trial to investigate its efficacy in decreasing the severity and duration of influenza A and B infections (Zakay-Rones et al 2004). Sixty patients aged between 18 and 54 years were enrolled in the study when they had three or more symptoms of influenza (fever, malaise, nasal discharge etc). Patients were given 15 mL 4 times daily with meals for 4 days. The first dose was given within 48 hours of the onset of symptoms. The global evaluation scores for the elderberry group using visual analogue scales showed a significant improvement after an average of 3.1 days ($\pm$ 1.3) as compared to 7.1 ($\pm$ 2.5) days for the placebo group ($P < 0.001$).

The same extract was investigated in a previous study in 27 children and adults during an outbreak of influenza B Panama (Zakay-Rones et al 1995). Children were given 2 tablespoons of mixture for 3 days, whilst adults received 4 tablespoons for the same duration. Patients were followed for 6 days and their symptoms were monitored. A significant

improvement in symptoms was seen in 93.3% of the cases in the treatment group within 2 days as compared to 91.7% of the patients in the placebo group who were feeling better after 6 days ($P < 0.001$).

Cholesterol

A recent randomised, double-blind, placebo-controlled pilot study investigated the effect of elderberry juice on serum cholesterol and triglyceride levels (Murkovic et al 2004). Two studies were performed; in the first 34 healthy volunteers took capsules containing either spray-dried elderberry juice (400 mg containing 10% anthocyanes) or placebo three times a day for two weeks. A subgroup of 14 participants continued for another week to further evaluate the resistance of LDL-cholesterol to copper-induced oxidation. In the second study six subjects took a single dose of elderberry juice 50 mL together with a fat-laden breakfast to test the short-term effects of elderberry on serum lipid levels.

Results from the first study found that a small but not statistically significant change was noted in cholesterol concentrations in the elderberry group (from 199 to 190 mg/dL) compared to the placebo group (from 192 to 196 mg/dL). Additionally, elder didn't improve LDL-cholesterol oxidation within the three-week study period. Results from the second experiment also showed that elder failed to significantly reduce postprandial triglyceride concentrations after a high fat meal.

OTHER USES

Colds, fever, inflammation of the eyes, skin disorders, wounds, bronchitis, sinusitis, chronic nasal catarrh, hay fever, pleurisy, sore throat, measles and scarlet fever.

Commission E approves the use of elderflowers as a diaphoretic and to increase bronchial secretion (Blumenthal et al 1998).

DOSAGE RANGE

General guide

Flowers

- Tea: 10–15 g flowers/day.
- Liquid extract: 2–6 mL of 1:2 extract/day.

Berries

- Elderberry syrup: usually contains 30–38% elderberry; dose at 15 mL, 3 times daily (Sambucus nigra (elderberry) 2005).
- Powdered extracts: often available in 500 mg capsules, dose 2–3 times daily (Sambucus nigra (elderberry) 2005).

According to clinical studies

- Influenza: 15 mL of the syrup, 4 times daily.

ADVERSE REACTIONS

Elderberries have been generally well tolerated in clinical trials (Zakay-Rones et al 1995, 2004). Although there are no clinical studies using elderflowers, it is generally thought that they are most likely to also be very safe. In large doses elder may produce nausea, diarrhoea and polyuria (Mills & Bone 2005).

SIGNIFICANT INTERACTIONS

Controlled studies are not available. therefore interactions are based on evidence of activity and are largely theoretical and speculative.

Diuretic drugs

Elderflower appears to possess diuretic effects. Increased diuresis is possible with concomitant use — observe (Beaux et al 1999).

Hypoglycaemic drugs

Elderflower has demonstrated hypoglycaemic effects in vitro; the clinical significance of this observation remains unknown — observe (Gray et al 2000, Gallagher et al 2003).

CONTRAINDICATIONS AND PRECAUTIONS

A small number of people in the general population may experience allergy to elderflowers as shown by skin prick and RAST tests (Forster-Waldl et al 2003). Avoid in sensitive patients.

Never consume unripe or uncooked berries. They contain cyanogenic glycosides and can be dangerous.

PREGNANCY USE

Elder is likely to be safe when consumed in dietary amounts, however safety is not known when used in larger quantities.

PRACTICE POINTS/PATIENT COUNSELLING

- Elder is a popular herbal medicine and both the fruit and berry are used medicinally.
- Elderflower exhibits anti-inflammatory, antioxidant, diaphoretic, diuretic and anti-diabetic properties. The berry also possesses antioxidant properties and is also anti-viral.
- Commission E approves the use of elderflowers as a diaphoretic and to increase bronchial secretion.
- Elderflower has been used traditionally to treat colds, influenza, scarlet fever, bronchitis, sinusitis, hay fever and skin disorders.
- Clinical evidence supports the use of elderberry in influenza.
- The unripe and uncooked berries however should never be consumed as they contain cyanide.

PATIENTS' FAQs

What will this herb do for me?

Elder may be useful in the treatment of colds and flu, sinusitis and bronchitis. It may also be used to treat diabetes, however this use is less certain.

When will it start to work?

Clinical trials of elderberry in influenza have shown that on average the duration of illness was reduced from 6 days to 3 days, suggesting that elder works quite quickly. Elder, when taken as a hot infusion, appears to work immediately by increasing diaphoresis.

Are there any safety issues?
Elderflowers and berries appear to be very safe. The unripe and uncooked berries however should never be consumed as they contain cyanide.

Eucalyptus

HISTORICAL NOTE Indigenous Australians traditionally used eucalyptus to treat fevers and respiratory infections, accounting for its name 'fevertree'. European settlers also recognised the medicinal qualities of eucalyptus and surgeon Considen is credited with producing the first essential oil sample in 1788. Bosisto investigated oils from several Australian plants and in 1854 eventually produced essential oils commercially in association with Müeller, a pharmacist. Bosisto and Müeller concentrated on oils rich in 1,8-cineole, which includes *Eucalyptus* species. In the late 1800s, articles about its medicinal use appeared in medical journals such as *The Lancet*, focusing on its potential in scarlet fever and diphtheria.

COMMON NAME
Eucalyptus

OTHER NAMES
Aetheroleum Eucalypti, cineole, *Oleum Eucalypti*, *Essence of eucalyptus rectifiee*

Common names include Australian fever tree leaf, blue gum, eucalyptol, fever tree, gum tree, red gum, stringy bark tree.

BOTANICAL NAME/FAMILY
Eucalyptus species (family Myrtaceae)

The species most commonly used in healthcare are:
- *Eucalyptus globulus* (blue gum)
- *Eucalyptus citriodora* (lemon scented gum)
- *Eucalyptus dives* (broad leaf peppermint)
- *Eucalyptus polybractea*.

There are more than 500 species of eucalyptus trees and shrubs native to Australia, but many species are cultivated in other parts of the world.

PLANT PARTS USED
The essential oil is extracted by steam distillation from fresh twigs and leaves. Modern eucalyptus essential oils are primarily extracted from *E. polybractea*, *E. dives*, *E. leucoxylon*, *E. sideroxylon*, and *E. radiata* in Australia, but other species are used in other countries (Lassak & McCarthy 2001).

CHEMICAL COMPONENTS
The major chemical constituents under the general heading 'eucalyptus' consist of oxides and hydroterpenes, primarily 1,8-cineole, which is the most significant constituent and ranges from 54–95% depending on the species. The 1,8-cineole component is particularly high in *E. globulus* and *E. radiata*. Eucalyptus also contains citronellal, camphone, fenchone, limonene, phellandrene and pinene depending on the species (Clarke 2002).

The exact chemical composition of an oil depends on the particular species from which it

is extracted. There are small amounts of alpha-pinene (2.6%), alpha-cymene (2.7%), aromadendrene, ciminaldehyde, globulol and pinocarveol and *d*-limonene, alpha-phellandrene, camphene and alpha-terpinene (Bisset 1994, Bruneton 1995, Serafino et al 2008).

Other essential oils high in 1,8-cineole include *Rosmarinus officinalis* ct. cineole, *Laurus nobilis, Cinnamomum camphora* ct. cineole and *Melaleuca cajuputi*.

MAIN ACTIONS

The main reported actions are expectorant, antitussive (Misawa & Kizawa 1990), nasal decongestant (Burrows 1983, FDA 1994), analgesic (Gobel 1995) and antispasmodic in animal and human studies. Antimicrobial and anti-inflammatory activity has also been reported in animal and human studies.

Antitussive

Antitussive effects were compared with codeine in guinea pigs in which cough was mechanically stimulated. Essential oil 5% in normal saline was administered by inhalation and had a significant antitussive effect relative to codeine ($P < 0.05$) (Misawa & Kizawa 1990). The antitussitive effects of 1,8-cineole were demonstrated in humans in 1980 in a single blind cross over study in healthy volunteers using a commercially available chest rub where eucalyptus was the active ingredient in the blend (Packman & London 1980). It appears that 1,8-cineole interacts with the M8 (TRPM8) receptor potential channel, the cool-sensitive thermoreceptor primarily affected by menthol, which produces a cooling sensation (Behrendt et al 2004). However, the antitussive effect may also be due to an effect on pulmonary C-fibres, which also contain TRPM 8 receptors.

Nasal decongestant

Two clinical studies have demonstrated that inhalation of eucalyptus oil reduces nasal congestion (Burrows 1983, FDA 1994). Likewise, Cohen & Dressler (1982) showed statistically significant differences in patients with acute coryza inhaling a volatile mixture of menthol 56% and eucalyptus oil 9% for 20 minutes compared to a control group on 14 of the 22 indices of respiratory function, measured from baseline to 60 minutes after inhalation. In contrast, Burrows et al (1983) showed no decongestant effect of inhaling camphor, eucalyptus or menthol for five-minute periods via a face mask ($n = 31$), although cold receptors in the nose were stimulated, creating a sensation of increased airflow and improved comfort.

Antimicrobial

Previous studies indicate eucalyptus has antimicrobial activity in vitro against *Pseudomonas aeruginosa*, *Bacillus subtilis*, *Enterococcus faecalis* and *Escherichia coli* (Kurrerath & Mundulaldo 1954), herpes simplex (Schnitzler et al 2001) and oral pathogens (Takarada et al 2004). A clinical observational study involving 30 patients with head and neck cancer and necrotic malodorous ulcers demonstrated improved quality of life and social interaction with the addition of a twice daily cleansing of the ulcers with an essential oil mix whose main component was eucalyptus (Warnke et al 2006). In addition, the researchers reported evidence of re-epithelialisation and anti-inflammatory effects.

Anti-inflammatory

Eucalyptus inhibits prostaglandin synthesis in vitro (Wagner 1986) at a concentration of 37 micromol/L. Anti-inflammatory and antinociceptive effects have been demonstrated in animal models (Ulbricht & Basch 2005). Alternatively, a study in which 1,8-cineole was injected into the rat hindpaw demonstrated that eucalyptus induced oedema, most likely due to the release of mast cell mediators (Santos & Rao 1997). The clinical implications of this finding for topically applied eucalyptus oil require further investigation. Anti-inflammatory activity of *E. radiata* has been demonstrated in patients with dry and weeping dermatitis, most probably due to inhibition of inflammatory markers such as TNF-alpha, COX enzymes, 5-lipoxygenase and other leukotrienes, and it could be an alternative to topical steroid medicines (Hadji-Minglou & Bolcato 2005, Santos & Raos 2000). Juergens et al (2003) demonstrated 1,8-cineole maintained lung function four times better than controls in a double blind clinical trial of patients ($n = 32$) with severe steroid-dependent bronchial asthma. Patients were randomly assigned to 1,8-cineole 200 mg 3 times daily for 3 weeks or placebo. Steroid doses were reduced by 2.5 mg every 3 weeks. Twelve of the 16 receiving 1,8-cineole remained stable despite reduced steroid doses.

Analgesic

Analgesic properties are attributed to the monoterpene components of eucalyptus oil. The monoterpenoid profile differs among eucalypt species and may account for variations in therapeutic effect. *E. globulus* has a high 1,8-cineole content (60–90%) (Juergens et al 1998). Silva et al (2003) investigated the analgesic and anti-inflammatory effects of *E. tereticornis, E. citriodora* and *E. globulus* in rats. The results showed central and peripheral analgesic effects of the three oils.

OTHER ACTIONS

Eucalyptus oil is metabolised in the liver; however, evidence is contradictory as to whether it induces the cytochrome P450 enzyme system. One study conducted with an animal model demonstrated a slight increase in CYP4A expression (Ngo et al 2003), whereas 1,8-cineole has demonstrated CYP450 induction in vitro and in animal studies (Ulbricht & Basch 2005). *E. globulus* induces a cell-mediated immune response, and morphological and functional activation in human macrophages stimulates the phagocytic response (Serafino et al 2008).

CLINICAL USE

Eucalyptus oil has been investigated in numerous forms; however, there is a lack of controlled, clinical studies.

Respiratory conditions

Eucalyptus oil is used as symptomatic treatment in obstructive respiratory conditions such as bronchitis, asthma, the common cold and other conditions associated with catarrh of the upper respiratory tract. Although it is used internally and externally in Europe for these indications, in Australia the oil is generally used externally in vaporisers, chest rubs and nasal inhalations.

Nasal decongestant properties were assessed in 31 healthy volunteers using inhalations of 10 mL of essential oil for 5 minutes. There was no effect on nasal resistance to air flow, but there was a stimulant effect on the cold receptors in the nose and the majority of subjects reported being able to breathe more easily (FDA 1994). A single-blind, parallel clinical trial (n = 234) was conducted to assess whether vaporised essential oil reduced nasal congestion compared with steam. The essential oil was significantly more effective ($P < 0.02$), but only in the first hour after inhalation. Other researchers found no significant differences in nasal decongestion compared with placebo (Burrows 1983). There was no significant difference between placebo and topically applied *E. piperita* to the forehead and temples to treat headache in a randomised, double crossover trial (n = 32); however, cognitive performance and muscle and mental relaxation were greater in the essential oil group (Gobel 1995).

Aromatherapy

Eucalyptus, as it is traditionally used in aromatherapy, has not been systematically investigated under clinical trial conditions. Therefore, most evidence is derived from traditional sources.

Aromatherapists use eucalyptus for its mentally uplifting and stimulating effects and to aid concentration. It is also used in massage and vaporisers to relieve respiratory symptoms, treat minor skin infections and acne, and relieve headache and muscular aches and pain. Usually eucalyptus oil is included in a blend of 3–5 essential oils for a massage but may be used alone for an inhalation.

One study investigating the effects of topical application of eucalyptus oil to the forehead and temples found it was an ineffective treatment for headache (Gobel 1995).

OTHER USES

Eucalyptus oil is often included in OTC and other medicines in various formulations such as rubs, mouthwashes, 'cold and 'flu' preparations, cleansing products, inhalers, soaps and insect repellents in which the 1,8-cineole content is standardised to 80–90%. Bosisto's Eucalyptus Oil is commonly sold in supermarkets and has an Aust R label (10908). It is not used in aromatherapy and is dispensed in a ribbed poison bottle with a childproof cap.

Dust mite removal

Eucalyptus oil can be formulated with a kitchen detergent concentrate to form an inexpensive acaricidal wash that reduces the number of live mites found in blankets during normal machine washing (Tovey & McDonald 1997). When compared with detergent concentrate alone, a 30-minute pre-wash soak of woollen blankets with the eucalyptus oil/detergent formula reduced the number of live mites that could be recovered by 97%. This eliminates the need for very hot water and may maintain low allergen levels in bedding for longer than normal laundering alone because mites are adversely affected by low concentrations of eucalyptus oil vapour, which lingers for 2–3 days. In this study, the dishwashing liquid detergent concentrate (Kit, L&K, Rexona, Sydney, Australia) was used to form an emulsion in water because the essential oil is not soluble in water.

Cleaning agent

Washing in diluted eucalyptus oil is also used as a method of removing stains from fabric; however, it does leave a faint characteristic odour for 2–3 days despite rinsing and drying, and some people may find this irritating.

Malodorous necrotic ulcers

These ulcers are a major concern for cancer patients and can lead to social isolation and reduced QOL because current treatments inadequately reduce the foul smell to acceptable levels. A paper published in 2006 reported that rinsing the ulcers twice a day with an antibacterial essential oil mixture (mainly eucalyptus oil) resulted in complete disappearance of odour by day 3 or 4 in all patients (n = 30) (Warnke et al 2006). The eucalyptus was used in combination with a standard course of antibiotics. A number of beneficial secondary findings were anti-inflammatory activity, promotion of healing and complete re-epithelialisation, and emotional relief on resolution of the condition.

DOSAGE RANGE

Dose recommendations vary, but generally low doses are used. Internal formulations may take longer to show an effect than conventional medicines.

- Inhalation: 12 drops in 150 mL of boiling water or 5 drops in a nebuliser, which delivers approximately 35 mg (unpubl. data: Harris & Harris – Aromatic Medicine: The Interfaces of Absorption, seminar course notes, Melbourne, 2003). High doses are not recommended because they can irritate the eyes and mucous membranes and may trigger an asthma-like attack.
- Mouth wash: 20 mL (0.91 mg/mL) solution gargled twice daily.
- Massage: traditionally aromatherapists use essential oils as 3.5–5% in a carrier substance but doses between 5 and 20% are used for adults and much lower doses for children and older people.
- Ointments, creams, gels and poultices: 5–10% in a carrier substance such as beeswax.
- Internal use: 0.3–0.6 mL/day essential oil 1–4 times daily; capsules 100–200 mg; lozenges 0.2–15.0 mg dissolved slowly in the mouth every 30–60 minutes.

Most Australian aromatherapists do not currently administer essential oils via the internal route (oral, vaginal and rectal), but they are administered via these routes in other countries, especially France.

TOXICITY

Toxicity symptoms occur rapidly, but may be delayed for hours and include altered conscious state, drowsiness and unconsciousness, which are dose-dependent. Symptoms reported in other studies include epigastric burning, nausea, vomiting, dizziness, muscular weakness, delirium and convulsions.

The acute oral LD_{50} dose of 1,8-cineole in rats is 2.48 g/kg and the dermal LD_{50} dose in rabbits is > 5 g/kg.

Fatal poisoning has occurred in children after accidental ingestion of whole or diluted eucalyptus oil in amounts ranging from 2 to 10 mL. Tibballs (1995) reported 109 children who were admitted to hospital for eucalyptus oil poisoning in an 11-year period; 27 had been accidentally poisoned when an adult administered the oil orally by mistake and most of the remaining 82 children had ingested the oil from a vaporiser. Another review of 41 cases of eucalyptus oil poisoning (Webb & Pitt 1993) indicated that 80% were asymptomatic. There was no relationship between the amount of oil ingested and the presence and severity of symptoms.

The Victorian Poisons Information Centre (see Appendix 3) recommends all patients who ingest ≥ 1 mL of eucalyptus oil be assessed in an emergency department. The centre attributes the toxicity to the cineole, terpene and phellandrene content and indicates that although hydrocyanic acid is only present in small amounts it may be responsible for most of the toxicity.

ADVERSE REACTIONS

Eucalyptus oil is generally safe when used externally in an appropriate manner.

A number of adverse reactions are reported for topical application, including systemic toxicity in a 6-year-old girl, and urticaria, contact dermatitis and skin irritation in other cases (Darben 1988). However, when considering the risks of topical application of eucalyptus oil the state of the skin must be considered as well as the individual's susceptibility to atopic conditions such as eczema and asthma.

Allergic reactions to lozenges have also been reported anecdotally.

Inhalations may irritate the eyes and mucous membranes.

SIGNIFICANT INTERACTIONS

Due to the lack of clinical evidence, interactions are theoretical and speculative.

CNS depressants

Oral ingestion of eucalyptus has been associated with CNS depression, therefore additive effects are theoretically possible — caution.

Drugs metabolised by CYP 450

Some evidence suggests CYP induction is possible; however, it is not known which CYP enzymes are affected, thus making recommendations difficult. Interactions are unlikely when used topically or inhaled, but could theoretically occur when used internally (Springhouse Corporation 2001).

PRACTICE POINTS/PATIENT COUNSELLING

- Eucalyptus essential oils are steam distilled from a number of *Eucalyptus* species, and have different chemical compositions depending on the species. Most contain a large proportion of 1,8-cineole, which appears to be responsible for the action on the respiratory system.
- Eucalyptus is primarily used in aromatherapy as an inhalation to relieve nasal congestion and in massage to relieve muscular aches and pain, as well as in ointments, gels and compresses, and via a vaporiser for mental stimulation and to aid concentration.
- It is used internally in lozenges, tinctures and conventional medicines.
- When used topically in an appropriate manner, eucalyptus oil is considered safe; however, several cautions exist to reduce the risk of adverse reactions and toxicity. People using eucalyptus essential oil should be monitored for allergies and it should not be applied to the face of children. Eucalyptus should not be used internally unless it is diluted and used in the recommended doses and dose intervals.
- Signs of poisoning usually occur rapidly and include confusion, irritability, respiratory distress, hypotension, nausea and vomiting. If poisoning is suspected medical care should be sought urgently. Do not induce vomiting. Use charcoal and monitor consciousness.
- Several drug interactions are theoretically possible; however, their clinical significance is unknown.

Hypoglycaemic agents

If used in combination with oral glucose-lowering conventional or complementary medicines it may contribute to hypoglycaemia (oral doses) — blood glucose levels should be monitored (Springhouse Corporation 2001).

CONTRAINDICATIONS AND PRECAUTIONS

Essential oils are not recommended in the first 3 months of life because the barrier function of the skin is not fully developed. In addition, inhaling menthol can induce transient apnoea in premature infants due to its effects on the TRPM 8 receptor (Javorka et al 1980); thus, essential oils containing 1,8-cineole should not be applied on or near the face of babies and small children. *E. globulus* may cause skin allergy in susceptible individuals (those prone to asthma and allergies, and with a previous reaction to eucalyptus).

Eucalyptus oil should not be administered internally to children or people with inflammatory gastrointestinal tract disease or impaired liver function, or during pregnancy.

Eucalyptus oil should not be applied to the face, especially of infants and young children because of the risk of bronchospasm and irritation.

The oil should be stored out of the reach of children and confused people.

Vaporisers containing eucalyptus essential oils should also be placed out of reach. Poisoning has occurred following ingestion from vaporisers.

Oily carrier fluids should not be used for nasal sprays because they inhibit protective nasal ciliary movements and could cause lipid pneumonia.

The essential oil is highly flammable and represents a fire risk when used in candle vaporisers.

PREGNANCY USE

No studies have been undertaken. The essential oil is not teratogenic in animal studies, but doses of 500 mg/kg cross the placenta in large enough amounts to stimulate hepatic activity in rodents (Jori & Briatico 1973). Aromatherapists do not use eucalyptus essential oil during pregnancy, especially in the first trimester.

PATIENTS' FAQs

What will this essential oil do for me?

Eucalyptus essential oil can be used in a vaporiser or on tissues to help clear the nose and make breathing easier in the presence of an URTI. It can also increase mental alertness. In a massage blend eucalyptus can help relieve muscular and arthritic pain.

Eucalyptus oil can be added to the washing machine to help kill dust mites in human clothes and animal bedding. Dust mites are responsible for many respiratory conditions, such as asthma.

When will it start to work?

Inhaled eucalyptus oil usually acts quickly and provides symptomatic relief quickly. Oral doses and massage blends usually take longer to have an effect.

Are there any safety issues?

Ingested eucalyptus oil has caused poisoning especially in children and therefore any source of the oil, including vaporisers, should be placed out of reach.

Eucalyptus can irritate the eyes and mucous membranes. It should be kept away from the face, especially of infants and children.

Ingested eucalyptus oil could affect the action of some medicines such as antidepressants, sedatives and anaesthetic agents. It increases absorption of nicotine.

Evening primrose oil

OTHER NAMES
EPO, primrose oil, butter rose, cow slip, fever plant, huile d'onagre, king's cure all, mayflower, Our Lady's key, palsywort, sundrop.

BOTANICAL NAME/FAMILY
Oenothera biennis (family Onagraceae)

PLANT PART USED
Fixed oil from the seed. A suitable extract must be obtained from cold-pressing rather than heat extraction to avoid damaging the oil.

CHEMICAL COMPONENTS
Evening primrose oil contains essential fatty acids (EFAs). EFAs are polyunsaturated fatty acids containing two or more double bonds. EPO contains about 70% linoleic acid (LA) and 9% gamma-linolenic acid (GLA) (Horrobin 2000), as well as oleic, palmitic and stearic acids, campesterol and beta-sitosterol. Due to the position of its double bonds, EPO is classified as an omega-6 (n-6) fatty acid.

Borage seeds (18–26%) and blackcurrant oil (15–20%) also contain high amounts of GLA; however, research suggests that they are not necessarily any more potent on a gram-for-gram basis and it has been postulated that this is possibly due to other biologically active components of EPO or the minor stereodimensional differences in the GLA contained within the different oils (Fan & Chapkin 1992).

MAIN ACTIONS
The two main actions of EFAs are related to their roles in the structures of membranes and in the synthesis of a wide variety of derivatives that regulate numerous aspects of cellular activity. With regard to EPO, its main actions relate to its EFA content, GLA in particular.

Anti-inflammatory
Although GLA is a theoretical precursor for arachidonic acid (AA) and as such could also generate pro-inflammatory eicosanoids, such as the 2-series prostaglandins, 4-series leukotrienes and platelet-activating factor, the evidence to date suggests that GLA can encourage uptake of dihomo-GLA (DGLA) into cell membranes and this in turn inhibits the synthesis of AA metabolites. In addition to this, the direct metabolites of DGLA include prostaglandin E_1 (PGE_1), which has been shown to inhibit inflammation, regulate immunity, cause vasodilation and reduce blood pressure, improve flexibility of red blood cell membranes, induce insulin receptors and inhibit platelet aggregation and thrombosis (Horrobin 1990). Consequently, the net effect of this omega-6 oil is anti-inflammatory, which distinguishes it clearly from other non-GLA n-6 oils (Fan & Chapkin 1998).

GLA and DGLA have been shown to reduce inflammation and excessive immune reactivity in experimental models of arthritis, autoimmune disease, allergic and chronic inflammatory disorders (Godfrey et al 1986; Kunkel et al 1981a, 1981b, Mertin 1984, Tate et al 1988).

Dermatological effects
The anti-inflammatory effect of EPO has been most extensively studied in relation to skin disorders. In addition, n-6 fatty acids are involved in maintaining the integrity of the water impermeability barrier of the skin. Both LA and GLA, but not other EFAs, seem to be capable of this (Horrobin 1990).

Antithrombotic activity
GLA is metabolised to DGLA, which is a precursor to the 1-series of PGs. Increases in PGE_1 production result in a cascade of reactions that ultimately inhibit platelet aggregation and cause vasodilation. Additionally, red cell membranes deficient in EFAs become stiffer than normal, resulting in reduced capacity of red cells to flow through the capillaries and, therefore, adequately oxygenate target tissues (Horrobin 1990).

Other actions
Bone metabolism
Oral GLA and eicosapentaenoic acid (EPA) in the ratio 3:1 have been shown to significantly increase intestinal calcium absorption, calcium balance and bone calcium in rats, compared with controls that consumed LA (sunflower oil) and alpha-LA (linseed oil) (3:1) or a commercially available rat chow (Claassen et al 1995).

Hypotensive effects
Vegetable oils, including sunflower oil, linseed oil and EPO, have been shown to enhance the effects of several antihypertensive drugs, including dihydralazine, clonidine and captopril, in rats under experimental conditions (Hoffmann et al 1984).

A study examining the effects of salt-loading on blood pressure development in borderline hypertensive rats found that dietary sunflower and fish oils abolished the pressor response, reducing blood pressure below control levels (Mills et al 1989).

Antidiabetic effects
Several studies have indicated that treatment with EPO can prevent or reverse diabetic neuropathy in animals. The effect does not seem to be mediated neither by regulating the sorbitol or other polyol levels in peripheral nerves, nor by having any effect on the control of blood sugar. The interval between oral intake of EPO and its effect in peripheral nerves of rats was studied 35 days after induction of diabetes. EPO did not affect nerve conduction velocity in the first 12 h of its administration, but significantly increased it 24 h later. Nerve conduction needed 10 days to stabilise. The latency suggests that neuroactivity of EPO may be mediated by its metabolic products synthesised in the body, and not by constituents of the oil (Julu 1996). In another

experiment, diabetic rats not receiving EPO showed highly significant elevations of nerve sorbitol and fructose combined with a depletion of nerve myo-inositol. The rats had increased immunoreactivity and reduced nerve conductivity. Treatment of other diabetic rats with EPO attenuated conduction deficiency and in some cases completely prevented the development of the motor nerve conduction velocity deficit (Tomlinson et al 1989).

Alcohol metabolism

Many reports have now confirmed the teratogenic potential of alcohol in humans and in laboratory animals. A characteristic pattern of congenital anomalies is present in infants born to mothers with chronic alcoholism. Chronic consumption of ethanol causes a depletion of EFAs, partly by blocking GLA formation and partly by depleting DGLA. Treatment of pregnant rats with ethanol and EPO (Efamol), a rich source of GLA, led to a significant reduction in the embryopathic activity of ethanol (Varma & Persaud 1982).

Renal effects

Evening primrose oil, safflower oil and salmon oil have all shown a favourable effect on progression of renal failure in partially nephrectomised rats compared with controls that were fed beef tallow. The regulation of thrombotic and inflammatory mediators may explain the protective role of these oils (Barcelli et al 1986). Further studies showed that EPO and safflower oil may help to prevent diabetic nephropathy (Barcelli et al 1990). Compared with beef tallow, the oils appeared to have a clear beneficial effect on proteinuria, glomerular sclerosis and tubular abnormalities in diabetic rats. The effect was mediated via PG and thromboxane metabolism. No significant changes in plasma lipid composition were observed. Fish oils did not have an effect on renal disease, but decreased plasma lipids and inhibited eicosanoid synthesis by platelets and kidney cortex.

Diets containing fish oils, EPO or a combination all lowered plasma triglyceride and total cholesterol levels compared with diets containing beef tallow in experimentally induced nephritic syndrome in rats. However, only the combination of EPO and fish oil (75:25) affected HDL cholesterol levels. The combination prevented the 10-fold suppression of aortic 6-keto-PGF_{1alpha} caused by the fish oils. These changes in plasma lipids and eicosanoid production are potentially anti-atherogenic and may prevent glomerular sclerosis. The combination of EPO and fish oils may offer advantages over either family of fatty acids in nephrotic syndrome (Barcelli et al 1988).

Metabolites of EPA and GLA have been shown to slow or modulate the development of experimentally induced glomerulonephritis in rats (Papanikolaou 1987).

Antitumour effect

Excess dietary fat has been identified as a risk factor in the development of human breast carcinoma. However, the quality of fat may be more important than the overall quantity. Animals treated with EFAs from EPO and fish oils developed tumours that were significantly smaller than the two control groups treated with dietary olive oil or normal laboratory feed (Pritchard et al 1989).

CLINICAL USE

Although this review focuses primarily on GLA, evidence now suggests that n-6 fatty acid intake must be considered in relation to concurrent omega-3 (n-3) fatty acid intake to have a more consistent anti-inflammatory effect. As such, many studies are now using combination supplements or dietary changes that alter the ratio of n-3 to n-6 EFAs.

For more information about the n-3:n-6 fatty acid balance, which has implications in cardiovascular disease and cancer, refer to the monograph on Fish oils.

Deficiency

Like other essential nutrients, EFAs must be supplied by the diet; however, elucidation of a daily minimum requirement is not yet possible. Based on large dietary surveys and epidemiological evidence demonstrating a protective effect against cardiovascular disease incidence and mortality, a suggested dietary target for LA of 4–10% of total kJ intake has been set (NHMRC 2005). Besides insufficient intake, secondary deficiency states are also possible due to faulty EFA metabolism.

The first and rate-limiting step in EFA metabolism is the LA desaturation, requiring delta-6-desaturase amongst other enzymes. A deficiency or significant impairment of the desaturase enzyme, due to dietary or lifestyle factors, could lead to a deficiency of GLA. Excessive consumption of LA could also lead to a relative deficiency of GLA. Direct supplementation with GLA may be clinically beneficial in both scenarios (Horrobin 1990).

It is now suspected that a number of common conditions, such as dermatitis, may be aggravated by, or in part caused by, an imbalance between n-3 and n-6 EFAs and a relative GLA deficiency.

Dermatitis and psoriasis

Research from the 1930s to the 1950s established that an n-6 EFA deficiency leads to inflammatory skin conditions in both animals and humans. While there is no deficit of LA in atopic eczema, with concentrations of LA tending to be elevated in blood, milk and adipose tissue of patients with atopic eczema, concentrations of its metabolites are substantially reduced. This suggests reduced conversion of LA to GLA (i.e. delta-6-desaturase impairment). In most studies, but not all, GLA administration has been found to improve general skin health: the clinically assessed skin condition, the objectively assessed skin roughness and the elevated blood catecholamine concentrations of atopic eczema. Together with ongoing research suggesting that atopic eczema may be a minor inherited abnormality of EFA metabolism in some cases (Businco et al 1993, Horrobin 2000, Kitz et al 2006, van Gool et al 2003), interventional studies using EPO or other

GLA rich oils have curiously failed to demonstrate efficacy on the whole.

Clinical studies

Earlier promising results, including a 1989 meta-analysis (Morse et al 1989), have been overshadowed by recent predominantly negative findings.

Evening primrose or borage oil, either alone or in combination with fish oils, in the most recent studies was found to be ineffective for atopic dermatitis in adults (Berth-Jones & Graham-Brown 1993, Henz et al 1999, Takwale et al 2003) and children (Takwale et al 2003) and adult psoriasis (Oliwiecki & Burton 1994). A study supplementing newborns considered high risk for atopy with GLA (≈40 mg/day), either directly through formula or via the mother, for up to 6 months, failed to reduce atopic dermatitis incidence; however, treatment lowered IgE levels for the first year of life (Kitz et al 2006).

In 2000, a substantial review was conducted by the National Health Service (NHS) Health Technology Assessment Programmes, looking at more than 15 studies involving either EPO or borage oil in the treatment of atopic dermatitis, and it was concluded that the largest and best-reported studies showed no convincing effect (Hoare et al 2000). A 2004 meta-analysis of EPO studies in atopic dermatitis concurred with these findings (van Gool et al 2004).

In spite of much negative evidence, occasional positive findings continue to surface. One such result published in 2008 comes from a study of Indian children with atopic dermatitis, administered EPO (500 mg to 5 g dependent upon age) for 5 months. A response rate of 96% was achieved in the EPO group compared with 32% for placebo and EPO was concluded to be an effective treatment.

Finally, both oral and topical EPO applications have been investigated in the uraemic pruritis experienced by hemodialysis patients with some success; however, more research is warranted to confirm efficacy for this specific presentation (Chen et al 2006, Yoshimoto-Furuie et al 1999).

Clinical note — Company interest bias in the evidence?

The research into the efficacy of EPO has attracted much criticism from different members of the scientific community. In particular, attention has been paid to the contrast between early 'strikingly' positive findings and the negative conclusions currently being drawn as a result of more in-depth analysis regarding the efficacy of EPO in the treatment of some conditions. While some may argue these results are due to improvement in research methodology, one editorial published in 2003 in the *British Medical Journal* implies that research funding from the manufacturers, selective inclusion of positive only studies in previous reviews and meta-analyses as well as partial suppression of negative findings has had a part to play (Williams 2003).

Female reproductive system disorders

Without doubt, the most popular use for EPO supplements relates to conditions of the female reproductive system. On the whole, the evidence, however, has been plagued by small and poorly designed studies (Stonemetz 2008).

Premenstrual syndrome

Interest in EPO supplements as a potential treatment for Pre Menstrual Syndrome (PMS) began in the early 1980s, largely as a result of investigational work published by David Horrobin, of three double-blind placebo-controlled studies and two open trials in women with premenstrual syndrome (Horrobin 1983).

Shortly afterwards, results from a study conducted by Brush et al provided a rationale for considering EPO supplementation for PMS. This study found that phospholipids' LA levels in women with PMS were significantly above normal, yet the concentrations of all metabolites were significantly reduced (Brush et al 1984). Based on these findings, researchers suggested that some women with PMS may not be able to adequately convert LA to GLA and as a result, sensitivity to luteal phase prolactin and steroids may be increased. As such, supplementation directly with GLA would bypass the problem and potentially normalise sensitivity and result in reduced symptoms.

For a time, these results stood unquestioned, until in 1990 another double-blind placebo-controlled trial involving 38 women failed to show evidence of efficacy over six cycles (Khoo et al 1990).

A comprehensive review published in 1996 identified seven placebo-controlled trials, although in two the randomisation was unclear. The two most well-controlled studies failed to detect a benefit for EPO supplements; however, as they were small, modest benefits cannot be excluded (Budeiri et al 1996). Interestingly, in one of these studies, the only significant benefit noted by the subjects was a mild reduction in breast pain.

Mastalgia

In spite of the earlier promising findings (Gateley et al 1992a, 1992b), a more recent 6-month, randomised, double-blind trial did not find that EPO, EPA or a combination of the two were significantly better than placebo in reducing the symptoms of mastalgia. Corn oil and corn oil with wheat germ oil were used as control oils. The decrease in days with pain was 12.3% for EPO and 13.8% for its control oil; the decrease in days with pain was 15.5% for fish oil and 10.6% for its control oil (Blommers et al 2002). A recent meta-analysis concurs with these findings, suggesting that EPO is no more effective than placebo in the treatment of mastalgia (Srivastava et al 2007); however, there has been ongoing speculation regarding the possible effects of the 'control oils' used in these trials (Stonemetz 2008).

Evening primrose oil has also been assessed for its ability in preventing fibro-adenomas. A small study of 21 patients found that EPO had no significant influence over the natural history of breast fibroadenomas (Kollias et al 2000). A more recent study

has also yielded negative results when compared with topical Non Steroidal Anti Inflammatory Drugs (NSAIDs), with significantly reduced efficacy, more reported adverse effects and ratings of less acceptability by the patients (Qureshi & Sultan 2005).

Dysmenorrhoea

Similar to the original findings of impaired omega-6 metabolism in PMS sufferers, recent research in dysemenorrhoeic women has revealed poor conversion of LA into DGLA, predisposing individuals to a pro-inflammatory state (Wu et al 2008). The study, which compared the effects of borage, sunflower and fish oil over 3 months, produced increased DGLA:AA in healthy women taking borage oil but not in dysmenorrheoic women. While this trial did not investigate clinical outcomes such as pain relief, EPO supplementation does not appear promising.

Endometriosis

A combination of GLA and EPA is better than placebo in relieving the symptoms of endometriosis according to one placebo-controlled study. Of those in the treatment group, 90% reported relief of symptoms compared with 10% of those in the placebo group (Horrobin 1990).

Oedema and hypertension during pregnancy

In a partially double-blind, placebo-controlled clinical trial, a combination of EPO, fish oil and magnesium oxide was found to be superior to placebo in lowering the incidence of oedema ($P = 0.004$) in pregnant women. Significantly, fewer women developed hypertension in the group receiving the oils and magnesium oxide. The three cases of eclampsia all occurred in the control group (D'Almeida et al 1992).

Menopausal hot flushes

According to one randomised, double-blind placebo-controlled study, EPO supplementation significantly reduces the maximum number of nighttime flushes, although other symptoms failed to respond. The study used a dose of four capsules daily (each containing 500 mg EPO and 10 mg vitamin E) over 6 months (Chenoy et al 1994).

A position statement of the North American Menopause Society (2004) concluded that evidence was lacking to warrant the use of EPO in the treatment of vasomotor symptoms of menopause.

Pregnancy

EFA supplementation during pregnancy has tended to focus on the omega-3s; however, several investigations of maternal docosahexaenoic acid (DHA) supplementation revealed a corresponding negative effect on plasma arachidonic acid (AA) levels of mothers (Geppert et al 2008). AA, like the omega-3s, is essential for fetal brain development and function; hence questions have been raised regarding possible ramifications of such an effect. Additionally, epidemiological research suggests that low intrauterine levels of (D)GLA may be linked to an increased risk of obesity, insulin resistance and hyperlipidaemia in later life. To address this issue, a placebo-controlled study was undertaken, administering 3.4 g of an EPO and fish oil blend (456 mg DHA, 73 mg EPA, 14 mg AA, 353 mg GLA) over 8 weeks in a group of 40 women. The co-administration of GLA at this dose appeared to counter the previously observed negative effect on plasma AA and researchers are proposing further trials to assess cognitive and other outcomes in offspring of mothers following such a protocol (Geppert et al 2008).

Another small study, published only as a conference abstract, investigated the effects of EPO 1 g three times daily in pregnant women over 1 week close to term (Ty-Torredes 2006), reporting a significant reduction in cervical length in the treatment versus placebo group and improved Bishop score. EPO is proposed as a potential cervical priming agent to enhance the success of vaginal delivery; however, no background theory to explain this hypothesis is provided.

Diabetes

The activity of delta-6-desaturase enzyme is compromised in patients with type 1 and type 2 diabetes mellitus, which can decrease the production of PGE_1, therefore possibly contributing to an overall inflammatory excess in these conditions, as demonstrated by increased levels of PGE_2 (Halat & Dennehey 2003).

The first randomised, double-blind placebo-controlled study investigating EPO as a treatment agent in type 1 and type 2 diabetes mellitus involved 22 patients with mild distal diabetic neuropathy. Patients were administered 360 mg/day of GLA or placebo for 6 months. Patients receiving GLA had statistically significant improvements in all measures of nerve function, wrist and ankle heat threshold values, as well as overall symptom scores. As there was no change in HbA_{1c} in the patients receiving EPO, improvements in symptoms were deemed to be independent of any effect on glucose control.

A subsequent larger, randomised, double-blind placebo-controlled study involved 111 patients with type 1 or 2 diabetes and mild or moderate neuropathy. Patients received either placebo or 480 mg/day of GLA for 1 year. At 1 year, patients who received GLA had a statistically significant increase in 13 of 16 neural function measurements compared with placebo, including a variety of motor conductivity, action potential and sensory tests. Greater benefits were observed in those patients who had glycohaemoglobin values less than 10% at baseline (Jamal & Carmichael 1990).

Currently, there is a need for more conclusive research; however, the evidence to date appears promising for EPO supplementation in mild to moderate neuropathy, even as an adjunct to conventional treatments.

Rheumatoid arthritis (RA)

EPO supplementation increases DGLA, a competitive inhibitor of pro-inflammatory PGs and leukotrienes, and therefore reduces the inflammatory response (Belch & Hill 2000). As such, EPO supplements have been investigated in the management of RA, producing mixed results (Belch et al 1988,

Brzeski et al 1991, Hansen et al 1983, Jantti et al 1989, Veale et al 1994, Zurier et al 1996).

In one study, 16 patients with RA were given 540 mg GLA/day (EPO), 15 patients 240 mg EPA and 450 mg GLA/day (EPO/fish oil) and 18 patients an inert oil (placebo). The initial 12-month treatment period was followed by 3 months' placebo for all groups. Results at 12 months showed a significant subjective improvement for EPO and EPO/fish oil compared with placebo. Additionally, within 12 months, the patients receiving EPO and EPO/fish oil had significantly reduced their NSAID intake. After 3 months' placebo, those receiving active treatment had relapsed. Despite the decrease in NSAIDs, measures of disease activity did not worsen. It is suggested that EPO and EPO/fish oil produce a subjective improvement and allow some patients to reduce or stop treatment with NSAIDs. There is, however, no evidence that they act as disease-modifying agents (Belch et al 1988).

In a randomised, single-blind placebo-controlled trial (Zurier et al 1996), treatment with 2.8 g/day GLA resulted in a significant and clinically relevant reduction in RA symptoms and signs of disease activity. GLA therapy demonstrated a significant improvement in swollen joint count and score, tender joint count and score, duration of morning stiffness, patient's global assessment, patient's assessment of pain and degree of disability compared with baseline (measured by Health Assessment Questionnaire score). Not all of these parameters were significantly improved compared with placebo, but this may be due to the choice of safflower oil as a placebo. Olive oil, which contains oleic acid, also found in safflower oil, has been reported in other studies to benefit patients with RA (Brzeski et al 1991).

In one group of patients who were treated with GLA for 12 months, 16 of 21 showed meaningful improvement and 7 patients were able to decrease their NSAID and/or prednisolone dosage. GLA does not have a disease-modifying effect and supplementation must be long term. After 3 months without GLA supplementation, most patients experienced an exacerbation of symptoms. GLA was well tolerated during the trial with only three minor adverse reactions reported. Complete blood count and platelet count did not show abnormal results (Zurier et al 1996).

More recently, a 2004 systematic review of complementary medicine treatments for arthritis included 11 trials of GLA rich oils in RA (Soeken 2004). It was concluded that there was strong evidence that GLA supplementation significantly reduces the pain associated with this condition.

Cardiovascular diseases

There has been little clinical investigation of EPO in cardiovascular diseases, however when taken together with ongoing animal research, there is some evidence of cardiovascular actions.

Hypertension

A double-blind placebo-controlled study with a crossover design found that the combination of EPO and fish oils significantly lowered blood pressure in 25 non-obese black patients with mild–moderate uncomplicated essential hypertension after 8–12 weeks compared with placebo (sunflower and linseed oil) (Venter et al 1988). Other smaller studies have found a similar beneficial effect in hypertensive patients. A combination of 4 g GLA and DHA daily for 6 weeks reduced blood pressure in nine mildly hypertensive patients compared with placebo (sunflower oil) (Deferne & Leeds 1992).

EPO (1.3 g/day) significantly lowered blood pressure in mildly hypertensive but otherwise healthy subjects in a small placebo-controlled, double-blind short-term trial. EPO treatment led to a group reduction of systolic pressure (8.98 mmHg) and diastolic pressure (12.25 mmHg). The authors suggest that the effect may be mediated via GLA's effects on PG metabolism (Leeds et al 1990).

A study conducted in 2001 in mice demonstrated that consumption of a GLA-based diet significantly reduced aortic vessel wall medial layer thickness and reduced atherosclerotic lesion size. These results were reported by the researchers to indicate that dietary GLA can suppress smooth muscle cell proliferation in vivo and potentially retard the development of atherosclerotic plaques. Human trials are now required to confirm this effect (Fan et al 2001).

Lipids

Several animal studies using EPO have demonstrated lipid-lowering effects (Dasgupta & Bhattacharyya 2007, Fukushima et al 1997, Fukushima et al 2001), most consistently reducing triglycerides while increasing HDL concentrations, with few yielding negative results (Ford et al 2001). A small study comparing the effect of 30 g olive oil or 3 g EPO/day over 2 weeks produced similar results in 24 patients with coronary artery disease (Stolyhwo Gofron et al 2006). Interestingly, both statin and fibrate classes of lipid-lowering drugs affect physiological GLA concentrations in contrasting ways, with statins lowering phospholipid and cholesterol ester concentrations; fibrates increasing GLA triglyceride levels. The significance of these actions upon net lipid-lowering effects is yet to be determined (Nyalala et al 2008).

Other

Animal research has demonstrated GLA as being protective against ventricular fibrillation (Charnock 2000) while a human trial of EPO compared to five other oils taken over 8 months failed to improve endothelial function (Khan et al 2003). Recently, a new hypothesis of impaired desaturation of both omega-6 and -3 fatty acids as a potential initiator and perpetuator of atherosclerosis has also been postulated (Das 2007).

OTHER USES

Alcoholism

Essential fatty acids are major structural components of the brain and through their effects on membrane properties are essential for the proper

actions of neurotransmitters and nerve conduction. Ethanol has three main known actions on EFA and PG metabolism: it reduces blood LA levels and induces or exaggerates EFA deficiency states; it blocks metabolism of LA to EFA metabolites, which are known to be important in brain structure; and it enhances the conversion of DGLA to PGE_1 (Horrobin 1987).

Small clinical studies have found EPO somewhat beneficial in the treatment of alcoholism. In a double-blind placebo-controlled clinical trial, EPO significantly reduced the severity of the withdrawal syndrome and improved liver function during the early weeks of withdrawal from alcohol. Relapse rates over 6 and 12 months did not improve, but in those who did not relapse certain parameters of cerebral function improved significantly (Horrobin 1990).

Migraine

Gamma-linolenic acid may be beneficial in the prevention of migraine headache when used in combination with other nutritional supplements and as part of an overall management plan, according to an open, prospective, uncontrolled trial involving 168 migraine patients. In the study, patients took a combination of GLA and alpha-LA (1800 mg/day), other vitamins, coenzymes and antioxidants, and were instructed to lower their arachidonic acid intake. They were also instructed on correct techniques of self-medication and in stress-reduction and progressive relaxation techniques. Of the 129 patients who were evaluated after 6 months, 86% reported an improvement, with 22% of the total being free from migraine, while 14% were not able to implement the self-management of progressive relaxation and stress-reduction techniques. Severity and frequency of attacks were decreased in patients reporting a positive response. Significant reduction in nausea and vomiting was reported in all groups except the failure group (Wagner & Nootbaar-Wagner 1997). Although encouraging, further research using GLA as a stand-alone treatment is required to determine its role in achieving these impressive results.

Schizophrenia

A 2000 review of clinical trials concluded that although EPA (from fish oils) may help up to one-third of people avoid initiation of standard treatment with antipsychotic drugs, there is no clear evidence of any benefit from EPO (Halat & Dennehey 2003, Joy et al 2000). Some authors in fact suggest that EPO is not recommended in this population although there is conflicting evidence regarding this (Stonemetz 2008).

Raynaud's syndrome

Prostaglandin E_1 and prostacyclin have been used in Raynaud's syndrome, but as these compounds are unstable and require intravenous administration, other treatments that increase the body's own production of these chemicals have been sought, for example, by administration of the precursor EFA. A small, double-blind placebo-controlled study of 21 patients with Raynaud's phenomenon found that EPO significantly reduced the number of attacks as the weather worsened compared with placebo. Visual analogue scales assessing the severity of attacks and coldness of hands improved in the EPO group, but no changes were seen in either group for objective measures of blood flow although changes in platelet behaviour and blood prostanoids were observed (Belch et al 1985).

DOSAGE RANGE

- Like other essential nutrients, EFAs must be supplied by the diet. Unlike other essential nutrients, it has not yet been possible to identify a minimum daily requirement.
- To reduce the risk of rancidity, EPO is mostly administered in sealed soft gel capsules that are taken orally and should be cold-pressed form of the oil.

According to clinical studies

- Diabetic neuropathy 360–480 mg GLA, which is approximately four to six 1 g capsules per day (Halat & Dennehy 2003).
- Alcoholism, cardiovascular and inflammatory disorders: 0.5–2.8 g GLA/day (approximately 5.0–28.0 g EPO/day) (Belch & Hill 2000, Leeds et al 1990, Zurier et al 1996).
- EPO may be applied topically in the treatment of skin disorders.

ADVERSE REACTIONS

Mild gastrointestinal symptoms, such as nausea, flatulence, loose bowels and bloating have been reported (Bamford et al 1985, Stonemetz 2008). High doses of 5–10 mL/kg/day administered in animal models failed to detect toxic effects or carcinogenicity (Everett et al 1988).

SIGNIFICANT INTERACTIONS

Phenothiazines

Several case reports suggest that EPO may reduce seizure threshold and reduce drug effectiveness in patients with schizophrenia treated with phenothiazines (Vaddadi 1981, Stonemetz 2008). Avoid concomitant use.

Oral anticoagulants

Due to the antithrombotic effect of EPO, concomitant use may theoretically increase the risk of bleeding — use caution and monitor bleeding time and signs and symptoms of excessive bleeding (Stonemetz 2008).

Antiplatelet drugs

Concomitant use may theoretically increase risk of bleeding, but enhanced anti-inflammatory effects may also develop, making this a useful combination — observe patients taking this combination.

CONTRAINDICATIONS AND PRECAUTIONS

There is mixed evidence for EPO lowering the seizure threshold in people with epilepsy (Spinella 2001). Until safety can be better established, EPO should be used with caution by people with a history of partial complex seizure disorders such as

temporal lobe epilepsy. Schizophrenics treated with neuroleptic drugs (phenothiazines) should also use this supplement with caution as it may lower seizure threshold. Suspend use of high doses 1 week before major surgery (Stonemetz 2008).

PREGNANCY USE

Safety has not yet been firmly established in pregnancy, although studies with experimental models suggest it is safe (Stonemetz 2008). Furthermore, EPO combined with fish oils has been used successfully to reduce the incidence of pre-eclampsia (D'Almeida et al 1992). According to a small study investigating the effects of EPO in pregnant women close to term, EPO has potential as a cervical priming agent (Ty-Torredes 2006).

PRACTICE POINTS/PATIENT COUNSELLING

- Evening primrose oil contains a number of EFAs, most notably GLA, which is thought to be the most important for exerting pharmacological activity.
- It is suspected that GLA supplementation results in increased production of useful metabolites such as PGE_1, which inhibits inflammation, regulates immunity, causes vasodilation and reduces blood pressure, improves flexibility of red blood cell membranes, induces insulin receptors and inhibits platelet aggregation and thrombosis.
- Evening primrose oil appears beneficial in the treatment of diabetic neuropathy, RA and elevated triglycerides.
- In many disorders, EPO is combined with fish oils (EPA) for best results.

PATIENTS' FAQs

What is EPO?

Evening primrose oil is the oil from the seed of the plant known as evening primrose. A similar oil is made from borage seeds. The oil contains high amounts of GLA, which is the main active compound.

What will this supplement do for me?

Current evidence supports the use of EPO in the treatment of diabetic neuropathy, RA and cardiovascular disease.

When will it start to work?

Beneficial effects have been reported in some studies within 2–4 weeks' continuous use. However, long-term use is necessary for chronic diseases such as RA.

Are there any safety issues?

Evening primrose oil is generally well tolerated. Only minor gastrointestinal upset may occur. Should this happen, it is recommended the capsules be taken with meals. EPO should be avoided by some people taking anti-epileptic medicines and blood thinning medicines.

Fenugreek

HISTORICAL NOTE Fenugreek's seeds and leaves are used not only as food, but also as an ingredient in traditional medicine. It is indigenous to Western Asia and Southern Europe, but is now mainly cultivated in India, Pakistan, France, Argentina and North African countries. In ancient times, it was used as an aphrodisiac by the Egyptians and, together with honey, for the treatment of rickets, diabetes, dyspepsia, rheumatism, anaemia and constipation. It has also been described in early Greek and Latin pharmacopoeias for hyperglycaemia and was used by Yemenite Jews for type 2 diabetes (Yeh et al 2003). In India, China and the Middle East, it is still widely used as a therapeutic agent. In the United States, it has been used since the 19th century for postmenopausal vaginal dryness and dysmenorrhoea (Ulbricht & Basch 2005).

COMMON NAME
Fenugreek

OTHER NAMES
Trigonella seeds, bird's foot, Greek hay, hu lu ba, methi, trigonella

BOTANICAL NAME/FAMILY
Trigonella foenum-graecum (family Leguminosae)

PLANT PARTS USED
Dried mature seed, although leaves are used less commonly.

CHEMICAL COMPONENTS
The main chemical constituents are fibre, tannic acid, fixed and volatile oils and a bitter extractive, steroidal saponins, flavonoids, polysaccharides, alkaloids, trigonelline, trigocoumarin, trigomethyl coumarin, mucilage (up to 30%), seven essential amino acids and vitamins A, C, D, B1, B2 and B3 (Bin-Hafeez et al 2003, Fisher & Painter 1996, Shang et al 1998, Zia et al 2001).

MAIN ACTIONS

Hypoglycaemic
The hypoglycaemic effect of fenugreek seeds has been demonstrated in numerous studies involving experimentally induced diabetes (both type 1 and type 2) in rats, dogs, mice, rabbits as well as diabetic humans (Alarcon-Aguilara et al 1998, Eidi et al 2007, Mohammad et al 2006, Madar et al 1988, Raju et al 2001, Ribes et al 1984, 1986, Riyad et al 1988, Sharma et al 1990, Vats et al 2002), and the effect has been described as slow but sustained (Puri et al 2002). Interestingly, no reduction of fasting or postprandial blood sugar levels was observed in a placebo-controlled study in non-diabetic people who used a dose of 5 g/day over 3 months (Bordia et al 1997).

The mechanism for the hypoglycaemic effect of fenugreek has been explored in many in vivo trials. The viscous fibre, galactomannan, reduces intestinal absorption of glucose and thus postprandial blood glucose (Srichamroen et al 2009). Fenugreek also has an insulinomimetic effect and may increase the sensitivity of tissues to available insulin (Puri et al 2002) and enhance utilisation of glucose (Al Habori et al 2001).

Anti-ulcerogenic activity
Both an aqueous extract and a gel fraction isolated from the seeds demonstrated significant ulcer-protective effects in vivo (Pandian et al 2002). The seed fractions given orally to test animals provided dose-dependent gastric protection against the effects of ethanol, which was as potent as that of omeprazole. Furthermore, histological studies found that the soluble gel fraction was significantly more protective than omeprazole. Preliminary research suggests that the polysaccharide composition and/or flavonoid components of the gel are responsible for the gastroprotective and antisecretory activities of the seeds.

Hypocholesterolaemic effect
Significant cholesterol-lowering activity has been demonstrated in several animal studies and human studies with diabetic volunteers (Boban et al 2008, Gupta et al 2001, Petit et al 1995, Rao et al 1996, Stark & Madar 1993, Sharma et al 1990, Sowmya & Rajyalakshmi 1999). Although the mechanism of action is still unclear, it appears that the fibre and steroidal saponins interact with bile salts in the digestive tract (Stark & Madar 1993). In one study, an unusual amino acid, 4-hydroxyisoleucine 5, was isolated and tested in dyslipidaemic hamsters and was found to significantly decrease plasma triglyceride levels by 33%, total cholesterol by 22% and free fatty acids by 14%, accompanied by an increase in HDL cholesterol:total cholesterol ratio by 39% (Narender et al 2006).

Immunostimulant activity

Enhanced humoral immunity, significant increases in macrophage activity and a stimulatory effect on lymphoproliferation have been demonstrated in vivo (Bin-Hafeez et al 2003). Stimulatory effects were observed at 100 mg/kg and in some cases at 250 mg/kg.

Anti-inflammatory and antipyretic activity

Potent anti-inflammatory activity was demonstrated in an animal model for both single-dose and chronic-dose applications of a dried leaf decoction of fenugreek (Ahmadiani et al 2001). The effectiveness of the 1000 mg/kg dose of the extract was relatively equal to 300 mg/kg sodium salicylate for single dosing; however, chronic administration was more effective than sodium salicylate. Additionally, the fenugreek decoction exhibited stronger antipyretic activity than that of sodium salicylate. These findings have been supported in a recent in vivo trial of a water-soluble fraction of fenugreek seed that was shown to have significant analgesic and anti-inflammatory actions (Vyas et al 2008).

Antinociceptive effects

Two studies in animal models have identified antinociceptive activity for fenugreek (Ahmadiani et al 2001, Javan et al 1997). This seems to be mediated through central and peripheral mechanisms. According to Javan et al (1997), the antinociceptive effects of 2000 mg/kg of the extract were more potent than those of 300 mg/kg sodium salicylate.

Effect on thyroid hormones

Administration of fenugreek seed extract for 15 days to both mice and rats significantly decreased serum liothyronine (T_3), suggesting that thyroxine (T_4)-to-T_3 conversion is inhibited and leads to increases in T_4 levels (Panda et al 1999).

Stimulates digestion

Traditionally, fenugreek is used to improve digestion. In vivo studies have identified that it enhances the activities of pancreatic and intestinal lipases, and sucrase and maltase, thereby providing support to this traditional use (Platel & Srinivasan 1996, 2000).

OTHER ACTIONS

Positive findings for other properties of fenugreek have been found in vitro and in vivo, including antioxidant, antihypertensive, hepatoprotective and chemoprotective actions (Annida & Stanely Mainzen Prince 2005, Amin et al 2005, Balaraman et al 2006, Bhatia et al 2006, Dixit et al 2005, 2008). The polyphenolic compounds of fenugreek seeds confer antioxidant and hepatoprotective properties comparable to silymarin in trials on rats (Kaviarasan & Anuradha 2007, Kaviarasan et al 2004, 2006, 2008). Antineoplastic activity has been observed for fenugreek in the Ehrlich ascites carcinoma model in mice (Sur et al 2001). Protodioscin, purified from fenugreek, has also exhibited antineoplastic activity on human leukaemia cell lines in vitro (Hibasami et al 2003). Fenugreek extract induces apoptosis in vitro to breast, pancreatic and prostate cancer cell lines, but not normal cells (Sebastian & Thampan 2007, Shabbeer et al 2009). Ethanol extract (50%) seemed to possess profound antiplasmodial activity in vitro (Palaniswamy et al 2008), but no in vivo trials have yet been undertaken. Although fenugreek contains coumarin constituents, a placebo-controlled study found that it does not affect platelet aggregation, fibrinolytic activity or fibrinogen (Bordia et al 1997). Traditionally, it is thought to promote lactation in nursing mothers and act as a general tonic.

CLINICAL USE

Dyspepsia and loss of appetite

Although controlled studies are unavailable, the increased activities of pancreatic and intestinal lipases seen in animal studies provide a theoretical basis for its use in dyspepsia.

Commission E approved the internal use of fenugreek seed for loss of appetite (Blumenthal et al 2000).

Elevated lipid levels

Several clinical studies conducted in people with and without diabetes have identified significant lipid-lowering activity with different fenugreek preparations, such as defatted fenugreek, germinated seed and hydro-alcoholic extracts (Bordia et al 1997, Gupta et al 2001, Sharma et al 1990, Sowmya & Rajyalakshmi 1999). As can be expected, the dose used and type of preparation tested have an influence over results.

An open study using a daily dose of 18 g germinated fenugreek seed in healthy volunteers demonstrated significant reductions in total cholesterol and LDL cholesterol levels. A placebo-controlled study found no effect after 3 months with a lower dose of 5 g seed daily (Bordia et al 1997, Sowmya & Rajyalakshmi 1999), suggesting that higher intakes may be required for lipid-lowering activity to become significant.

Diabetes

Fenugreek is a popular natural treatment used to aid blood sugar regulation in diabetes. In recent years, many in vitro and in vivo studies have been conducted in different models providing support for its use in diabetes; however, there have been relatively few human trials. Overall, clinical studies have produced positive results; however, interpretation is difficult because trials have used diverse preparations, various dosage regimens and outcome measures.

In one open study involving 60 people with type 2 diabetes, 25 g fenugreek seed powder taken together with lunch and dinner for 24 weeks produced significant reductions to fasting blood sugar levels and symptoms of diabetes, and improved glucose tolerance (Sharma et al 1996). A shorter 10-day randomised study of people with type 1 diabetes found that defatted fenugreek seed powder (50 g twice daily) significantly reduced fasting blood sugar level and improved glucose tolerance (Sharma

et al 1990). A double-blind, placebo-controlled study involving 25 volunteers with mild to moderate type 2 diabetes showed that 1 g/day hydroalcoholic extract of fenugreek seeds for 2 months improved insulin resistance and increased insulin sensitivity but had no effect on fasting blood glucose level at this low dose (Gupta et al 2001).

More recently, the efficacy and safety of fenugreek in the treatment of patients with type 2 diabetes mellitus were investigated in 69 patients whose blood glucose levels were not well controlled by oral sulfonylureas. This 12-week trial demonstrated that combined treatment of fenugreek with sulfonylureas improved glycaemic control, further reduced blood glucose levels and ameliorated clinical symptoms in the treatment of type 2 diabetes (Lu et al 2008). Fenugreek treatment was also found to be safe.

Lipid lowering in diabetes

Studies investigating the effects of fenugreek seed and seed powder have demonstrated significant lipid-lowering activity in this population. Oral doses of 25 g fenugreek seed powder taken twice daily significantly reduced serum total cholesterol, triacylglyceride and LDL cholesterol in hypercholesteraemia according to a study of hypercholesterolaemic type 2 diabetic patients. Results were taken at 3 weeks and 6 weeks (Moosa et al 2006). A placebo-controlled study using a lower dose of 2.5 g unaltered fenugreek seed twice daily over 3 months found that this was ineffective in type 1 diabetes but did have a lipid-lowering effect in patients with diabetes and coronary artery disease (Bordia et al 1997). In this population, total cholesterol and triglyceride levels were significantly reduced.

Studies with defatted fenugreek seed (100 g/day) in patients with type 1 diabetes also identified significant reductions in total cholesterol, LDL and VLDL cholesterol and triglyceride levels but no changes to HDL cholesterol under randomised conditions (Sharma et al 1990).

Ethanolic extracts of fenugreek have also demonstrated good results. A 2001 double-blind, placebo-controlled study found that a dose of 1 g ethanolic extract of fenugreek was able to significantly decrease serum triglyceride levels and increase HDL cholesterol in mild-to-moderate type 2 diabetes mellitus (Gupta et al 2001). Previously, similar results were obtained with an ethanolic extract of defatted fenugreek seeds in vivo, which produced an 18–26% reduction in plasma cholesterol level (Stark & Madar 1993).

In combination

A combination powdered mixture of three traditional Indian medicinal plants — fenugreek seeds, bitter gourd and jamun seeds — in raw and cooked form produced benefits in a study of 60 non-insulin-dependent people with diabetes. Daily supplementation of 1 g of this mixture for a 1.5-month period and then a further increase to 2 g for another 1.5 months significantly reduced the fasting and postprandial glucose levels in this population. A significant decrease in oral hypoglycaemic drug requirements was observed and for some subjects, cessation of drug therapy could be achieved after the 3-month feeding trial (Kochhar & Nagi 2005).

Promoting lactation

Although fenugreek has been used traditionally for centuries to increase milk production and improve lactation, no controlled studies are available to confirm effectiveness.

Externally — to reduce local inflammation

Although controlled studies are not available, evidence of anti-inflammatory and antinociceptive activity provides a theoretical basis for this indication.

Commission E approves the external use of fenugreek as a poultice for local inflammation (Blumenthal et al 2000).

OTHER USES

In Ayurvedic and Unani systems of medicine, fenugreek is used for treating fever, epilepsy, paralysis, gout, dropsy, chronic cough and piles. In Morocco, fenugreek is used as a preventive treatment against the development of kidney stones. There are some tests in experimental models, which provide some support for this use (Laroubi et al 2007).

The seeds are reported to have nutritive properties and to stimulate digestive processes, and have been used to treat a range of gastrointestinal disorders in the Indian system of medicine. It is also used as a general tonic, mixed with milk and sugar, to promote lactation and to lower lipid and glucose levels.

DOSAGE RANGE

Internal use

According to clinical studies

- General dose range: liquid extract (1:2): 2–6 mL/day.
- Diabetes: 50–100 g seed daily taken in divided doses with meals, or 1 g/day ethanolic seed extract.
- Lipid-lowering activity: according to the above studies, 18.0 g germinated fenugreek or 100 g defatted seeds daily taken in divided doses with meals.

External use

- As a poultice: 50 g powdered seed in 0.5–1 L hot water applied topically to affected area.

TOXICITY

Safety studies indicate that fenugreek is extremely safe. When consumed as 20% of the diet, it did not produce toxic effects in animal tests.

ADVERSE REACTIONS

One clinical study found that a dose of 50 g taken twice daily produced mild gastrointestinal symptoms, such as diarrhoea and flatulence, which subsided after 3–4 days. Allergic reactions have been reported, more usually a consequence of

cross-reactivity in patients with peanut allergy. Primary fenugreek allergy is rare (Faeste et al 2009). Rats fed a diet of 30% fenugreek seeds exhibited antifertility effects to the point of toxicity (Kassem et al 2006). Proportional doses in humans would be near impossible to administer.

SIGNIFICANT INTERACTIONS

Where controlled studies are not available, interactions are speculative and based on evidence of pharmacological activity and case reports.

Hypoglycaemic agents

Additive effects are theoretically possible in diabetes and drug dose reductions may be required in some patients — monitor serum glucose levels closely — potentially beneficial interaction.

Iron

Frequent use of fenugreek can inhibit iron absorption — separate doses by 2 hours.

Warfarin

Although there is a theoretical concern that concomitant use could increase bleeding risk due to the herb's coumarin content, this is unlikely. A placebo-controlled study found that fenugreek does not affect platelet aggregation, fibrinolytic activity or fibrinogen (Bordia et al 1997).

CONTRAINDICATIONS AND PRECAUTIONS

Fenugreek is contraindicated in people with allergy to the herb, which has been observed in several case reports (Patil et al 1997), or those with allergy to chickpeas, because of possible cross-reactivity (Ulbricht & Basch 2005). Monitor patients with thyrotoxicosis when using this herb at doses above usual dietary intake.

PREGNANCY USE

When taken in usual dietary amounts, fenugreek is likely to be safe; however, the safety of larger doses has not been scientifically evaluated.

PRACTICE POINTS/PATIENT COUNSELLING

- Fenugreek's seeds and leaves are used not only as food but also as an ingredient in traditional medicine systems.
- Clinical studies have identified significant hypoglycaemic and lipid-lowering activity; however, dosage forms and treatment regimens varied.
- In animal studies, fenugreek has been shown to exert immunostimulant, anti-inflammatory and antinociceptive activity, stimulate digestive enzyme production and provide significant antiulcerogenic effects.
- In practice, it is used to manage blood sugar levels in patients with diabetes, to lower cholesterol levels, to provide symptom relief in dyspepsia and to promote lactation.
- Externally it is made into a poultice with hot water and used as an anti-inflammatory application.

PATIENTS' FAQs

What will this herb do for me?

Fenugreek can lower blood sugar levels in patients with diabetes, reduce cholesterol levels and stimulate digestion. It may also protect the gastrointestinal tract from ulcers, stimulate immune function and provide anti-inflammatory and antipyretic effects. Traditionally, it has also been used to promote lactation.

When will it start to work?

Studies suggest that blood sugar effects can be seen within 10 days in type 1 diabetes, whereas lipid-lowering effects can take up to 3 months to establish. Traditionally, digestive effects are thought to occur soon after ingestion of the seeds.

Are there any safety issues?

Used as a food, fenugreek appears extremely safe but may interact with blood-thinning medicines. When used in high doses as a medicine, it may cause flatulence, diarrhoea and mild stomach discomfort. Allergies to fenugreek are possible. When used with diabetic medicine, it may increase sugar-lowering activity and safety should be monitored.

Feverfew

HISTORICAL NOTE Feverfew has been used for centuries in Europe to treat headaches, arthritis and fever and used as an emmenagogue and anthelmintic agent. In the 1970s, it was 'rediscovered' by the medical establishment and subjected to clinical studies, which produced encouraging results that suggested feverfew was an effective prophylactic medicine for migraine headache.

OTHER NAMES
Altamisa, bachelor's button, camomile grande, featherfew, featherfoil, chrysanthemum parthenium, mutterkraut, matrem, tanaceti parthenii herba/folium

BOTANICAL NAME/FAMILY
Tanacetum parthenium (family [Asteraceae] Compositae)

PLANT PART USED
Leaf

CHEMICAL COMPONENTS
The leaves and flowering tops contain many monoterpenes and sesquiterpenes as well as sesquiterpene lactones (chrysanthemolide, chrysanthemonin, 10-epi-canin, magnoliolide and parthenolide), reynosin, santamarin, tanaparthins and other compounds. Until recently, the sesquiterpene lactone parthenolide was thought to be the major biologically active constituent. However, in vitro and in vivo research suggests that others are also present (Brown et al 1997, Pugh & Sambo 1988).

MAIN ACTIONS

Anti-inflammatory and analgesic
Several in vivo studies have identified anti-inflammatory and antinociceptive activity for feverfew extracts and parthenolide. When feverfew extracts were orally administered, or pure parthenolide was injected IP, significant dose-dependent, anti-inflammatory and antinociceptive effects were observed in animal models (Jain & Kulkarni 1999). Similarly, when feverfew extracts and parthenolide from *Tanacetum vulgare* was administered orally in a rat model, gastric ulcer index was significantly reduced (Tournier et al 1999).

The mechanisms responsible for these effects are not well elucidated. Jain and Kulkarni (1999) demonstrated that the antinociceptive effect was not mediated through the opiate pathway and was not associated with sedation. With regard to the anti-inflammatory effect, several mechanisms appear to be responsible.

Clinical note — Natural variations in parthenolide content
The amount of parthenolide present in commercial preparations of feverfew leaves varies significantly, with some exhibiting levels as high as 1.7% dry weight and others as low as 0.01% to non-detectable (Cutlan et al 2000). The study by Cutlan et al measured the parthenolide content in plants produced from seeds taken from over 30 different sources and germinated under identical conditions. According to this study, feverfew collected from the wild and distributed by botanical gardens or US Department of Agriculture seed banks yielded plants with the highest mean parthenolide value, and plants with yellow leaves also had significantly higher parthenolide levels than those with green leaves.

Two in vitro studies have found evidence of COX and lipoxygenase inhibition (Capasso 1986, Pugh & Sambo 1988), while other tests reveal no effect on COX (Collier et al 1980, Makheja & Bailey 1982). Inhibition of phospholipase A_2 has also been suggested (Heptinstall 1988). Direct binding and inhibition of I-kappa B kinase beta, an important subunit involved in cytokine-mediated signalling, has been demonstrated for parthenolide in test tube studies (Kwok et al 2001). Parthenolide also inhibits NO production, an important regulator and inducer of various inflammatory states (Wong & Menendez 1999). More recently, results from an in vivo study confirm that parthenolide inhibits proinflammatory cytokine responses, although the authors propose that proinflammatory mediators, including chemokines (MIP-2), plasma enzyme mediators (complement, kinin and clotting systems) and lipid mediators (COX, PG, platelet-activating factor) are also likely to be involved (Smolinski & Pestka 2003).

The essential oil constituent of feverfew, chrysanthenyl acetate, inhibits PG synthetase in vitro and also seems to possess analgesic properties (Pugh & Sambo 1988).

Antispasmodic
The results from several in vitro studies generally indicate that feverfew decreases vascular smooth muscle spasm (Barsby et al 1992, 1993a, 1993b, Collier et al 1980).

Inhibits serotonin release and binding
Parthenolide and several other sesquiterpene lactone constituents inhibit serotonin release but do not bind to $5HT_1$ receptors, according to in vivo data (Groenewegen & Heptinstall 1990, Marles et al 1992, Weber et al 1997a). Some tests with $5HT_{2A}$ receptors show parthenolide is a low-affinity antagonist (Weber et al 1997b), whereas other tests found no effect on $5HT_{2A}$ or $5HT_{2B}$ receptors. Feverfew extract potently and directly blocked $5HT_{2A}$ and $5HT_{2B}$ receptors and neuronally released 5HT, suggesting that feverfew powder or extracts are more effective than isolated parthenolide (Mittra et al 2000).

Anticancer activity
In the last five years, there has been increasing investigation into the parthenolide constituent from feverfew as an anticancer agent. It displays multiple mechanisms, which make it an attractive candidate for further cancer research.

Parthenolide has been shown to withdraw cells from cell cycle or to promote cell differentiation, and finally to induce programmed cell death (Pajak et al 2008). It has an ability to induce apoptosis in a variety of cancer lines, has chemosensitising properties and is non-toxic to normal cells. The potent anticancer activity of parthenolide is in part due to its ability to inhibit transcription factor NF-kappaB, thereby reducing survival potential in a number of cancer cells (Anderson & Bejcek 2008, Pajak et al 2008, Zunino et al 2007). The effect is specific to tumour cells. Parthenolide-induced generation of

reactive oxygen species (ROS) in cancer cells has also been shown to play a role in promoting apoptotic cell death. Interestingly, experiments in animal models indicate that in non-cancerous cells, parthenolide acts as an antioxidant molecule by increasing levels of intracellular glutathione resulting in a decrease in ROS. In contrast, an increase in ROS generation in response to parthenolide appears to increase apoptotic cell death in cancer cells.

Parthenolide is cytotoxic to several breast cancer cell lines such as one human cervical cancer cell line (SiHa), prostate tumour-initiating cells isolated from prostate cancer cell lines as well as primary prostate tumour-initiating cells, glioblastoma cells, pre-B acute lymphoblastic leukaemia (ALL) lines (Anderson & Bejcek 2008, Kawasaki et al 2009, Wu et al 2006, Zunino et al 2007).

A comparison of parthenolide treatment with that of the standard chemotherapy drug cytosine arabinoside (Ara-C) found it was much more specific to leukaemia cells (Guzman et al 2005), whereas Ara-C killed both leukaemia cells and normal cells to an equivalent extent; parthenolide showed significantly less toxicity to normal haematopoietic cells from bone marrow and cord blood.

An in vitro and in vivo study of parthenolide in breast cancer found that parthenolide has significant in vivo chemosensitising properties in the metastatic breast cancer setting (Sweeney et al 2005). Parthenolide was effective either alone or in combination with docetaxel in reducing colony formation, inducing apoptosis and reducing the expression of prometastatic genes *IL-8* and the antiapoptotic gene *GADD45beta1* in vitro. In an adjuvant setting, animals treated with parthenolide and docetaxel combination showed significantly enhanced survival compared with untreated animals or animals treated with either drug. The enhanced survival in the combination arm was associated with reduced lung metastases. In addition, nuclear NF-kappaB levels were lower in residual tumours and lung metastasis of animals treated with parthenolide, docetaxel or both.

Studies have now begun with a series of amino-parthenolide analogues, which have been synthesised by a conjugate addition of several primary and secondary amines to the alpha-methylene-gamma-butyrolactone function of the sesquiterpene lactone, parthenolide (Nasim & Crooks 2008).

OTHER ACTIONS

Inhibits platelet aggregation

Evidence is contradictory as to whether feverfew inhibits platelet aggregation. Several test tube studies and animal models have observed inhibition of platelet aggregation (Heptinstall et al 1988, Jain & Kulkarni 1999, Makheja & Bailey 1982). However, no significant effects were seen in a clinical study of 10 patients receiving feverfew (Biggs et al 1982).

Mast cell stabilisation

Tests with rat mast cells indicate that feverfew extract inhibits histamine release, but the mechanism of action is different from cromoglycate and quercetin (Hayes & Foreman 1987). Recent in vivo tests confirm that parthenolide significantly inhibits IgE-antigen-induced mast cell degranulation in a dose-dependent manner (Miyata et al 2008). The formation of microtubules is well known to be crucial for IgE-antigen-induced degranulation in mast cells, and parthenolide exhibits tubulin/microtubule-interfering activity. The mast cell stabilisation effect is rapid in vivo as an immediate-type allergic response was induced in test animals and strongly inhibited by parthenolide administration.

CLINICAL USE

Prophylaxis of migraine headache

Traditionally, feverfew has been used in the treatment and prevention of headaches. Its growing popularity in the UK, in the 1970s and 80s, prompted researchers to investigate its usefulness under controlled trial conditions. The first double-blind study investigating feverfew in migraine prophylaxis was published in 1985 and involved 17 patients who had been chewing fresh feverfew leaves on a daily basis (Johnson et al 1985). Therapeutic effect was maintained when capsules containing freeze-dried feverfew powder were continued, whereas those allocated placebo capsules experienced a significant increase in the frequency and severity of headache, nausea and vomiting during the early months of withdrawal.

Clinical note — Migraine

Migraine is a common episodic familial headache disorder characterised by a combination of headache and neurological, gastrointestinal and autonomic symptoms. It has a 1-year prevalence of approximately 18% in women, 6% in men and 4% in children before puberty (Silberstein 2004). Several underlying mechanisms are considered responsible for the onset of migraine.

One of the genes linked to migraine is associated with dysfunction in P-type neuronal calcium channels, which mediate 5-HT and excitatory neurotransmitter release. This dysfunction can impair release of 5-HT and predispose patients to migraine attacks or impair their self-aborting mechanism (Silberstein 2004). Additionally, NO may be involved in the initiation and maintenance of migraine headache (Ferrari 1998). Migraine aura is now thought to be caused by neuronal dysfunction, not ischaemia, and headache begins while cortical blood flow is reduced.

In clinical practice, the three goals of migraine-preventive therapy are to reduce attack frequency, severity and duration, improve responsiveness to treatment of acute attacks, and improve function and reduce disability. Ultimately, choice of treatment should be based on efficacy, adverse effects and co-existing conditions with a full therapeutic trial taking 2–6 months.

Since then, numerous clinical studies have been conducted to determine the role of feverfew in the prevention of migraine headache.

In 2000, Ernst and Pittler published a systematic review of six randomised, placebo-controlled, double-blind trials of feverfew as a prophylactic treatment and concluded that the current evidence favours feverfew as an effective preventative treatment against migraine headache, and is generally well tolerated.

A more recent Cochrane systematic review of five placebo-controlled, randomised, double-blind trials (n = 343) concluded that there was insufficient evidence to determine whether feverfew was superior to placebo in reducing migraine frequency or incidence, severity of nausea or severity of migraines (Pittler & Ernst 2004). A closer look at the studies reveals that results were mixed, methodological quality varied and various dosage regimens, administration forms and extracts were used. One study used three different dosing regimens for a CO_2 extract, two studies used an alcoholic and CO_2 extract, three studies used dried feverfew leaves for 8–24 weeks and one study used an alcoholic extract for 8 weeks. Interpretation of test results is made even more difficult when one considers the naturally occurring chemical variations among the preparations.

The authors have offered several explanations for the inconsistent clinical findings and point out that previous negative studies used extracts standardised for parthenolide concentration; however, it is possible that other compounds found in whole-leaf preparations may also be important for pharmacological activity. In vivo studies support this view (Mittra et al 2000). Additionally, the negative results obtained by some studies may be due to underdosing.

Since then, positive results were obtained for a CO_2 extract of feverfew in a randomised, double-blind, placebo-controlled, multicentre study of 170 patients (Diener et al 2005). Active treatment with feverfew (MIG-99) at a dose of 6.25 mg, three times daily, significantly reduced the frequency of migraine headache episodes over a 16-week period.

In combination

A number of trials have tested feverfew in combination with other herbs and nutritional supplements. Shrivastava et al (2006) tested a combination of willow bark (600 mg/day) and feverfew (600 mg/day) known as Mig-RL in a 12-week prospective study for the prophylaxis of migraine and shown to significantly reduce attack frequency and severity. The combination was selected because previous in vitro studies identified that feverfew and willow bark inhibit binding to 5-HT(2A/2C) receptors and the combination of willow bark with feverfew further inhibited 5-HT(1D) receptors, whereas feverfew on its own did not. Combination herbal treatment significantly reduced migraine attack frequency by 57.2% at 6 weeks ($P < 0.029$) and by 61.7% at 12 weeks ($P < 0.025$) in nine of 10 patients, with 70% of patients having a reduction of at least 50%. Attack intensity was reduced by 38.7% at 6 weeks ($P < 0.005$) and by 62.6% at 12 weeks ($P < 0.004$) in ten of ten patients, with 70% of patients having a reduction of at least 50%. Attack duration decreased by 67.2% at 6 weeks ($P < 0.001$) and by 76.2% at 12 weeks ($P < 0.001$) in ten of ten patients. Two patients were excluded for reasons unrelated to treatment. Self-assessed general health, physical performance, memory and anxiety also improved by the end of the study. The treatment was well tolerated and no adverse events occurred (Shrivastava et al 2006).

The combination of feverfew with ginger (GelStat Migraine) in a sublingually administered fluid was evaluated as an acute treatment in an open-label study involving 29 patients with 1-year history of migraine meeting International Headache Society (IHS) diagnostic criteria with or without aura, 2–8 migraines per month and ≤15 headache days per month. People ingested the test substance during the early mild headache phase of an oncoming migraine. Herbal treatment was found to totally relieve pain in 48% of people within 2 hours and a further 34% reported pain had remained mild and not worsened. Of the group, 59% were satisfied with their response to GelStat Migraine therapy (Cady et al 2005). Of note, the product is marketed as a homeopathic product and contains extremely small amounts of both herbs.

Feverfew (100 mg) combined with riboflavin (400 mg) and magnesium (300 mg) was compared to stand-alone riboflavin (25 mg) treatment in a randomised, double-blind study of migraine sufferers (Maizels et al 2004). Both treatments showed a significant reduction in number of migraines, migraine days and migraine index in the 3-month trial, which was greater than responses for placebo in other trials of migraine prophylaxis. When treatment responses were compared, no significant differences were seen between the groups indicating that feverfew at this low dose is ineffective.

Arthritic conditions

Although traditionally used as a treatment for inflammatory joint conditions, the results of a randomised, double-blind study involving 41 patients with symptoms of rheumatoid arthritis (RA) found no difference between chopped dried feverfew (70–86 mg) or placebo after 6 weeks' treatment (Pattrick et al 1989).

OTHER USES

Dermatology

Parthenolide-free feverfew extract is being investigated in various dermatological conditions. It protects skin against inflammation and UV-induced damage (Finkey et al 2005) When the parthenolide-free feverfew extract was topically applied, it significantly reduced the loss of cell viability, the increase in proinflammatory mediator release and the induction of DNA damage induced by solar-simulated UV radiation in a human epidermal model. It also exhibited potent antioxidant activity in vitro and has been shown to dismutate superoxide, thereby protecting cells from the pro-oxidant

depletion of endogenous skin antioxidants. In the next phase of testing, a clinical study was conducted with an emollient containing the parthenolide-free feverfew extract, which confirmed that treatment significantly reduced the erythema effects of acute EVB exposure by up to 60% compared to placebo. Assessment was done by a blinded clinical grader and a chromameter. These results suggest that topical application of parthenolide-depleted feverfew extract can protect skin from UV-induced damage and from oxidative damage and help to repair damaged DNA.

Oncology

Parthenolide has demonstrated potent antitumour activity in a variety of experimental models (in vitro and in vivo), and its mechanisms of action are becoming better elucidated. The positive results obtained in these preliminary studies indicate that it may have potential in the treatment of cancer; however, no clinical studies have been published to date to determine its efficacy in humans.

Traditional use

Feverfew has been used traditionally to treat coughs and colds, fevers, atonic dyspepsia, worm infestation, menstrual disorders, nervous debility, joint pain and headaches. It has also been used to promote expulsion of the placenta after childbirth.

DOSAGE RANGE

- Dried leaf: 50–200 mg daily.
- Fresh plant tincture (1:1): 0.7–2.0 mL/day.
- Dried plant tincture (1:5): 1–3 mL/day.
- Prevention of migraine headaches (based on clinical studies): 125–600 mg/day of powder, standardised to contain a minimum parthenolide content of 0.2%, or 400 microgram, which should be taken for at least 4 months. It is still controversial as to whether standardised extracts are best for migraine prophylaxis or not.

TOXICITY

Unknown, although no major safety issues have been identified (Ernst & Pittler 2000).

ADVERSE REACTIONS

According to a Cochrane systematic review of five studies (Pittler & Ernst 2004), feverfew is well tolerated and adverse events are generally mild and reversible. Symptoms were most frequently reported by long-term users and were predominantly mouth ulceration and gastrointestinal symptoms. Contact dermatitis, mouth soreness and lip swelling have also been reported when leaves are chewed. People allergic to the Compositae family of plant, or feverfew in particular, should avoid feverfew products that contain parthenolide, as it is this component which is thought to be the main inducer of the allergic response (Sharma & Sethuraman 2007).

SIGNIFICANT INTERACTIONS

Controlled studies are not available; therefore, interactions are based on evidence of activity and are largely theoretical and speculative.

Anticoagulants

Theoretically, feverfew may increase bruising and bleeding; however, although feverfew inhibits platelet aggregation in vitro and in vivo, no effects were seen in a clinical study (Biggs et al 1982) — observe patients taking this combination.

CONTRAINDICATIONS AND PRECAUTIONS

Hypersensitivity to plants in the Asteraceae (Compositae) (daisy) family (e.g. chamomile, ragweed).

PREGNANCY USE

Contraindicated in pregnancy. An in vitro and in vivo preliminary screen using a rat model suggested that feverfew consumption may have detrimental effects in pregnancy, a finding which needs to be more fully explored in a larger study (Yao et al 2006). Feverfew-treated animals had reduced litter sizes, a greater proportion of smaller fetuses than the control group and increased preimplantation loss indicating maternal and embryonic effects. However, it should be noted that the doses used were 59 times the accepted human dose, and therefore the clinical relevance of the findings are unclear. A full reproductive toxicity study is warranted to determine whether the observed effects are clinically significant.

PRACTICE POINTS/PATIENT COUNSELLING

- Although early studies were positive and showed a preventative effect for migraine headache, not all studies have been positive, which may be related to variations in preparations and dosing. Further research is required to determine its place in practice for this indication.
- Of the studies that have produced positive results for migraine therapy, feverfew reduced severity of symptoms such as vomiting and visual disturbances, but did not alter the duration of an episode.
- Tincture or solid-dose preparations may be better tolerated than chewing the fresh leaves, which have been associated with mouth ulcers and lip swelling in some individuals.
- Traditionally, feverfew has also been used to treat coughs and colds, fevers, atonic dyspepsia, worm infestation, menstrual disorders, nervous debility, joint pain and headaches.
  - Parthenolide-free feverfew shows promise as a dermatological and UV protective agent when used topically.
  - Many preliminary studies with parthenolide confirm that it has potent antitumour activity; however, it has not yet been tested in humans.
- Use is contraindicated in pregnancy.

PATIENTS' FAQs

What will this herb do for me?

Some evidence suggests that feverfew may reduce the frequency and severity of migraine headaches; however, test results are inconsistent. Topical application with parthenolide-free feverfew cream shows promise as a dermatological preparation to

reduce redness after sun exposure and help heal damaged skin.

When will it start to work?

Of those studies producing positive results, it appears that approximately 4 months' continual use may be required; however, in practice, some patients experience benefits within the first 4 weeks.

Are there any safety issues?

Feverfew should not be used in pregnancy or by people with Compositae allergy.

Fish oils

BACKGROUND AND RELEVANT PHARMACOKINETICS

One of the two human essential fatty acids (EFA) is alpha-linolenic acid (ALA or 18:3n-3), which, due to the position of its first double bond, is classified as an omega-3 essential fatty acid (n-3 EFA). Although mammals have the ability to introduce double bonds into most positions of the fatty acid chain in fat metabolism, therefore producing various unsaturated metabolites, they lack the capacity to insert double bonds at the n-3 and n-6 positions. Consequently, linoleic acid (LA) and alpha-linolenic acid (ALA), which already have the double bond at the n-3 or n-6 position, respectively, are considered essential and must be consumed in the diet. When the EFAs are consumed in this precursor state they follow a pathway of further elongation and desaturation via the action of delta-6- and delta-5-desaturase until they form the 'active' fatty acids: eicosapentaenoic acid (20:5n-3) (EPA) and docosahexaenoic acid (DHA) (22:6n-3), also referred to as the omega 3 long chain polyunsaturated fats (n-3 LCPUFAs).

Fish oils, also known as marine oils, are rapidly absorbed from the gastrointestinal tract and compete with arachidonic acid (AA) for incorporation into phospholipids, particularly of platelets, erythrocytes, neutrophils, monocytes and liver cells (Simopoulos 1999). When stimulated, the cell membranes release polyunsaturated fatty acids (PUFAs), which are then converted into 20-carbon eicosanoids, which have profound and extensive physiological effects. The most active of these metabolites are prostaglandins, prostacyclins and thromboxanes, which affect blood chemistry, muscle contraction, immune function and inflammation. Dietary fats not used in this way are stored in adipose tissue and ultimately oxidised to produce energy. The FA cell membrane profile of different tissues will have varying ratios of EPA and DHA, but generally DHA is considered the major component of phospholipids in the retina, brain, male reproductive tissue and myocardium (Groff & Gropper 2004).

Supplements based on fish liver oils, such as cod and halibut, contain EPA and DHA together with high levels of vitamins A and D. As such, they have additional actions and safety issues, besides those found with traditional marine lipid supplements. This review will focus on the research surrounding those fish oils that are not liver extractions.

CHEMICAL COMPONENTS

Dietary fish contains a number of nutrients important for health, such as several B vitamins, vitamin E, calcium, magnesium and potassium and are an excellent source of protein with a low saturated fat content. Importantly, they also contain the two PUFAs: EPA and DHA. EPA has 20 carbon atoms and 5 double bonds, and DHA has 22 carbon atoms and 6 double bonds. Both are derived from ALA and are considered conditionally essential. The EPA and DHA found in whole fish are predominantly esterified in the *sn*-2 position of triacylglycerols and glyercophospholipids; however, when found in supplements, most commonly exist as ethyl esters (Visioli et al 2003). This minor chemical distinction may explain the speculated superior bioavailability of these fats when derived from the diet as opposed to supplements.

Clinical note — Are ALA-rich oils a worthy substitute for fish oils?

Both EPA and DHA are derived from ALA, so food sources containing ALA are seen as indirect dietary sources. ALA is commonly found in non-hydrogenated canola oil, linseed oil, soybean oil, flaxseed, pumpkin and walnuts. Studies investigating the effects of ALA supplementation have not consistently produced the same positive results as for fish oils, most likely due to inefficient conversion of ALA into EPA and DHA. This is reportedly poor in healthy individuals, with only 5–10% of ALA converted to EPA and 2–5% of ALA converted to DHA (Davis & Kris-Etherton 2003). Consequently, the few foods that contain both EPA and DHA in their preformed state offer a significant advantage over other sources. The most concentrated dietary source of both EPA and DHA is fish oil. (See Flaxseed monograph for further information.)

FOOD SOURCES

Most dietary EPA and DHA are consumed in the form of fish or seafood. Deep sea cold water fish, such as salmon, mackerel, halibut and herring, provide the most concentrated sources. Current Australian estimates of intake indicate inadequate consumption according to WHO standards (Meyer et al 2003).

DEFICIENCY SIGNS AND SYMPTOMS

Based on epidemiological studies, the low levels of n-3 LCPUFAs are associated with:

- fetal alcohol syndrome (DHA) (Horrocks & Yeo 1999)
- attention deficit hyperactivity disorder (DHA) (Horrocks & Yeo 1999)
- learning deficits (DHA) (Horrocks & Yeo 1999)
- cystic fibrosis (DHA) (Horrocks & Yeo 1999)
- phenylketonuria (DHA) (Horrocks & Yeo 1999)
- cardiovascular disease, including an increased risk of sudden death due to heart disease (Siscovick et al 2003).
- inflammatory disorders
- rheumatoid arthritis (Navarro et al 2000)
- unipolar depression (DHA) (Horrocks & Yeo 1999)
- senile dementia

In addition to these symptoms, lack of dietary EFAs has been implicated in the development or aggravation of numerous diseases such as breast

cancer, prostate cancer, RA, asthma, preeclampsia, depression and schizophrenia (Yehuda et al 2005).

Primary deficiency

Full-term babies fed a skim milk formula low in ALA are at risk of primary deficiency. In the past, patients fed long-term with fat-free TPN solutions were at risk, but fat emulsions are now in general use and prevent deficiency. Studies have demonstrated lower plasma levels of EPA and DHA in vegetarians and vegans, suggesting they may be at risk of deficiency; however, the findings of a recent cross-sectional study comparing the dietary intakes and plasma levels of 196 meat-eating, 231 vegetarian and 232 vegan men in the United Kingdom did not suggest that there is cause for alarm (Rosell et al 2005). Vegans and vegetarians had significantly lower levels of these fatty acids; however, they remained steady and there is evidence of some conversion of ALA into EPA and DHA.

There is much discussion regarding the inadequate intake of EPA and DHA generally in the Western diet. Recent Australian data, based on dietary intake records from the 1995 National Nutrition Survey, have estimated the average daily intake of EPA and DHA to be 0.008 g and 0.015 g, respectively. If correct, this indicates that the majority of Australians are failing to meet recommended amounts (Meyer et al 2003).

Secondary deficiency

People with fat malabsorption syndromes, serious trauma or burns are at risk of reduced PUFA levels (Beers et al 2003). A secondary deficiency may also manifest as a result of abnormal or compromised activity of the delta-6 and delta-5 desaturase enzymes, for example in diabetics, patients with a variety of metabolic disorders and individuals with increased dietary saturated fats and *trans* fatty acids, alcoholics and the elderly (Davis & Kris-Etherton 2003, Houston 2005).

MAIN ACTIONS

As precursors of eicosanoids, PUFAs found in fish oils exert a wide influence over many important physiological processes.

Cardiovascular effects

Fish oils exert myriad different effects on the heart and vessels, demonstrated in both experimental models and human studies. It is speculated that the clinical effects attributed to n-3 PUFA are due to the summation of many small pharmacological effects, adding up to a larger protective effect on mortality and/or cardiovascular events.

Prevent malignant cardiac arrhythmias

Dietary fish or fish oil intake has been shown to prevent cardiac arrhythmias and associated sudden death in numerous animal studies (Billman et al 1997, 1999, Kang & Leaf 1996, 2000, McLennan et al 1988, 1990), in vitro and more recently human clinical trials (Jung et al 2008). This has been achieved using intakes below those required to alter plasma lipids or blood pressure. It appears that the myocardial membrane phospholipid content increases in DHA but not always EPA, with fish intake. The preferential accumulation of DHA affords protection against ventricular fibrillation induced under a variety of conditions such as ischaemia and reperfusion (McLennan 2001).

Inadequate DHA in myocyte membranes has been reported to be associated with altered sodium, calcium and potassium ion channel functions, mitochondrial function and increased arrhythmia susceptibility with an increased prevalence of sudden cardiac death (Jung et al 2008, Siscovick et al 2003). One in vivo study suggests that fish oils electrically stabilise myocytes, increasing the electrical impulse required to produce an action potential by approximately 50% and prolonging the refractory time by 150% (Kang & Leaf 2000).

Triglyceride (TG)-lowering activity

Fish oil supplements effectively reduce TG levels as demonstrated in human studies. This is of particular interest, given only moderate elevations in TG levels have been associated with a progressively increased risk of ischaemic heart disease, independent of other major risk factors, including HDL cholesterol (Jeppesen et al 1998).

Lipoprotein effects

Both n-6 and n-3 LCPUFAs can inhibit the expression of genes involved in fatty acid and TG synthesis (Jung et al 2008). Dietary n-3 LCPUFAs, in particular, and their metabolites, through this mechanism are reported to increase beta-oxidation and inhibit adipogenesis. Ultimately, this may result in reduced substrate for TG synthesis and thus explain n-3 PUFAs' profound TG-lowering effects.

Concerns raised previously about increased LCPUFAs in lipoproteins increasing the susceptibility to oxidation of the LDLs have recently been moderated, with a demonstrable difference between EPA and DHA. While increased levels of EPA (4.8 g/day) did increase the LDL susceptibility to damage, DHA supplementation (4.9 g/day) had no effect on the oxidation process (Mesa et al 2004). Concurrent supplementation with antioxidants however appears prudent with high doses of n-3 PUFAs.

Improved endothelial function

Studies have indicated that fish oils can improve endothelial relaxation by enhancing NO- and non-NO-induced vasodilatation (Holub 2002).

A double-blind study conducted by Mori et al (2000) showed that relative to placebo, DHA, but not EPA, enhances vasodilator mechanisms and attenuates constrictor responses in forearm microcirculation.

Reduce blood pressure

Two meta-analyses have concluded that fish oils exert a significant blood pressure-lowering effect in hypertensive people; however, the effects can only be described as modest, between 2 and 5 mmHg (Geleijnse et al 2002, Morris et al 1993). Hypotensive activity appears to be dose-dependent

Clinical interest — Do fish oil supplements cause bleeding?

A search through Medline reveals several case reports where bleeding episodes are attributed to fish oil ingestion (Buckley et al 2004, Jalili & Dehpour 2007, McClaskey & Michalets 2007). In each case, the person affected was elderly and also taking warfarin. One was a report of an elderly man taking high-dose omega-3 fatty acids (6 g/day) with both aspirin and warfarin who developed a subdural haematoma after a minor fall (McClaskey & Michalets 2007). Another case is reported of a 67-year-old woman taking warfarin for 1.5 years who doubled the fish oil dose from 1000 to 2000 mg/day causing an associated elevation in INR from 2.8 to 4.3 within 1 month (Buckley et al 2004). A third case was of a 65-year-old male who had been taking warfarin for 6 months and then was recommended trazodone and fish oils causing his INR to rise to 8.06 (Jalili & Dehpour 2007).

Although these case reports would lead us to believe that omega-3 fatty acids interact with warfarin and increase the risk of bleeding, several intervention studies have come to a different conclusion. One randomised study of 511 patients taking either aspirin (300 mg/day) or warfarin (INR aimed at 2.5–4.2) found that a dose of 4 g/day of fish oils did not increase the number of bleeding episodes, bleeding time or any parameters of coagulation and fibrinolysis (Eritsland et al 1995). A smaller placebo-controlled study by Bender et al of patients receiving chronic warfarin therapy found that fish oils doses of 3–6 g/day produced no statistically significant difference in INRs between the placebo lead-in and treatment period within each group. There was also no difference in INRs between groups (Bender et al 1998).

Most recently, Harris examined 19 clinical studies which used doses of fish oils varying from 1 g/day to 21 g/day in patients undergoing major vascular surgery (coronary artery bypass grafting, endarterectomy) or femoral artery puncture for either diagnostic cardiac catheterisation or percutaneous transluminal coronary angioplasty (Harris 2007). Of note, in 16 studies patients were taking aspirin and in three studies patients were taking heparin. The review concluded that the risk for bleeding was virtually non-existent. Frequent comments accompanying the studies were 'no difference in clinically significant bleeding noted' or 'no patient suffered from bleeding complications'. The same conclusion was reached in a 2008 review which stated no published studies have reported clinically significant bleeding episodes amongst patients treated with antiplatelet drugs and fish oils (3–7 g/day) (Harris et al 2008).

Overall, when we consider the body of evidence available regarding omega-3 fatty acid supplementation, it is clear that the benefits for cardioprotection far outweigh the risk of bleeding. This not only applies to patients taking aspirin but also those patients about to undergo coronary artery bypass surgery or percutaneous transluminal coronary angioplasty. Whilst the evidence suggests that fish oils in low to moderate doses do not increase bleeding risk with warfarin, a general caution should still apply to patients taking high doses.

and DHA may have greater effect than EPA. Alternately, a 2006 Cochrane review found no significant changes to SBP or DBP with n-3 LCPUFAs consumption (Hooper et al 2006). The review assessed studies that used both plant- and fish-based n-3 fatty acids, dietary sources and supplements.

While the mechanism is unknown, current theories include EPA stimulation of prostacyclin synthesis and increased NO production — both vasodilators. An additional action may be improved autonomic nervous system function, and inhibition of the adrenal activation (Din et al 2004, Ross 2005); however, these are inconsistent with the attribution of action to DHA. In addition to the actions improving endothelial function generally, other posited mechanisms for a hypotensive effect include: blunting of the rennin–angiotensin–aldosterone system via reduced adrenal aldosterone synthesis, altered arachidonic acid metabolism, modulation of calcium release and influx into vascular smooth muscle cells and activation of vascular adenosine triphosphate (ATP)-sensitive potassium channels (Jung et al 2008).

Reduce and possibly reverse atherogenesis

Omega-3 fatty acids alter eicosanoid synthesis and inhibit smooth muscle cell proliferation, suggesting a role in reducing atherosclerotic development (Holub 2002). One controlled study demonstrated that fish oil ingestion had a clinically significant influence on atherosclerosis (von Schacky et al 2001). This randomised, double-blind study of 223 patients found that a dose of 1.5 g n-3 fatty acids reduced progression and increased regression of established coronary artery disease as assessed by coronary angiography.

Antithrombotic and antiplatelet

Dietary n-3 PUFAs enhance anti-aggregatory and anti-adhesive platelet activity by inducing increased production of prostacyclin I_3 and suppressing synthesis of the chemotactic platelet adhesion-promoting substances, leukotriene B4 and thromboxane A_2 (Jung et al 2008, Kinsella 1987). Independent of this, n-3 LCPUFAs reduce levels of several coagulating factors (e.g. VII and X, and fibrinogen) (Jung et al 2008).

In animal models of arterial thrombosis, fish oil-enriched diets have been shown to have an antithrombotic effect; however, there is evidence suggesting that this is most likely to occur when associated with reduced saturated fat intake (Hornstra 1989).

Clinical observations of Eskimos have found lowered platelet counts, inhibition of platelet aggregation and prolonged bleeding times compared

with age- and sex-matched Danes. However, intervention studies using fish oil supplements have produced conflicting results (Hellsten et al 1993, Kristensen et al 1989, Radack et al 1990) and more recently, a review of clinical studies concluded that there was no clinically significant effect on bleeding with usual therapeutic doses (Harris 2007).

Anti-inflammatory

Fish oils induce a series of chemical changes in the body that ultimately exert an anti-inflammatory action. They partially replace AA in inflammatory cell membranes, and compete with it for the enzymes cyclo-oxygenase (COX) and lipoxygenase (LOX), leading to reduced production of proinflammatory metabolites such as 2-series PGs and 4-series leukotrienes (Calder 2002, 2003, Cleland et al 2003).

Besides this, n-3 PUFAs suppress the production of proinflammatory cytokines, and reduce the expression of cell adhesion molecules, critical in recruiting circulating leucocytes to the vascular endothelium (Calder 2002, Din et al 2004). According to new research, it appears that anti-inflammatory activity may vary among different sources of fish oils due to variations in EPA/DHA content (Bhattacharya et al 2006).

Neurological effects

Fatty acids are major components of the brain and are found in high concentrations in two structural components: the neuronal membrane and the myelin sheath. About 50% of the neuronal membrane is composed of fatty acids (1/3 from n-3 LCPUFAs), while in the myelin sheath lipids constitute about 70% (Yehuda et al 2005). The lipid component has a relatively high turnover, in contrast to the protein component, which is fundamentally stable.

Omega-3 fatty acids play an active role in neuronal membrane function, fluidity and control of neuronal growth factors. They also potentially influence each step in biogenic amine function, including neurotransmitter synthesis, degradation, release, reuptake and binding (Bruinsma & Taren 2000). Studies indicate that dietary PUFAs may influence noradrenergic and serotonergic neurotransmission and receptor function in the nervous system and, thereby, have a direct effect on function, mood and behaviour. Other actions at the neuronal cell membrane include suppression of the phosphatidyl-associated signal transduction pathways, blocking of the calcium ion influx through L-calcium channels and direct inhibition of protein kinase C, which are similar actions to those exhibited by pharmaceutical mood stabilisers.

Prenatal and postnatal neurological development

DHA plays an important, if not critical, role in the growth and functional development of the brain during the third trimester and the early postnatal period when maximal growth occurs (Horrocks & Yeo 1999). Given that 15% of brain growth occurs during infancy, much attention has been paid to the consequences of variable n-3 levels during late pregnancy and early infancy. It also plays an important role in retinal development, where DHA constitutes 60% of total PUFAs.

Chemopreventative effects

Marine fatty acids, particularly EPA and DHA, have been consistently shown to inhibit the proliferation of breast and prostate cancer cell lines in vitro and to reduce the risk and progression of these tumours in animal experiments (Bagga et al 2002, Terry et al 2003). Similar effects have also been observed for colorectal and prostate cancers (Calder et al 1998, Llor et al 2003, Stoll 2002).

Chemopreventative actions demonstrated by n-3 LCPUFAs include suppression of neoplastic transformation, cell growth inhibition and enhanced apoptosis and anti-angiogenicity (Rose & Connolly 1999). The proposed mechanisms for these are extensive, including the suppression of n-6 eicosanoid synthesis; influences on transcription factor activity, gene expression, and signal transduction pathways; effects on oestrogen metabolism; increased or decreased production of free radicals and reactive oxygen species, and influences on both insulin sensitivity and membrane fluidity (Larsson et al 2004). Ongoing research is attempting to elucidate the specific chemopreventative mechanisms of fish oils with the individual cancer cell lines.

CLINICAL USE

Thousands of studies have been conducted in various populations to determine the clinical consequences of regular fish consumption or fish oil supplementation. Some have focused on n-3 fatty acids intake as a whole and included both vegetable and marine-based sources; however, in light of the lack of bioequivalence and clinical efficacy between the n-3 precursors (e.g. ALA) and their long chain derivatives (e.g. EPA/DHA), the results of these studies are likely to be confounded. Similarly, early study designs investigating the effects of n-3 PUFAs often produced inconsistent results due to improper placebo selection (e.g. olive oil). While these oils were considered at the time to be inert, our progressive understanding of EFA metabolism attributes such 'placebos' with actions of their own, again confounding the results (Pizzorno & Murray 2006). It is important to note that few studies or reviews have also considered the effect of variations in n-3:n-6 ratio which may be important.

Prevention of morbidity and mortality of cardiovascular disease

For over 25 years, fish and fish oils have been linked to cardiovascular health. This association was first recognised when significantly lower death rates from acute myocardial infarction (MI) were found among Greenland's Inuit population, despite only moderate differences between the Inuits' blood cholesterol levels and those of other populations (Holub 2002). A high dietary n-3 LCPUFAs intake in the form of marine mammals (seal, whale) and various fish were thought to be responsible for the protective effect (Bang et al 1980). In 1989, results from the first large, randomised, clinical trial investigating the effects of fatty fish consumption

on survival and risk of secondary MI confirmed a link to cardiovascular health (Burr et al 1989). The Diet and Reinfarction study (DART) found that a modest intake of 2–3 portions weekly of fatty fish reduced mortality in men who had previously experienced a MI and produced a relative reduction in total mortality of 29% during the 2-year follow-up, attributed mainly to a reduction in deaths from coronary heart disease (CHD). Increased consumption of fish (RR = 0.66 for five or more times per week) was further confirmed in the Nurses Study as significantly reducing risk in both CHD and CHD-related mortality independent of the cardiovascular status (Hu et al 2002).

Various epidemiological trials and intervention studies have also been conducted to investigate the association between fish consumption and CVD and whether similar or superior effects could be obtained with concentrated fish oil supplements. Overall, epidemiological and interventional approaches have clearly demonstrated that individuals with a diet rich in fish (30–35 g/day) or supplemented with EPA and DHA (up to 665 mg/day) show a 30–50% reduction in CHD and CHD-related mortality compared to individuals who did not eat fish (Russo 2009). It appears that whilst primary CVD prevention occurs, secondary prevention effects are more notable.

Not surprisingly, in 2004, the FDA reported that it would allow products containing omega-3 fatty acids to claim that eating the product may reduce the risk of heart disease. The FDA based its decision on the wealth of scientific evidence that suggests a correlation between omega-3 fatty acids such as EPA and docosahexaenoic acid and a reduced risk of coronary artery disease (CAD). The FDA subsequently approved omega-3 fatty acids as a treatment to reduce plasma TGs (Frishman et al 2009).

The largest study is known as the GISSI trial, which involved 11,324 survivors of MI, demonstrating that a low-dose fish oil supplement significantly reduced the risk of all-cause death, non-fatal MI and non-fatal stroke (Stone 2000). This study was re-analysed and subsequently published again in 2002 (Marchioli et al 2002). This time it specifically showed that the reduction in risk of sudden cardiac death was nearly significant at 3 months, accounting for 67% of the overall mortality benefit, became significant at 4 months, and was highly significant at 3.5 years, the end of the study, when it accounted for 59% of the n-3 PUFA advantage in mortality. The reduction observed in all-cause mortality and in cardiovascular mortality resulted mainly from the prevention of sudden cardiac death by the n-3 LCPUFAs.

Meta-analyses

In 2002, a high-quality systematic review of 11 RCTs on the effect of fish-based dietary or supplemental omega-3 fatty acids on cardiovascular morbidity and mortality in people with CHD found a strongly significant benefit (Bucher et al 2002); however, a 2006 Cochrane review came to a different conclusion (Hooper et al 2006). The review assessed 48 studies that compared at least 6 months of omega-3 fats (vegetable- and fish-based) with placebo or control and used data involving 36,913 participants. Meta-analysis of the studies assessing the effects of increased omega-3 fats on total mortality or combined cardiovascular events found strongly significant statistical heterogeneity. When randomised studies considered to be at medium or high risk of bias were removed, there was no significant effect of omega-3 fats on total mortality; the relative risk was 0.87 (95% confidence interval 0.73 to 1.03, with significant heterogeneity), whereas the cohort studies suggested significant protection, the relative risk was 0.65 (95% confidence interval 0.48 to 0.88, no significant heterogeneity).

It is important to note that until the publication of the DART-2 trial in 2003 (Burr et al 2003), the evidence showed that omega-3 from oily fish or supplements reduced the risks of fatal MI, sudden death and overall mortality among people with existing disease. Inclusion of the DART-2 trial in the Cochrane review had a major influence on the conclusion, as removing it produced relative risks similar to those in the Bucher review (fatal MI: RR 0.70, 95% confidence interval 0.54 to 0.91; sudden death: RR 0.68, 95% confidence interval 0.42 to 1.10; overall mortality: RR 0.83 (95% confidence interval 0.75 to 0.91). The DART-2 trial included 3114 men with stable angina and tested the hypothesis that the main benefit of omega-3 fat is derived from its anti-arrhythmic action in the presence of chronic disease. Surprisingly, it did not confirm this, showing an excess of sudden and total cardiac deaths most clearly in participants taking fish oil capsules rather than eating oily fish. Authors of the Cochrane review report that something about the DART-2 study is different from the other included studies; however, further investigation has failed to clarify the issue. It is possible that, based on this latest review, the effect of omega-3 fats on CVD is smaller than previously thought or that effects in people who have had a MI are protective, but the effects in men with angina and no MI are not.

Congestive heart failure

In 2005, an association between the consumption of tuna or other broiled or baked fish (but not fried) and lower incidence of CHF was observed among older adults (Mozaffarian et al 2005). In 2008, a large, placebo-controlled trial in patients with CHF (GISSI-HF) demonstrated that the use of 1 g of omega-3 essential fatty acids was associated with a statistically significant 9% reduction in all-cause mortality (Tavazzi et al 2008). The double-blind study involved patients (n = 6975) with chronic heart failure of New York Heart Association class II–IV.

Patients with implantable cardioverter defibrillators (ICDs)

Patients with ICDs administered 2.6 g/day of combined EPA and DHA in one study demonstrated significantly increased time to first ICD event for ventricular tachycardia, fibrillation or death (Jung et al 2008). However, not all studies have produced such positive results, with some suggesting that the n-3 LCPUFAs are ineffective in this patient group (Jenkins et al 2008, Nair & Connolly 2008).

Clinical note — The n-3:n-6 balance: implications in cardiovascular disease and cancer

In recent years, attention has been drawn to the importance of not only n-3 fatty acid intake but also its relation to concurrent n-6 fatty acid intake (Simopoulos 2008). When there is increased n-3 LCPUFAs in the diet and in our bodies, a shift in AA metabolism occurs, which results in the production of metabolites that have beneficial effects on cardiovascular physiology and cancer incidence and promotion (Leaf 2002). For example, when EPA is available to compete with AA, production of thromboxane A2 (a potent vasoconstrictor and platelet activator) is reduced and production of thromboxane B3 results, which is only weakly active. Additionally, several forms of research implicate n-6 PUFAs as stimulating processes that promote human cancer development and progression, whereas n-3 LCPUFAs have the opposite effect (Weisburger 1997). Once again, competition with AA is thought to be involved, although several other protective mechanisms have also been identified. Overall, it seems that in order to obtain maximal cardiovascular and chemopreventative benefits, intake of n-3 LCPUFAs should be increased and intake of n-6 PUFAs must be reduced.

It has been estimated that the ratio of n-6 to n-3 essential fatty acids in the Western diet is some 15:1 to 20:1 or higher, whereas the optimal ratio appears to be closer to 2:1 or 1:1 (Leaf 2002, Simopoulos 1999, 2008).

Elevated TG levels

DHA and EPA supplementation significantly reduces TG levels in both normo- and hyperlipidaemic individuals and is used as sole therapy in cases of elevation or as adjunctive therapy with cholesterol-lowering medication when indicated. Omega-3 LCPUFAs reduce TG concentrations in a dose-dependent manner, with intakes approximating 4 g/day lowering serum TGs by 25–30% in patients hyperlipidaemic at baseline (Balk et al 2006, Din et al 2004, Jung et al 2008). Recently, studies have emerged using n-3 LCPUFA in combination with statins for the treatment of hyperlipidaemia (Barter & Ginsberg 2008). While LDL reduction is the primary target of statins, fish oil co-supplementation both enhances this action and produces additional beneficial changes in other lipid parameters (e.g. HDL, TGs and lipoprotein particle size).

Overall, it appears that the smallest amount of n-3 LCPUFAs required to lower serum TG levels significantly is approximately 1 g/day, as provided by a fish diet, or as little as 0.21 g EPA and 0.12 g DHA/day for those with hyperlipidaemia (Weber & Raederstorff 2000).

Hypertension

According to two meta-analyses, fish oils have a significant but modest dose-dependent effect on blood pressure in hypertension (Geleijnse et al 2002, Morris et al 1993). The DHA component is likely to have stronger effects than EPA. In contrast, a 2006 Cochrane review found no significant changes to SBP or DBP with n-3 EFA consumption of vegetable or fish origin (Hooper et al 2006).

The first meta-analysis was of 31 placebo-controlled trials involving 1356 subjects and detected a statistically significant dose–response effect on blood pressure when studies were grouped by omega-3 fatty acid dose: –1.3/–0.7 mmHg at doses ≤3 g/day, –2.9/–1.6 mmHg at 3.3–7 g/day, and –8.1/–5.8 mmHg at 15 g/day (Morris et al 1993). The hypotensive effect was strongest in hypertensive subjects and those with clinically evident atherosclerotic disease or hypercholesterolaemia, whereas no effect was detected in healthy subjects.

The 2002 meta-regression analysis considered the results from 36 trials, of which 22 had a double-blind design, to determine whether fish oil had a significant effect on blood pressure (Geleijnse et al 2002). Fish oil intake (median dose: 3.7 g/day) was found to reduce SBP by 2.1 mmHg and DBP by 1.6 mmHg when all trials were considered. When restricted to double-blind studies only, effects were not as large, but still apparent. Overall, the effects of fish oil on blood pressure tended to be greater in older people (>45 years) and in hypertensive populations (BP ≥140/90 mmHg).

More recent studies have produced comparable results with doses of 3–5.6 g/day associated with reductions of 5.5 mmHg and 3.5 mmHg in systolic and diastolic pressures, respectively (Jung et al 2008). Another meta-analysis of 30 RCTs found that fish oil supplementation reduced heart rate by 1.6 beats/min.

Prior to cardiac surgery

Whilst many secondary coronary heart disease prevention trials require months of treatment before the benefits of omega-3 fatty acid supplementation are detected, a clinical study with cardiothoracic surgical patients suggests acute benefits within weeks. Calo et al conducted a randomised, placebo-controlled study which found that patients taking 2 g/day of fish oils for at least 5 days prior to coronary artery bypass grafting and until discharge had a significantly reduced incidence of postoperative atrial fibrillation (AF) (Calo et al 2005). Specifically, 15.2% of patients receiving fish oils experienced postoperative AF compared with 33.3% of patients who were not taking the supplement. In addition, hospital length of stay was significantly reduced by one day. Except for a single case of allergy, no adverse effects were observed.

Intermittent claudication

A recent Cochrane review of six studies involving 313 subjects suffering from intermittent claudication and treated with n-3 LCPUFAs (typical dose 1.8 g EPA and 1.2 g DHA per day) over weeks to years found that, in spite of some haematological improvements (e.g. reduced viscosity), there were no demonstrable improvements in clinical outcomes (Sommerfield et al 2007).

Clinical note — Would you like methylmercury (MeHg) or organohalogen pollutants (OHPs) with that?

In aquatic environments, inorganic mercury, either naturally occurring or as an industrial by-product (e.g. coal-fired power plants, waste incinerators), is converted into MeHg by microorganisms present in sediment or within the intestine of fish themselves (Dorea 2006). The MeHg, which is the most hazardous dietary form, then accumulates in the aquatic food chain, making fish the primary source of exposure for most individuals (FSANZ 2004). There has been increasing public awareness and concern regarding MeHg exposure secondary to fish consumption. This has been partly in response to the health warnings issued by Food Standards Australia and New Zealand (FSANZ) in March 2004 regarding maximal intake of selected fish species during pregnancy and childhood (Bambrick & Kjellstrom 2004). Interestingly, while the main public concern relates to neurodevelopmental toxicity, emerging data show a relationship between increasing MeHg exposure and cardiovascular disease, in particular MI (Stern 2005). Postulated mechanisms include the oxidative stress and reactive oxygen species observed with in vitro exposures to MeHg, as well as impaired calcium homeostasis and kidney function.

MeHg concentrations in fish and shellfish species, which represent 80–90% of the mercury present, range from <0.1 ppm for shellfish, such as oysters and mussels, to multiple parts per million in large predatory fish such as tuna, marlin, swordfish and shark. Consequently, MeHg intake depends on the species and age of fish consumed, as well as the quantity eaten. Previous American data determined that adults consumed an average of 18 microgram MeHg/day, with 80–90% coming from fish and shellfish (Mahaffey et al 2004).

Inorganic mercury is readily excreted in the urine, whereas MeHg accumulates in erythrocytes across a wide range of exposures (Mahaffey et al 2004). Multiple international studies assessing MeHg exposure levels have revealed that approximately 10% of blood samples were high. American studies have identified populations at greater risk, among them a subpopulation consuming a substantial amount of fish in pursuit of health benefits. Blood MeHg analysis revealed blood mercury levels up to 90 microgram/L (Hightower & Moore 2003). This is concerning given levels >5 microgram/L have been reported as potentially detrimental in women of childbearing age.

Some researchers propose that the potentially cardiotoxic effects of MeHg is countered by the presence of the omega-3 oils also found within fish, and interestingly there is some overlap between those species with the highest concentrations of both (Bambrick & Kjellstrom 2004). However, there is also concern that the converse is true and MeHg could counteract the health-giving benefits of fish.

While fish oil supplements are not a major source of mercury and as such there is no need to restrict their intake (Bays 2007, FSANZ 2004, Levine et al 2005, Schaller 2001), OHPs such as polychlorinated biphenyls (PCBs), dioxins, organochlorine pesticides etc., widely used in flame retardants, pesticides, paints, electrical equipment etc, prior to their ban in the 1980s in most countries (Bays 2007) may be present in these products. OHPs also accumulate in the aquatic food chain and are lipophilic carcinogens as well as being associated with other health risks (Dorea 2006). Data across the board confirm significantly higher OHPs in farmed fish and the supplements produced from these (Jacobs et al 1998, 2004) compared with wild harvested samples. These higher levels are attributed most consistently with use of contaminated feed (Domingo & Bocio 2007, Dorea 2006, Easton et al 2002, Jacobs et al 2002, Melanson et al 2005).

A UK study analysing the OHP content of 21 commercially available fish (both whole body fish and cod liver oil) and vegetable oil dietary supplements in 2004 found that levels in all fish oil products had increased dramatically in brands tested 8 years previously (Jacobs et al 1998, 2004). For example, OHP levels in cod liver oils, which originally ranged from 0–13 ng/g were found to contain 15–34 ng/g in the most recent analysis. The findings of an American study contrast with this, however, with OHP levels below the level of detection in five over the counter fish oil products (Melanson et al 2005). There is no published data on Australian products.

There remains little doubt that the discriminating inclusion of fish is an important part of a healthy diet while several risk/benefit analyses of fish intake at currently recommended levels have recently been published (Domingo 2007, Foran et al 2005, Mozaffarian & Rimm 2006). Many of these make a distinction between the consumption of farmed and wild varieties, with researchers concluding that some of the benefits of increased fish consumption may be negated by the high level of OHPs found in the former, which elevate cancer risk (Foran et al 2005, Mozaffarian & Rimm 2006, Tacon & Metian 2008). A smaller number of papers have specifically considered the risks associated with fish oil supplementation, concluding that their net effect is still a health-promoting one (Bays et al 2007, Melanson et al 2005).

Neurological effects

There is evidence that alterations to n-3 fatty acid metabolism and the composition of the phospholipids in serum and membranes are involved in the pathogenesis of some neurological disorders (Ulbricht & Basch 2005). Also, several epidemiological studies have reported low-plasma DHA status in individuals with schizophrenia, attention-deficit hyperactivity disorder (ADHD), dyslexia, personality disorder, depression and bipolar disorder (Riediger et al 2009). As a result, there has been much interest

in understanding the effects of supplemental n-3 fatty acids in neurological development, cognitive function, behavioural problems and other neurological conditions.

Cognitive function

Low-serum DHA level is considered a significant risk factor for the development of Alzheimer's dementia (Conquer et al 2000). Additionally, both DHA and total n-3 LCPUFAs are significantly lower in cognitively impaired but non-demented people and people with other dementias. One of the first interventional studies was a small RCT of 4.3 g/day DHA in 20 elderly nursing home residents, assessing the efficacy of fish oil in the treatment of vascular dementia. DHA supplementation resulted in a small improvement in dementia rating scores within 3 months of treatment (Terano et al 1994).

The results from numerous animal studies, demonstrating neuroprotection and slowing of neurodegeneration from the n-3 LCPUFAs, appear promising (Hashimoto et al 2005, Mucke & Pitas 2004); however, more clinical trials are required to confirm these positive findings.

Alzheimer's dementia

Epidemiological studies have shown that dementia and CVD may share several common risk factors, including high intakes of dietary total fat, high saturated fat, high n-6:n-3 fatty acid ratio, and low fish intake (Riediger et al 2009). Considering n-3 fatty acids possess anti-inflammatory properties and inflammatory markers have been located in the brain of patients with Alzheimer's disease, it seems reasonable to suggest that n-3 fatty acids may delay the onset of Alzheimer's disease by reducing brain inflammatory state. This may be one of the reasons behind prevention of Alzheimer's disease/dementia by adequate DHA/EPA intake suggested by the Framingham heart study (Kalmijn 2000, Kalmijn et al 2004), the Rotterdam study (Kalmijn et al 1997) and the 2003 prospective study by Morris et al (Morris et al 2003) although later follow-up of the Rotterdam study found no association (Engelhart et al 2002).

In 2005, a review of the evidence prepared for the US Department of Health and Human Services concluded that there is a significant correlation between fish consumption and reduced incidence of AD. Total n-3 LCPUFA and DHA consumption correlated with this risk reduction; however, ALA and EPA did not (Maclean et al 2004). A Cochrane review came to a similar conclusion, reporting that there is a growing body of evidence from biological, observational and epidemiological studies to suggest a protective effect of n-3 LCPUFAs against dementia; however, further research is required before firm conclusions can be made (Lim et al 2006). A recent study investigating supplementation with 1.8 g/day of fish oils over 24 weeks in subjects with either mild-to-moderate Alzheimer's disease or mild cognitive impairment yielded greatest benefits in individuals suffering only mild cognitive impairment (Chiu et al 2008). Further studies using higher doses, larger sample sizes and only subjects mildly affected by the condition are recommended.

Autism

Two studies have found evidence of low levels of EPA and DHA in autistic patients (Curtis & Patel 2008). Despite this, surprisingly few studies have investigated the effects of n-3 LCPUFAs in autistic individuals. One study conducted in a sample of 12 children, employing 5 g/day of n-3 LCPUFAs over 6 weeks, produced significant remission of hyperactivity (Amminger et al 2007), while a more recent one using comparable doses in adults failed to demonstrate efficacy on any behavioural parameter (Politi et al 2008). The data obtained from research based on an online survey of 861 parents of autistic children suggests that consumption of a formula devoid in DHA and AA during infancy is associated with an OR of 4.41 for autism generally and 12.96 for regressive autism, compared with breastfed infants (Schultz et al 2006). However, the heavy reliance upon self-reporting in addition to the non-random sample leave these results open to scrutiny.

Pregnancy, breast feeding and infants

Although numerous studies of mothers and infants have demonstrated that consuming greater amounts of EFAs had a positive effect on the subsequent cognitive development and IQ of their young offspring (Cohen et al 2005, Helland et al 2003, Williams et al 2001), the Evidence Report/Technology Assessment prepared for the Agency of Healthcare Research and Quality of the US Department of Health and Human Services concludes that, based on the small number of current well-designed studies, there is no conclusive evidence of any benefit (Moher 2005). The report makes the observation that studies demonstrating a positive relationship between n-3 LCPUFAs and cognition are those that assessed children under 1 year of age, whereas in studies of older children a significant statistical relationship is not sustained. Despite the conclusions of this report, several studies with longer follow-up periods have demonstrated both improved eye and hand coordination (Dunstan et al 2008) and IQ at 4 years old (Helland et al 2003), but not at 7 (Helland et al 2008). The latter is a recent Australian study, following up on 98 women who were supplemented with 2.2 g DHA and 0.1 g EPA per day or placebo from 20 weeks gestation. Children's eye and hand coordination scores correlated with n-3 LCPUFA levels in cord blood RBC and inversely correlated with n-6 LCPUFA at 2½ years of age.

According to the WHO and FAO, the pregnant woman should take at least 2.6 g of n-3 EFAs, incorporating 100–300 mg of DHA, daily to look after the needs of the fetus (Bambrick & Kjellstrom 2004). Postnatal deficiencies have been associated with reduced visual acuity, poor neurodevelopment and ill effects on behaviour. Breast-fed infants generally receive sufficient DHA if the maternal diet is adequate, but it is not known whether formula-fed

infants receive adequate amounts if their formula does not contain PUFAs.

Preventing depression

After adjusting for several confounding factors, Kamphuis et al reported that every 50 mg/day increase in n-3 fatty acid intake was correlated with a 7% risk reduction of depressive symptoms in elderly men (Kamphuis et al 2006). It has been suggested that the balance between n-6 and n-3 EFA influences the metabolism of biogenic amines, an interaction that may be relevant to changes in mood and behaviour (Bruinsma & Taren 2000). In several observational studies, low concentrations of n-3 LCPUFAs predicted impulsive behaviours and greater severity of depression. Additionally, early research by Horrobin et al (1999) revealed that almost all studies on depression have found increased PG_2 series or related thromboxanes and there is evidence that the older antidepressants (i.e. MAOIs and TCAs) either inhibit PFG synthesis or are powerful antagonists of their actions. The findings of a number of studies showing a correlation between low erythrocyte n-3 EFAs and suicide attempts go one step further. One demonstrated an eightfold difference in suicide attempt risk between the lowest and highest RBC EPA quartiles (Huan et al 2004). Belgian researchers have also speculated about seasonal variations in EFA status that correlates with seasonal patterns of suicide (De Vriese et al 2004); however, studies on larger populations of depressed people are required to confirm this link.

Treating depression

In spite of a plethora of epidemiological data correlating n-3 status with a range of depressive disorders, including major depression, postpartum depression and seasonal affective disorder, there are relatively few interventional studies. In addition to this, those published are typically compromised by small sample size and possess heterogeneous designs, particularly with regard to the composition and dose of the intervention itself (Grenyer et al 2007). Initial studies utilised products rich in EPA, while more recent studies have investigated DHA-rich preparations. There appears to remain much uncertainty regarding both the active ingredient and the optimal dose in the management of depression.

Peet and Horrobin studied 70 patients with treatment-resistant depression randomised on a double-blind basis to placebo or ethyl-eicosapentaenoate at dosages of 1, 2 or 4 g/day for 12 weeks. Patients continued standard medication during the study. The 1-g/day group showed a significantly better outcome than the placebo group on all three rating scales. The 2-g/day group showed little evidence of efficacy, whereas the 4-g/day group showed non-significant trend towards improvement. All of the individual items on all three rating scales improved with the 1-g/day dosage of ethyl-eicosapentaenoate compared to placebo with strong beneficial effects on items rating depression, anxiety, sleep, lassitude, libido and suicidality (Peet & Horrobin 2002).

In 2003, a pilot study by Su and colleagues compared 9.6 g/day n-3 LCPUFAs with placebo in 28 patients over 8 weeks using a randomised, double-blind design. All but one patient was medicated and remained on their medication throughout the trial. The group receiving n-3 PUFAs had significant reductions in their depression rating from the fourth week of treatment.

A 2005 study involved 77 depressed patients randomly assigned to receive either 8 g/day of DHA-enriched (1.23%) fish oil or olive oil, in addition to existing medication, over 12 weeks. Interestingly, the fish oil group did not show significant improvement over the olive oil group, but both groups improved in mood over baseline. This was significant at 2 weeks and remained so throughout the study (Silvers et al 2006). Similarly, an Australian study of 83 outpatients taking antidepressant medication, administered 2.2 g/day DHA and 0.6 g/day EPA over 4 months found no demonstrable benefit compared with those taking an olive oil placebo (Grenyer et al 2007). The use of olive oil placebos in both of these trials has been speculated as being a confounding variable.

A randomised study conducted in 28 children aged 6–12 years and diagnosed with depression using the Children's Depression Rating Scale (CDRS), Children's Depression Inventory (CDI) and Clinical Global Impression (CGI) found symptomatic improvement following 1 month of treatment with omega-3 fatty acids (Nemets et al 2006).

Bipolar disorder

In spite of a growing number of studies investigating fish oils in the treatment of this condition, data from these are plagued by methodological weaknesses, as evidenced by a recent Cochrane review which included only one study, Frangou et al (2006), following exclusion of 23 other trials for various reasons (Montgomery & Richardson 2008). Studies have employed either mixed EPA/DHA preparations or pure ethyl-EPA delivering a minimum of 1 g/day typically in combination with standard pharmaceuticals. A number of studies point towards improvement of depressive symptoms, with no evidence of benefit during manic phases.

Aggressive and impulsive behaviour

Animal studies demonstrate increased aggression test scores in rats and other species deprived of n-3 LCPUFAs either during gestation or early life which has been linked to deficits in neuronal arborisation and multiple indices of synaptic pathology, including deficits in serotonin and mesocorticolimbic dopamine neurotransmission (Hibbeln et al 2006, Liu & Raine 2006). Human data also support this proposition, whereby preterm delivery is associated with deficits in fetal cortical DHA accrual, and children/adolescents born preterm exhibit deficits in cortical grey matter maturation, neurocognitive deficits particularly in the realm of attention, impulsivity and increased risk of ADHD and schizophrenia (Hibbeln et al 2006, McNamara & Carlson 2006). While there is strong support for the biological basis for a relationship between n-3 LCPUFAs and aggressive and impulsive behaviour (Garland & Hallahan

2006), the results of interventional studies have been somewhat mixed.

DHA has been used to reduce aggressive behaviour in children and adolescents. One placebo-controlled study of 42 college students showed that DHA supplementation (1.5–1.8 g/day) prevented an increase in aggression towards others at times of mental stress (Hamazaki et al 1996); however, had no effect on aggressive behaviour under non-stressful conditions (Hamazaki et al 1998). A 2005 randomised, placebo-controlled clinical trial in 166 Japanese children aged 9–12 years administered 3.6 g DHA and 840 mg per week via both supplements and fortified foods over a period of 3 months (Itomura et al 2005). While reducing aggression in girls, concomitant with improved EPA:AA RBC ratios, the same effect was not evident in boys. Impulsivity amongst female subjects was also significantly reduced in the treatment group.

A recent interesting study examined the use of n-3 LCPUFAs in polysubstance abusers (Buydens-Branchey et al 2008). The intervention was 2.25 g EPA, 500 mg DHA administered over 3 months to 24 individuals and resulted in decreased anger and anxiety scores, corresponding with plasma increases in both EPA and DHA. Clinical studies also suggest that n-3 LCPUFA supplementation can improve the impulsivity/aggressivity dimension of borderline personality disorder (Diaz-Marsa et al 2008). However, in individuals exhibiting recurrent self-harm, scores for impulsivity, aggression and hostility remained unchanged, in spite of decreased depression and suicidality scores, when treated with 1.2 g EPA and 900 mg DHA per day over 12 weeks (Hallahan et al 2007).

Attention-deficit hyperactivity disorder

It has been reported that many children with ADHD have EFA deficiency (mainly n-3 FA) with a high correlation between severity of symptoms and severity of deficiency (Yehuda et al 2005). Deficiency may be due to insufficient dietary intake or inefficient conversion of EFA to LCPUFAs. Several studies have investigated the effects of supplemental fatty acids in ADHD with mixed results; however, interpretation of findings is difficult because of the use of different treatments, measurements and subject selection (Richardson & Puri 2000).

Schizophrenia

Schizophrenic patients have been frequently found to have low LCPUFAs (Peet 2003, 2006). A new study adds to this, demonstrating high saturated and monounsaturated fat in red cells at the expense of LCPUFAs of both the 3 and 6 families (Kemperman et al 2006). A key researcher in the area of EFAs and psychiatry also points to the significant overlap between core features of the metabolic syndrome and established physiological aberrations evident in schizophrenia, including visceral adiposity, insulin resistance, dyslipidaemias, increased inflammatory markers and reduced n-3 LCPUFAs in cell membranes (Peet 2006). Importantly, these similarities pre-date the introduction of the novel antipsychotics, which are known to be diabesogenic. Schizophrenic patients demonstrate a 2–4-fold increased risk of type 2 diabetes mellitus (T2DM) and 2–3-times greater risk of coronary artery disease mortality, which cannot be entirely related to secondary lifestyle behaviours.

According to a 2003 review, four out of five placebo-controlled, double-blind trials of EPA in the treatment of schizophrenia have produced positive results with a typical effective dose of 2 g/day of EPA for minimum of 3 months (Peet 2003). An updated Cochrane review of six studies, involving 353 subjects, has similarly concluded that ethyl-EPA may exert positive effects; however, more large well-designed, conducted and reported studies are needed (Joy et al 2006).

Cancer

It is well established that dietary fat has an influence on human cancer development and progression. Several forms of research implicate n-6 PUFAs as catalysts, whereas n-3 LCPUFAs have the opposite effect and have been shown to inhibit development and progression (Leitzmann et al 2004, Weisburger 1997). Therefore, it is the ratio of n-3 to n-6 PUFAs intake that appears to be an important factor influencing cancer incidence and progression.

This observation is supported by both animal and epidemiological studies. The largest to date involved 24 European countries and identified a significant inverse correlation with fish and fish oil consumption, when expressed as a proportion of total or animal fat, for both male and female colorectal cancer and for female breast cancer (Caygill et al 1996). Importantly, the protective effects were only detected in countries with a high animal fat intake, suggesting that fish oil protects against the promotional effects of animal fat in carcinogenesis.

Breast and prostate cancers

A 2003 review found that overall it remains unclear as to whether dietary fish or fish oil consumption exerts a protective effect against the development of breast and prostate cancers (Terry et al 2003). The assessment of EPA and DHA intake and their relation to n-6 fatty acid intake and cancer incidence still requires further examination before conclusions can be confidently made. An updated review conducted by the same researchers in 2004 (Terry et al 2004) reached a similar conclusion; however, they also observed that those studies that assess omega-3 intake concomitant with the omega-6 consumption were most likely to yield a statistically significant inverse relationship between fish oils and breast and prostate cancers. Once again this reinforces the understanding that the fats due to interrelated metabolism and actions should not be viewed independently.

A prospective cohort study in the USA of 47,866 men aged 40–75 years with no cancer history were assessed using a 131-item semiquantitative food-frequency questionnaire administered annually over 14 years, as part of the Health Professionals Follow-Up study. Nutrient intake data from this trial suggests an association between

ALA and advanced prostate cancer, but an inverse relationship with the ALA metabolites, EPA and DHA. Earlier studies investigating the relationship between ALA and prostate cancer have had mixed results while the inverse relationship with EPA/DHA appears to be largely supported. Again the authors demonstrate that ratios of omega 3:6 appear to be highly influential in conveyed risk (Leitzmann 2004).

Colorectal cancer

Epidemiological evidence investigating associations between fish intake and colorectal cancer have produced mixed findings (Caygill et al 1996, Daniel et al 2009), with the most recent prospective cohort study (Cancer Prevention Study-II Nutrition Cohort) involving over 99,000 individuals failing to demonstrate a protective effect of increased n-3 intake. In fact, increased consumption of ALA was associated with increased risk in women. Contrastingly, higher marine n-3 intake did appear protective. The latter finding is consistent with the results of other large prospective studies on this issue (Hall et al 2008).

Other sources of evidence attribute both EPA and DHA and their main dietary source, fish oil, with antineoplastic effects in colorectal cancer (Llor et al 2003). Fish oil supplementation, in one study, providing 4.1 g EPA and 3.6 g DHA per day in patients with sporadic adenomatous colorectal polyps was reported to reduce the percentage of cells in the S-phase in the upper crypt of the rectal mucosa (Anti et al 1992). The evidence to date as reviewed in 2004 by Roynette et al suggests a primary preventative effect with some residual ambiguity over the safety of n-3 LCPUFAs with respect to secondary tumour formation.

One study has investigated the effects of n-3 LCPUFA parenteral supplementation postoperatively on clinical outcomes and immunomodulation in colorectal cancer patients using a randomised, double-blind design (Liang et al 2008). Treatment effect comparisons revealed that those treated with n-3 LCPUFAs had significantly lower serum IL-, TNF-alpha and increased ratios of CD^{4+}/CD^{8+}. These patients also tended towards shorter postoperative hospital stays. Consequently, the authors conclude that such a treatment regime may have beneficial effects on lowering the magnitude of inflammatory responses and modulating the immune response in this patient group.

The results of a recent in vitro study have demonstrated synergistic inhibition of proliferating colon cancer cells using a combination of lycopene and EPA (Tang et al 2008). The results of other in vitro studies attribute the protective effects of n-3 LCPUFAs with DHA rather than EPA (Kato et al 2007). Both animal studies and RCTs are now required to clarify the 'active' fatty acid and confirm these findings.

Diabetes

Increasing the intake of n-3 LCPUFAs has been shown to be both preventative in a healthy population and beneficial in people with diabetes (Montori et al 2000, Nettleton & Katz 2005, Sirtori & Galli 2002, Sirtori et al 1997). Although there have been random reports of improved glucose control with fish oil supplementation, a review published in 2004 cites two large meta-analyses of trials with n-3 LCPUFAs in subjects with diabetes, which found no adverse or positive effect on glucose control or impact on glycated haemoglobin, with a recent Cochrane review making the same conclusion (Hartweg et al 2008).

Two meta-analyses found that fish oil supplementation lowers plasma TG levels in type 2 diabetic subjects; however, a possible rise in plasma LDL cholesterol may occur (Balk et al 2006, Montori et al 2000). The latter has been speculated, to be the result of enhanced conversion of VLDLs and studies in primates suggest that n-3 LCPUFA enriched LDLs do not convey the same atherogenic potential (Jung et al 2008). Additionally, no significant effect occurs on glycaemic control, total cholesterol or HDL cholesterol. In addition to this, more recent studies reveal an average of 7.4% increase in HDL levels concomitant with a 25% reduction in TGs in response to 203 g of EPA/DHA supplementation over 6 months (Sirtori et al 1998). Such findings are supported by the results of other trials in diabetics (Nettleton & Katz 2005).

Despite the potential benefits associated with n-3 LCPUFAs, a 2008 Cochrane review of 23 RCTs involving 1075 individuals concluded there is currently insufficient evidence to recommend high-dose fish oils to T2DM patients for cardiovascular benefits (Hartweg et al 2008).

Weight reduction

In addition to attenuating negative PUFA changes associated with weight loss regimes (Hlavaty et al 2008) and improving insulin resistance in overweight subjects (Ramel et al 2008), there is limited evidence that n-3 LCPUFAs may be associated with reduced incidence of obesity, ease of weight loss and maintenance of body weight in this population (Nettelton & Katz 2005). A recent study found that overweight and obese subjects consuming >1300 mg/day n-3 LCPUFAs compared with those consuming <240 mg/day demonstrated significantly increased satiety 2 hours post-prandially, which correlated with an increased omega 3:6 (Parra et al 2008).

Inflammatory diseases

Numerous clinical trials have investigated the effects of fish oil supplementation in several inflammatory and autoimmune diseases, such as rheumatoid arthritis, Crohn's disease, ulcerative colitis, lupus erythematosus and migraine headaches (Belluzzi 2002, Belluzzi et al 1996, Miura et al 1998, Simopoulos 2002). Although not all trials have produced positive results, many of the placebo-controlled trials reveal significant benefit in chronic disease, including decreased disease activity and sometimes reduced requirement for anti-inflammatory medicines (Adam et al 2003).

Rheumatoid arthritis (AR)

Of the inflammatory diseases, the use of fish oil supplementation is most widely seen and supported in RA. According to multiple randomised, controlled studies, fish oil supplements have been consistently shown to reduce symptoms in RA, such as the number of tender joints, pain intensity and morning stiffness (Adam et al 2003, Cleland et al 2003, Goldberg & Katz 2007, Kremer 2000, Ulbricht & Basch 2005, Volker et al 2000). Generally, supplements are taken daily as adjuncts to standard therapy with clinical effects appearing after 12 weeks. A dose ranging from 30 mg to 40 mg/kg of EPA and DHA daily has been used successfully, although some studies have found a minimum of 3 g/day is required. Results from a double-blind, crossover study suggest that the beneficial effects obtained from fish oil capsules are further enhanced when combined with an anti-inflammatory diet providing less than 90 mg/day of AA (Adam et al 2003).

Symptomatic relief with n-3 LCPUFAs in RA was more recently confirmed in a meta-analysis of 17 randomised controlled trials assessing the pain relieving effects in RA patients or joint pain secondary to inflammatory bowel disease and dysmenorrhoea (Goldberg & Katz 2007). Supplementation for 3–4 months significantly reduced patient-reported joint pain intensity, minutes of morning stiffness, number of painful and/or tender joints and non-steroidal anti-inflammatory drug (NSAID) consumption. Significant effects were not detected, however, for physician assessed pain or Ritchie articular index. These papers, together with other authoritative reviews, conclude that based on high-level evidence, n-3 LCPUFAs are an attractive adjunctive treatment for joint pain associated with rheumatoid arthritis and have a beneficial follow-on effect on cardiovascular morbidity and mortality pertinent to this population (Proudman et al 2008).

Although the anti-inflammatory activity of fish oil supplementation is thought to be chiefly responsible for symptom relieving effects, there is also evidence that n-3 LCPUFAs can modulate expression and activity of degradative factors that cause cartilage destruction (Curtis et al 2000). A 2005 randomised study found that fish oil supplements (3 g/day), whether taken alone or in combination with olive oil (9.6 mL), produced a statistically significant improvement ($P < 0.05$) compared to placebo on several clinical parameters (Berbert et al 2005). Significant improvements were observed for joint pain intensity, right and left handgrip strength after 12 and 24 weeks, duration of morning stiffness, onset of fatigue, Ritchie's articular index for pain joints after 24 weeks, ability to bend down to pick up clothing from the floor and getting in and out of a car after 24 weeks. The group using a combination of oils showed additional improvements with respect to duration of morning stiffness after 12 weeks, patient global assessment after 12 and 24 weeks, ability to turn taps on and off after 24 weeks and rheumatoid factor after 24 weeks. In addition, this group showed a significant improvement in patient global assessment compared with fish oils alone after 12 weeks.

Based on these results, it appears that while fish oils will not improve all parameters of RA, overall they have demonstrated symptomatic relief in the majority and result in significantly reduced use of anti-inflammatory and corticosteroid use, a fact that MacLean et al (2004) acknowledge and which is confirmed by a 2005 review by Stamp et al and meta-analysis by Goldberg and Katz (2007). There appears to be little evidence of sustained improvements following cessation of the supplements.

A 2008 paper from the Joint Nutrition Society notes that, in addition to modifying the lipid mediator profile, n-3 LCPUFAs exert effects on other aspects of immunity relevant to RA, such as antigen presentation, T-cell reactivity and inflammatory cytokine production (Calder 2008).

Reducing incidence of RA

A large prospective cohort study (n = 57,053) investigating the association between dietary factors and risk of RA found that each increase in intake of 30 g fatty fish (≥8 g fat/100 g fish) per day was associated with 49% reduction in the risk of RA (P = 0.06); however, a medium intake of fatty fish (3–7 g fat/100 g fish) was associated with significantly increased risk of RA (Pedersen et al 2005). No associations were found between risk of RA and intake of a range of other dietary factors, including long-chain fatty acids, olive oil, vitamins A, E, C and D, zinc, selenium, iron and meat. The authors caution that due to the limited number of patients who developed RA during follow-up, it is not yet possible to make firm conclusions.

Asthma

Omega-3 LCPUFAs exhibit anti-inflammatory activity and epidemiological evidence has demonstrated an inverse relationship between fish intake and asthma risk and improved lung function (Wong 2005). Recent evidence suggests that this protective effect may extend back as far as adequate fetal n-3 LCPUFAs exposure (Salam et al 2005). A recent 16-year follow-up investigation of offspring born to women supplemented with 2.7 g/day fish oils from week 30 until delivery as part of a RCT confirms this proposition (Olsen et al 2008). Children born to mothers in the fish oil group demonstrated a 63% reduction in asthma diagnoses and 87% reduction in the prevalence of allergic asthma. Results such as these may help to explain the lack of protective effects associated with increased n-3 LCPUFA levels in early childhood reported in some of the literatures (Almqvist et al 2007, Marks et al 2006).

A 2002 Cochrane review of nine RCTs conducted between 1986 and 2001 concluded that n-3 LCPUFAs supplementation demonstrated no consistent effect on any of the analysable outcomes: forced expiratory volume in 1 second, peak flow rate, asthma symptoms, asthma medication use or bronchial hyper-reactivity (Woods et al 2002). However, one of the RCTs involving children showed that when fish oil supplementation was

combined with dietary changes, positive results were obtained, as evidenced by improved peak flow and reduced asthma medication use.

An interesting recent crossover study of 72 asthmatic children aged 7–10 years, involved five randomised phases of treatment each lasting 6 weeks: placebo; omega 3 (300 mg/day combined EPA and DHA); zinc (15 mg/day); vitamin C (200 mg/day); combination of all nutrients (Biltagi et al 2009). While the n-3 LCPUFA supplementation was associated with improved lung function and a reduction in both sputum production and markers of airway inflammation, these positive effects were significantly augmented when combined with zinc and vitamin C, suggesting that a more broad nutritional approach to inflammation and oxidation control results in greatest clinical outcomes.

The equivocal nature of interventional studies with n-3 LCPUFAs, as documented by a 2005 review (Wong), may be clarified in future with the identification of a subtype of asthma more likely to respond to EFA manipulation.

Another interesting paper reports on three patients with disabling salicylate intolerance producing urticaria, asthma and anaphylactic reactions who, following administration of 10 g/day fish oils for 6–8 weeks, experienced complete or virtually complete resolution of symptoms (Healy et al 2008). Treatment response was so effective corticosteroids could be discontinued, however, symptoms reappeared following fish oil dose reduction.

In recent years, the focus for fish oils in asthma has broadened to include other populations such as athletes. One randomised, double-blind, crossover study of 16 non-atopic asthmatic patients with documented exercise-induced broncoconstriction (EIB) compared the effects of 3.2 g of EPA and 2.0 g DHA per day and placebo capsules for 3 weeks. During treatment with fish oils, subjects demonstrated improved pulmonary function to below the diagnostic EIB threshold, which was associated with a concurrent reduction in bronchodilator use. Measurement of leukotriene B(4) and B(5) levels also confirmed a significant reversal of the inflammatory picture (Mickleborough et al 2006).

Atopic dermatitis and eczema

In a sample of adult patients (n = 53), randomised to 5.4 g/day DHA or isoenergetic saturated fats for 20 weeks, active fish oil treatment produced significant clinical improvements which correlated with increases in plasma DHA (Koch et al 2008); however, due to the small sample size, larger studies are required to confirm these preliminary results.

Previously, a double-blind multicentre study involving 145 patients with moderate to severe atopic dermatitis showed that n-3 LCPUFAs (6 g/day) improved clinical symptom scores by 30% after 4 months' treatment (Soyland et al 1994). The results were confirmed by patients' subjective scoring. An earlier, 12-week, prospective, double-blind study produced similar results with a dose of 10 g/day (fish oil) improving overall severity of atopic dermatitis and reducing scaling (Bjorneboe et al 1989).

Clinical note — The 'new' fish oils?

Pressing issues of non-sustainability of both wild harvesting and aquaculture together with increasing contaminants in both fish and their products would have stimulated researchers to search for alternative sources to meet our increasing omega-3 demand (Racine & Deckelbaum 2007, Robert 2006). One burgeoning interest is algal sources of EPA/DHA, which may offer a genuine alternative as either supplements or fortificants (Doughman et al 2007, Kris-Etherton & Hill 2008, Racine & Deckelbaum 2007). Microalgae, such as *Crypthecodinium cohnii* and *Schizochytrium* spp., represent part of the coastal food chain as a primary food source for shellfish, contain naturally high levels of DHA, no contaminants (Arterburn et al 2000, Doughman et al 2007) and are currently commercially developed as sustainable crops (Doughman et al 2007, Whelan & Rust 2006). Initial human studies have confirmed both bioequivalence and comparable clinical efficacy with other DHA sources such as salmon (Arterburn et al 2000, Doughman et al 2007). Algal oils also have good safety profiles, as evidenced by approval of select species by the FDA (Whelan & Rust 2006). While this appears promising, a number of limitations regarding microalgal omega-3 sources have already been identified, including low EPA content, absence of other nutrients found in fish (e.g. protein), possible inhibition of elongases and desaturases secondary to high DHA intake and minor risk of allergenicity (Doughman et al 2007, Kris-Etherton & Hill 2008).

Reducing incidence of eczema

The results of a recent, prospective, longitudinal study from Sweden of 4921 infants' diets, exposure patterns and eczema diagnoses have found a protective effect for early introduction of fish (Alm et al 2009). Infants introduced fish prior to 9 months of age demonstrate reduced rates of eczema at 1 year (OR 0.76). This finding flies in the face of previous primary prevention strategies whereby many child health authorities have encouraged delaying the introduction of fish in order to reduce allergy.

OTHER USES

Fish oil supplements are also used in the management of acute respiratory distress syndrome, psoriasis, multiple sclerosis, osteoporosis and dysmenorrhoea and in children with dyslexia.

DOSAGE RANGE

- Fish should be considered part of a healthy diet for everybody and be consumed at least twice a week. Care should be taken to avoid intake of fish known or suspected to contain higher levels of mercury.
- Additional administration of n-3 LCPUFA supplements should be considered in specific groups.

- Fish meals should consist of deep sea oily fish, whereas fried or processed fish containing partially hydrogenated fats and salted or pickled fish should be avoided.

Cardiovascular disease

Secondary prevention trials after MI indicate that consumption of 0.5–1.8 g/day of EPA and DHA from fish or fish oil supplements may be beneficial. Intake of marine-derived omega-3 fatty acids can be increased through diet or with fish oil supplements.

- An expert US panel of nutrition scientists has recommended an intake of 0.65 g/day, whereas the British Nutrition Foundation's recommendation is 1.2 g/day (Din et al 2004).
- National Heart Foundation/Cardiac Society of Australia and New Zealand: >2 serves/wk.
- Patients who have experienced coronary artery bypass surgery with venous grafts: 4 g/day of n-3 LCPUFAs.
- Moderate hypertension: 4 g/day of fish oils.
- Elevated TG levels: 1–4.6 g/day of fish oils.

Other conditions

- Aggression induced by mental stress: DHA supplementation, 1.5–1.8 g/day.
- Anger and anxiety reduction in polysubstance abuse withdrawers: 2.25 g EPA, 500 mg DHA and 250 mg other omega-3 per day.
- Asthma prevention in pregnancy: 2.7 g/day from week 20 gestation until delivery.
- Asthma treatment in children: 300 mg combined EPA & DHA with 15 mg zinc and 200 mg vitamin C per day.
- Atopic dermatitis: 6 g/day fish oils or 5.4 g/day DHA.
- Autism: 5 g/day.
- Bipolar disorder: 1 g/day EPA.
- Colorectal cancer: 4.1 g EPA + 3.6 g DHA daily.
- Dementia: DHA supplementation, 4.32 g/day.
- Depression: 1 g/day EPA or 9.6 g/day fish oils.
- Exercise-induced asthma in non-atopic individuals: 3.2 g EPA + 2.0 g DHA daily.
- High blood pressure: 3–5.6 g/day.
- Intermittent claudication: 1.8 g EPA and 1.2 g DHA per day.
- Pregnancy: According to the WHO and FAO, the pregnant woman should take at least 2.6 g of n-3 EFAs, incorporating 100–300 mg of DHA daily to look after the needs of the fetus.
- Rheumatoid arthritis: 30–40 mg/kg body weight of EPA and DHA daily.
- Schizophrenia: 2 g/day EPA.
- Weight reduction and improved insulin sensitivity: 660 mg EPA and 440 mg DHA/day.

ADVERSE REACTIONS

Fish oil supplementation is generally safe and well tolerated. The few side effects reported are usually mild and can include gastrointestinal discomfort and loose bowels, halitosis and a fishy odour of the skin and urine.

SIGNIFICANT INTERACTIONS

Antiplatelet agents

Theoretically, concomitant use with antiplatelet agents may increase the risk of bleeding; however, multiple clinical studies have found no clinically significant effect on bleeding and one study has suggested that the combined effects may be beneficial (Engstrom et al 2001) — no clinically significant interaction expected at therapeutic doses.

Anticoagulants

Clinical studies of surgical patients taking warfarin have not found a clinically significant increase in bleeding. According to one clinical study, bleeding time is increased at very high doses of 12 g/day. Usual therapeutic doses, which tend to fall below this dosage, appear safe in this population although care should still be taken. Very high doses >12 g should be used only under professional supervision to ensure no adverse outcomes.

NSAIDs

Additional anti-inflammatory effects are theoretically possible with concurrent use of fish oil supplements, suggesting a beneficial interaction. Drug dosage may require modification.

Pravastatin

Low-dose pravastatin combined with fish oil supplementation is more effective than pravastatin alone for changing the lipid profile after renal transplantation, according to one clinical study — potential beneficial interaction.

CONTRAINDICATIONS AND PRECAUTIONS

One area of concern is the growing problem of heavy metal contamination found in fish, specifically mercury. In areas where contamination is possible, fish oil supplements may represent a safer option. According to the *Australia New Zealand Food Standards Code*, fish with higher levels of mercury include: swordfish, southern bluefin tuna, barramundi, ling, orange roughy, rays and shark. Fish considered to have lower levels of mercury include: mackerel, silver wahoo, Atlantic salmon, canned salmon and canned tuna in oil, herrings and sardines.

People with bleeding disorders should take fish oil supplements under medical supervision.

PREGNANCY USE

Fish oils appear to be safe during pregnancy at dietary doses and is likely to have benefits.

PATIENTS' FAQs

What will this supplement do for me?

Regular consumption of fish oils may reduce total mortality, cardiovascular mortality and morbidity, dementia and depression. Additionally, beneficial effects have been demonstrated in a wide variety of conditions.

When will it start to work?

This will depend on the dosage taken and indication for use.

Are there any safety issues?
People with bleeding disorders should take fish oil supplements under medical supervision.

PRACTICE POINTS/PATIENT COUNSELLING

- As precursors of eicosanoids, polyunsaturated fatty acids found in fish oils exert a wide influence over many important physiological processes.
- They have demonstrated anti-inflammatory, immunological, neurological, antiplatelet and chemopreventative effects, and a range of beneficial actions within the cardiovascular system.
- Daily ingestion of at least 1 g EPA and DHA (equivalent to fish eaten at least twice weekly) may result in a reduction in total mortality, cardiovascular mortality and morbidity and incidence of dementia and depression.
- Trials generally support the use of supplements in a range of inflammatory and autoimmune diseases such as rheumatoid arthritis and atopic dermatitis, elevated TGs, hypertension and other cardiovascular conditions, poor cognitive function and diabetes. Preliminary research suggests a possible role in depression.
- People with bleeding disorders should take fish oil supplements under medical supervision.

Flaxseed oil

HISTORICAL NOTE For over 5000 years, flaxseed in its various forms has been a part of the diet of people in Asia, Africa and Europe. It has a long history of use as both a food and a medicine, with the seed being most commonly used. The oil was also popular and has been a traditional food of the Egyptians from the time of the Pharaohs to the present day. The oil is also consumed by the Chinese, who documented its medicinal properties in the Pen-T's AO, the Great Chinese Pharmacopeia (Judd 1995). Its Latin name *usitatissimum* means 'most useful', suggesting its various uses have been recognised for centuries (Kolodziejczyk & Fedec 1995). Interestingly, research into its nutritional properties and effects on human health was not studied in earnest until the 1980s (Cunnane & Thompson 1995). In Australia in 1981, cultivation of a low alpha-linolenic acid (ALA) variety, now known as Linola, was pioneered in an attempt to improve the stability of the oil and increase its commercial viability as a cooking oil. Such modifications were successful and resulted in ALA content <3.0% and a higher concentration of linoleic acid than the naturally occurring form (Bhatty 1995, Hall et al 2006). These modified oils are not used for medicinal purposes.

OTHER NAMES

Flax oil and linseed oil

Internationally, it is accepted that 'flaxseed' refers to products for human consumption, whereas 'linseed oil' refers to products that have been denatured, made unfit for human consumption, and used in commercial products, such as paints and varnishes.

BOTANICAL NAME/FAMILY

Linium usitatissimum (family Linaceae)

PLANT PART USED

Fixed oil is derived from the seeds of the plant. Due to the highly polyunsaturated nature of the oil (≈ 73%), extracts are obtained by cold-pressing rather than heat extraction. Flaxseed oil (FSO) is highly susceptible to photo-oxygenation, so it is packaged in opaque bottles. It is also susceptible to auto-oxidation, resulting in the production of hydroperoxides and aldehydes that can give a rancid flavour. Encapsulated FSO is considered more stable, particularly when antioxidants are added (Kolodziejczyk & Fedec 1995).

Eating the seeds versus taking the oil

With the rash of flaxseed-based bakery goods that have arrived on the market in recent years, it is valuable to review the bioavailability and therapeutic potential of such products. A recent study compared the effect of consuming flaxseeds (30 g/day) versus both milled flaxseed (30 g/day) and FSO (6 g/day) over a 3-month period on corresponding blood lipid profiles (Austria et al 2008). These results reveal that while the milled preparation and oil extract produced significant physiological increases in ALA levels (with the FSO producing the largest effect), consumption of the whole seeds did not (Austria et al 2008). Effects in individuals consuming the whole seeds also demonstrated the greatest inter-individual variability, probably related to the degree of chewing each subject performed. Consequently, while the consumption of whole flaxseeds can boost dietary fibre and phytoestrogen content, they do not appear to be a reliable means to supplying ALA.

CHEMICAL COMPONENTS

Flaxseed oil contains several types of fatty acids (FAs). It contains a high concentration of ALA, ranging from 40% to 60%, and is the most concentrated plant source of omega-3 FA identified to date.

FSO also contains unsaturated FAs, such as linolenic acid, linoleic acid and oleic acid. Linoleic acid (LA or C18:2 n-6) and oleic acid each contribute 15% to the total FA content of the oil. Due to the range of FA present, it contains precursors for the

Clinical note — Is FSO equivalent to the fish oils?

FSO has been commercially promoted as the vegetarian or vegan alternative to fish oils, with many of the health benefits ascribed to fish oils also being attributed to the oil. A review of the literature suggests that FSO is unlikely to be equipotent with fish oils in the treatment of a variety of conditions.

The ALA present in FSO can theoretically undergo desaturation and elongation to synthesise eicosapentanoic acid (EPA) and docosahexaenoic (DHA), which are found in fish oil; however, most studies using oral FSO intake demonstrate only moderate increases in EPA and DHA remains unchanged (Allman et al 1995, Arterburn et al 2006, Barcelo-Coblijn et al 2008, Kelley et al 1993, Mantzioris et al 1994, Nestel et al 1997). Although results from one early study suggest that increases in DHA levels may be achieved with long-term supplementation (Cunnane et al 1993), more recent studies fail to confirm this result (Barcelo-Coblijn et al 2008, Harper et al 2006, Hussein et al 2005).

Conversion rates of ALA to EPA and docosapentaenoic acid (DPA) are reported to be < 10% (Harris et al 1997) and approximately 8%, respectively, whereas the DHA yield ranges from 0% to 0.5%. One explanation for this is that DHA synthesis is under separate regulatory control, a hypothesis supported by enzymatic studies (Burdge 2004). Theoretically, therefore, a 20 mL serve of FSO, providing 11.1 g of ALA, would result in a maximum of 880 mg DPA and 5 mg of DHA. A recent study investigating optimal minimal dosing of FSO, however, reported that increased red blood cell omega-3 concentrations are evident at a minimum of 2.4 g/day taken over 2 weeks, with the largest effect seen at the 6–8-week timeframe (Barcelo-Coblijn et al 2008). These authors also report that 1.2 g/day of fish oil produced comparable changes, concluding that FSO or other plant-based ALA sources represent a realistic alternative source of omega-3s and at doses much lower than previously studied.

However, there is marked inter-individual variation in conversion efficacy, even in the face of comparable background diets and some notable gender differences, with resultant DHA typically undetectable in males consuming high-dose ALA (Arterburn et al 2006). Adding to this puzzle is a wide range of other variables that can inhibit the conversion of ALA into its metabolites. For instance, high dietary intake of linoleic acid (LA), common in Western cultures (Arterburn et al 2006, Breslow 2006), inhibits both the uptake of ALA and its conversion to long-chain metabolites due to competition for shared enzymes. An interesting study conducted in 1998, which used radioactively labelled ALA, showed that a diet high in omega-6 fats reduced conversion by 40–50% (Gerster 1998), resulting in 70% net reduction of long chain omega-3 end products (Arterburn et al 2006). This adds weight to the argument that the ratios of FAs may have the primary influence on their resultant health benefits. The authors of this study suggest that the ratio of omega-6:omega-3 should not exceed 4. In contrast, the typical American diet demonstrates an LA:ALA ratio of ≥11.5 (Arterburn et al 2006, Breslow 2006). However, there are authors who refute that the ratios are a major determinant (Goyens et al 2006).

Other studies have reported abnormal or compromised activity of the delta-6 and delta-5 desaturase enzymes in the elderly, diabetics and patients with a variety of metabolic disorders, as well as those individuals with increased dietary intake of saturated fats, *trans*-fatty acids and alcohol (David & Kris-Etherton 2003). Studies using radioisotopes of ALA have revealed significant gender differences in conversion capability, with women demonstrating higher levels of FA metabolites. It is believed that this is due to their higher oestrogen levels, a theory supported by the increased conversion capacity evident in women taking synthetic oestrogens and speculated as representing a physiological adaptation that ensures adequate essential fatty acid (EFA) delivery to the fetus in pregnancy (Burdge 2004).

Finally, it appears that ALA conversion to long chain omega-3 FA is also self-limiting, with high intakes producing significantly increased oxidation and impairing conversion into EPA and DHA (Arterburn et al 2006, Schwab et al 2006). Based on the available evidence, it appears that ALA conversion is relatively inefficient in humans, making ALA a poor means of increasing omega-3 levels (Arterburn et al 2006).

omega-3, -6 and -9 families. Environmental factors can profoundly influence the unsaturated FA composition and ratios (Hall et al 2006). FSO may also contain varying amounts of the lignan, secoisolariciresinol diglycoside (SDG), which is a precursor to enterodiol and enterolactone.

Flax seeds contain 41% fat, 28% dietary fibre, 21% protein and significantly higher amounts of lignans, which behave as phyto-oestrogens (Morris 2001). This review, however, focuses on FSO.

MAIN ACTIONS

The main actions of FSO have been attributed to its high ALA content. ALA is subject to three different metabolic fates: (a) incorporation into structural, transport or storage pools, (b) beta-oxidation as an energy source and (c) elongation and further desaturation to form EPA, DPA and DHA. It appears that all three contribute to the biological effects of this oil.

ALA's direct role in cell membrane structure is likely to be minor, with ALA representing less than 0.5% of the total FA in cell membranes and blood lipids in healthy adults and possessing a limited distribution (e.g. adipose, rectal epithelium, cheek, heart) (Arterburn et al 2006). However, its limited propensity to generate the n-3 metabolites, EPA and DHA, the major FAs in cell membranes, could represent an indirect effect via this mechanism (Burdge 2004).

Studies exploring the metabolism of ALA have revealed that 22% of ALA undergoes beta-oxidation in women and 33% in men. Once broken down the carbon chain can be used as fuel or in the synthesis of cholesterol and other fatty acids such as palmitic, palmitoleic, stearic and oleic acids de novo (Burdge 2004). FSO also influences the eicosanoid production cascade via conversion of the n-3 and n-6 parent FAs in FSO to their respective metabolites.

It is also thought that some of the actions of FSO may be independent of its FA content and can be attributed to the lignan SDG. This has been partly supported by research conducted by Prasad et al in 1998 and again in 1999.

Anti-inflammatory

Metabolites of ALA and LA act as substrates for the formation of the anti-inflammatory eicosanoids, comprising prostaglandins, thromboxanes and leukotrienes (Gerster 1998). ALA suppresses AA production by interfering with the conversion of LA to AA, and reduces the biosynthesis of inflammatory eicosanoids, although not to the same extent as EPA and DHA (Morris 2001). Cytokines, another important group of inflammatory mediators, are generated in response to these eicosanoids and are influenced by changes in the n-3:n-6 ratios in cell membranes (James et al 2000). In one study, ingestion of FSO (equivalent to 13.7 g/day ALA) for 4 weeks by healthy male subjects resulted in a 30% reduction in TNF-alpha, 31% reduction in IL-1-beta, 29% reduction in eicosanoids thromboxane B(2) and 30% reduction in PGE_2 (Caughey et al 1996). In contrast, more recent studies have failed to demonstrate anti-inflammatory effects (Barcelo-Coblijn et al 2008, Paschos et al 2007).

In animal models, ALA has consistently demonstrated eicosanoid-mediated anti-inflammatory effects; however, the magnitude of the effect has been dependent on the levels of both ALA and LA in the diet, duration of use and type of tissue studied (Cunnane & Thompson 1995).

Immune effects

Evidence of ALA deficiency has been reported in patients on prolonged total parenteral nutrition (TPN), which resulted in reduced T-helper cells to below the normal range and impaired proliferation of peripheral blood mononuclear cells. Although supplementation with small doses of ALA corrected these abnormalities, the effect of ALA on human immune cells appears to be paradoxical, with evidence of immune function inhibition at higher doses (≥40 mL/day FSO) (Kelley 1992).

Cardiovascular effects

Because ALA can be converted to long-chain (n-3) PUFA in humans and may potentially reproduce the beneficial effects of fish oils, FSO and ALA have been studied as possible preventive or treatment agents for cardiovascular disease. Epidemiological evidence of secondary coronary event prevention from ALA, in the context of a modified Mediterranean diet, support this premise (Schwab et al 2006). While numerous studies have suggested that FSO and ALA exert a myriad of different mechanisms in the body, which can be beneficial in cardiovascular disease, inconsistent results have meant that much is still unknown and more research is required.

Antithrombotic and antiplatelet activities

The question of whether supplementation with ALA affects platelet aggregation remains unclear. A major determinant appears to be the degree of conversion to EPA (Garg et al 1989). When there is an increase in total EPA and reduced AA, due to ALA inhibition of LA conversion, the result is EPA replacing AA in the cell membrane and a decrease in thromboxane synthesis. In addition, SDG, another component of FSO, is metabolised to enterolactone and enterodiol and these substances may have antiplatelet-activating factor activity. Due to the variable lignan content of FSO, it is difficult to determine the clinical significance of this (Prasad 1999). Studies assessing the actual anti-aggregatory effect of FSO in humans have produced mixed results.

Reduced endothelial inflammation

A number of studies have confirmed that consumption of high-dose FSO reduces endothelium inflammation. One study assessing the cardiovascular effects of a diet in which 6.5% of total kilocalorie intake was contributed by ALA and compared with the Standard American Diet (SAD) showed that the ALA-enriched diet produced a 75% reduction in C-reactive protein, a 19% reduction in cellular adhesion molecule and a 15.6% reduction in vascular cellular adhesion molecule (VCAM) (Zhao et al 2004). An earlier study had reported these findings, demonstrating a 28% reduction in VCAM with additional reductions in soluble E-selectin (17%) (Thies et al 2001).

Lipid-lowering effect

Whole flaxseed is the form most commonly investigated in lipid-lowering studies, because the high fibre content and ALA have been speculated to act synergistically, therefore there are relatively few studies using FSO. Those that have been conducted with FSO have produced conflicting results with an almost 50/50 weighting of research showing no effect (Austria et al 2008, Kaul et al 2008, Harper et al 2006, Schwab et al 2006) or a positive one. At worst, FSO has produced increased fasting triacylglycerol concentrations and lower HDL cholesterol (Bemelmans et al 2002, Finnegan et al 2003, Wilkinson et al 2005). At best, it has been described in earlier studies as having comparable effects with bioequivalent doses of fish oils (Harris 1997, Singer et al 1986). The reality probably lies somewhere in between; however, further investigation is required. The results of a small study of 57 men by Wilkinson et al (2005), who substituted 45 g of fat per day with 15 g/day ALA derived from FSO over 12 weeks, adds to the puzzle. While confirming the mixed cardiovascular effects noted above, this treatment group also demonstrated a reduction of total cholesterol by 12.3% in comparison to a

reduction of 7.3% in the group receiving equivalent LA. While another study comparing the effects of an ALA-rich (6.8 g/day) versus EPA/DHA-rich (1.6 g/day) diet in mildly hypercholesterolaemic elderly subjects over 6 weeks revealed improved lipid responses in the ALA than the EPA/DHA group (Goyens & Mensink 2006).

The same equivocal trend is evident from studies assessing the effects of FSO on lipoproteins. Zhao's trial (2004) using an ALA-enriched diet produced a reduction in apolipoproteins A1 and B, the latter by almost 10%, however, more recent studies administering 3 g+/day of ALA from FSO over 6–26 weeks failed to demonstrate any effect on lipoprotein particle or size concentrations (Goyens & Mensink 2006, Harper et al 2006b). In spite of these seemingly disappointing findings, some researchers note that preventative effect against cardiovascular morbidity associated with increased ALA consumption in the substantial Lyon diet study, was not accompanied by cholesterol changes and therefore may point to an alternative mechanism (Kaul et al 2008).

Antiarrhythmic

Three recent studies have identified an antiarrhythmic effect mediated by ALA (Albert et al 2005, Ander et al 2004, Christensen et al 2005), although one meta-analysis concluded otherwise (Matthan et al 2005). Although the majority of research has been conducted in animals, one of the most interesting human trials involved 106 women with a mean age of 59.5 years referred for coronary angiography due to suspected coronary artery disease. Following adipose sampling for ALA levels and monitoring of 24-hour heart rate variability (HRV), it was concluded that a positive and independent association was present between ALA in adipose tissue and HRV, which was even stronger in smokers (Christensen et al 2005).

Antiatherogenic

Earlier positive findings and recent promising epidemiological data have been substantially challenged by RCTs of FSO in atherosclerosis. Following earlier positive outcomes in cardiovascular disease trials with whole flaxseed, a 1999 study showed that a low-ALA variety could produce comparable results with the earlier trials, suggesting that the antiatherogenic properties of flaxseed are independent of its ALA content (Prasad 1999).

More recent large-scale epidemiological studies continue to suggest a relationship between higher ALA intake and reduced coronary artery calcification (Djousse et al 2005); however, there is ongoing criticism that important variables have not been sufficiently accounted for, such as corresponding reductions in *trans*-FAs (Harris 2005, Wilkinson et al 2005).

Antiproliferative

ALA has demonstrated the capacity to inhibit tumour progression in animal models of mammary tumour (Chen et al 2002, Cognault et al 2000); however, the clinical significance of these findings needs to be examined further. An immunostimulant action, which is both eicosanoid and non-eicosanoid mediated, has been suggested as one possible mechanism of action. Another theory suggests that through ALA's competitive inhibition of LA, tumour cells may not receive sufficient LA, which would inhibit further cell growth (Johnston 1995). It is interesting to observe that higher dietary ALA intake is associated with a reduction in cancer deaths; however, this is not seen with higher EPA/DHA intakes, suggesting that the protective effect is not reliant on the conversion of ALA to EPA/DHA (Cunnane 1995). In addition, results from epidemiological studies show an association between low ALA consumption in humans and increased cancer deaths in general (Dolecek 1992).

Animal studies testing SDG and its metabolites from the seeds have produced promising results and suggest that they may act as selective oestrogen receptor modulating agents and therefore play a protective role against oestrogen-dependent cancers (Kitts et al 1999, Wang et al 2005).

Hypotensive

The mechanism for ALA's potential hypotensive action remains to be elucidated and in light of the bulk of negative findings, more researches to support these current results are necessary (Paschos et al 2007).

Insulin sensitising

Preliminary animal studies suggested a protective role for ALA against the development of insulin resistance and an ability to counter the associated oxidative stress (Ghafoorunissa & Natarajan 2005, Suresh & Das 2003). However, a series of clinical trials examining high-dose FSO in patients with type 2 diabetes failed to demonstrate any positive effect on glycaemic control (Barre et al 2008, Schwab et al 2006).

CLINICAL USE

Reduced mortality in coronary heart disease

The most likely mechanism by which ALA may prevent coronary heart disease (CHD) mortality is by reducing cardiac arrhythmia. In Western populations, almost 50% of all deaths from cardiovascular disease can be attributed to sudden cardiac death and the majority of sudden deaths are directly caused by acute ventricular arrhythmia (Brouwer et al 2004). A review in 2001 (Lanzmann-Petithory 2001) and a meta-analysis of three studies in 2004 (Brouwer et al) both found in favour of a protective effect from increased ALA consumption against fatal CHD (RR 0.24). The dose associated with this trend was small; only 1–3 g/day ALA higher than controls (Brouwer et al 2004). A study published in 2005, which derived data from the Nurses' Health Study (Albert et al), found that women consuming ALA in the highest two quintiles had a 38–40% lower risk of sudden cardiac death than women in the lowest quintile; however, the protective effect did not extend to other fatal forms of CHD or non-fatal myocardial infarction.

Much criticism has been directed at those researchers wanting to extrapolate prescriptive advice from these findings. An editorial by Harris (2005) notes that only one primary prevention study with ALA in CHD has been conducted and that was in the 1960s. The 1-year trial involved 13,578 Norwegian men and compared 10 g of FSO (providing 5.5/day ALA) with a sunflower seed placebo. In the analysis, there was no demonstrable difference in end points between the two groups. Recent attempts to explain this lack of effect, such as high baseline n-3 consumption by this population, appear to be well founded (Mozaffarian et al 2005).

There is an urgent need for RCTs using FSO in suitable populations to clarify the relationship between ALA and CHD mortality.

Anticlotting

There have been a surprising number of studies investigating the influence of ALA from FSO on coagulation and fibrinolysis, and enormous variation in results. Methodological issues have plagued the overall quality of evidence, with small sample sizes, inconsistent methodologies and diverse sample characteristics making interpretation difficult.

One early study compared different dietary ratios of n-6 and n-3 EFAs in relation to prostanoid production in a group of normolipidaemic men (Kelley et al 1993). The high ALA dietary intervention constituted an overall n-6:n-3 ratio of 2.7 versus control ratio of up to 27.4. Following the 18 days of the intervention, groups showed significant differences in measured outcomes, notably, that 6-keto-$PGF_{1\text{-alpha}}$ was significantly higher following the high ALA diet but no evidence of significant effect on bleeding time or thromboxane B2 production. A second study published in the same year also failed to show an effect on clotting; however, the dose of FSO used was only 4.3 g/day (Kelley et al 1993). In contrast, the results of a study using a much larger dose of 40 g/day of FSO over 23 days in 11 healthy men showed that FSO significantly reduced collagen-induced aggregation response when compared to 40 g/day sunflower seed oil (Allman et al 1995).

A follow-up study of 29 healthy males that was conducted over 6 weeks investigated the effects of a diet in which approximately 7% of the total kilocalories from polyunsaturated fat was made up of either an ALA-rich (n-3:n-6 = 1:1.2) or LA-rich diet (n-3:n-6 = 1:21). The ALA-enriched diet resulted in triple the EPA phospholipid levels compared to the LA-enriched diet, but had no demonstrable effect on coagulation or fibrinolysis, other than an increase in the ratio of activated protein C. The authors speculated that the latter finding may still prove significant, but suggest that future studies should be conducted in patients with vascular pathology, as healthy clotting profiles may have obscured the true effects of FSO (Allman-Farinelli et al 1999).

In the same year, another group of Australian researchers published the results of their study of 17 vegetarian men who were assigned to either a low- or a high-ALA diet (derived from FSO) for 28 days following a run-in baseline diet for 14 days. Again there were no significant differences in prothrombin time, activated partial thromboplastin time or plasminogen activities with the different ALA diets, despite increases in EPA and DPA levels (Li et al 1999).

Since 1994, Mutanen and Freese have conducted many studies assessing the effect of ALA and LA:ALA ratios on haemostatic factors (Freese et al 1994, Freese & Mutanen 1997, Mutanen & Freese 2001). Their 1997 study was the largest and involved a sample of 46 subjects who were given FSO to provide 5.9 g/day ALA or a fish/sunflower oil combination equal to 5.2 g/day EPA/DHA over 4 weeks. Extensive analysis of the sample throughout the intervention, as well as at the 12-week follow-up, revealed no difference in collagen-induced platelet aggregation, thromboxane production or bleeding time between the two groups, suggesting equivalent anticoagulant effects for FSO and fish oil when consumed in comparable quantities. This was despite smaller increases in EPA levels in the platelets of the subjects taking FSO.

The largest and most recent trial (Finnegan et al 2003) compared the effects of small increases in ALA (4.5 or 9.5 g/day) and EPA and DHA (0.8 or 1.7 g/day EPA + DHA) intake on blood coagulation and fibrinolytic factors over 6 months. The randomised, placebo-controlled, parallel study of 150 moderately hyperlipidaemic subjects found no significant differences in coagulation or fibrinolysis for any intervention.

Currently, the evidence is equivocal, but may indicate a minor antiaggregatory role for FSO in high doses. Further research, with more heterogeneous designs, is required to form any valid conclusion.

Endothelial function

In one 12-week study of healthy subjects aged 55–75 years, low levels of ALA (equivalent to approximately 5 mL/day of FSO) were shown to decrease some markers of endothelial activation (Thies et al 2001). More specifically, ALA decreased the plasma concentrations of soluble VCAM-1 by 16% and soluble E-selectin by 23%.

High blood pressure

In spite of a large number of studies which failed to demonstrate a relationship between ALA intake and blood pressure, a recent prospective trial, administering 8 g/day of ALA from FSO to middle-aged dyslipidaemic men over 12 weeks, produced a significant reduction in median blood pressure readings of 3–6% (≈5 mmHg) when compared to a similarly high intake of LA from safflower oil (Paschos et al 2007). The clinical significance of this result is questionable.

Lipid-lowering

The largest and most recent trial involved over 150 moderately hyperlipidaemic patients in a double-blind, placebo-controlled, 5-arm parallel design conducted over 6 months. Two groups received FSO at different doses (equivalent to 4.5 g/day and

Clinical note — Are vegetarians at risk of omega-3 deficiency?

Omnivores can obtain n-3 long-chain PUFAs in two ways: from the partial conversion of dietary ALA or directly through the consumption of fish, eggs or animal products (Li et al 1999). Lacto-ovovegetarians obtain n-3 EFAs from the conversion of plant-based ALA and a limited amount of preformed EPA and DHA from milk, dairy products and eggs; however, their EFA content is highly dependent upon animal diets. In contrast, strict vegetarians and vegans are at risk of inadequate n-3 EFA, DHA and EPA intake because they are solely reliant on plant-based ALA, which has poor conversion to n-3 EFA metabolites in the body and they have no dietary intake of preformed DHA or EPA.

This has been demonstrated in studies in which lower plasma and platelet levels of n-3 EFAs have been identified in vegetarians compared with omnivores, together with lower EPA and DHA levels (Arterburn et al 2006). For vegetarians and vegans, increased consumption and conversion of ALA has been proposed as a strategy to ensure omega-3 adequacy; however, the evidence to date suggests that this is not effective (Burdge 2004, Phinney et al 1990).

Average daily intake of ALA has been estimated at 1.3–1.5 g in the general population and may be lower in vegetarians and vegans. Based on current conversion calculations, general consumption levels already fall short of EPA and DHA requirements. Studies investigating increased ALA consumption at 9.5 g/day, the equivalent of approximately 17 mL FSO, found this increased EPA and DPA, yet failed to improve DHA concentrations, which further proves that ALA is not an effective substitute for animal-derived omega-3 EFAs (Burdge 2004).

To complicate matters, there is evidence suggesting that high intakes of ALA downregulate the delta-6-desaturase enzyme, therefore inhibiting its own conversion (Arterburn et al 2006, Gerster 1998). Vegetarian diets are also notoriously rich in the n-6 EFA, LA, which if consumed in significantly higher quantities than omega-3 will further retard conversion of ALA (Kris-Etherton & Skulas 2005). Alternatively, background omega 3 deficiency has been speculated to improve conversion efficacy, making vegetarians and vegans potentially superior converters (Arterburn et al 2006).

Vegans and vegetarians are recommended to consume additional sources of ALA, such as algae, that may contain some preformed EPA and DHA in an attempt to reduce risk of deficiency (Kris-Etherton & Skulas 2005, Li et al 1999).

9.5 g/day of ALA), two groups received bioequivalent levels of EPA/DHA and one group received LA and served as a control group. Although the higher ALA dose induced comparable changes in serum and cell membrane EPA levels to the fish oil group, ALA failed to significantly lower lipid levels, whereas EPA and DHA reduced triacylglycerides (Finnegan et al 2003).

Alternatively, a shorter study of only 2 weeks supplementing with much higher doses of FSO (60 mL/day) or sunflower oil or 130 g/day of mackerel in hypertensive males produced positive results. Subjects taking either FSO or consuming fish experienced an equal decrease in serum triglycerides, total cholesterol and LDL cholesterol (Singer et al 1986). Interestingly, FSO intake resulted in only marginal increases in EPA levels, suggesting that lipid-lowering activity is not reliant on conversion to EPA.

One possible explanation for this comes from the results of a number of trials conducted by Prasad (Prasad 1997, 1999, Prasad et al 1998), who investigated low-ALA FSO and later isolated extracts of the lignan SDG and found significant lipid-lowering effects in animal models. In rabbits, administration of the lignan at high doses produced significant changes to blood lipids, including a 33% reduction in total cholesterol, 35% reduction in LDL cholesterol and an astonishing increase of over 140% in HDL cholesterol by week 8 (Prasad 1999). As exciting as these results are, it is difficult to determine the clinical significance of these findings because the lignan content of FSO is variable. It is possible that the high dose of FSO (60 mL/day used by Singer 1986) contained a substantial amount of SDG, which could explain the effects seen; however, this is speculation.

Insulin sensitivity/metabolic syndrome

It has been proposed that FSO may be of benefit in insulin resistance (IR) based on its possible cardioprotective activities; however, direct evidence of improved insulin sensitivity remains elusive. One small study published in 1997 demonstrated improved systemic arterial compliance in 12 subjects with suspected IR, fed a high dose of ALA over 12 weeks, although an additional finding in this study was evident of slight deterioration in insulin sensitivity (Nestel et al 1997). Another study using relatively low-dose FSO (1.7 g/day ALA) in normoglycaemic adults found no changes in glycaemic response (Curran et al 2002). However, a series of more recent clinical trials examining high-dose FSO in patients with type 2 diabetes failed to demonstrate any positive effect on glycaemic control (Barre et al 2008).

Anticancer effects

Breast and colon cancer

Bougnoux et al (1994) made an important observation when they demonstrated an inverse relationship between ALA levels in breast tissue and risk of lymph node involvement and visceral metastases in breast cancer. This has been followed up with larger studies of similar design (Klein et al 2000, Maillard et al 2002) and one meta-analysis, all yielding comparable results (Saadatian-Elahi et al 2004). The data indicate that those women with the highest breast tissue concentrations of ALA have a relative

risk of breast cancer between 0.36 and 0.39, while other FA levels fail to exhibit a statistically significant relationship. Interestingly, an epidemiological study has identified an association between low consumption of ALA in humans and increased cancer deaths in general (Dolecek 1992). Currently, the only evidence from interventional studies using FSO as a chemoprotective agent is provided by animal trials, which demonstrate that dietary FSO is effective in preventing colon tumour development and malignant mammary tumours (Dwivedi et al 2005).

Prostate cancer

There is much debate surrounding research into the hypothesised link between ALA and the risk of prostate cancer. Giovannucci, a prolific prostate cancer researcher, has contributed to numerous papers on this topic, deriving data from large epidemiological or prospective cohort studies, including The Health Professionals Follow-Up, The Physician's Health Study and the Alpha-Tocopherol, Beta-Carotene Cancer Prevention Study (Gann et al 1994, Giovannucci et al 1993, Leitzmann et al 2004, Mannisto et al 2003). The conclusions oscillate between a positive independent association between increased ALA intake and prostate cancer risk (Gann et al 1994, Giovannucci et al 1993, Leitzmann et al 2004) to no significant association (Mannisto et al 2003). Further support of ALA as a risk factor has come from a large Norwegian epidemiological study (Harvei et al 1997), a review by Astorg (2004) and a meta-analysis by Brouwer et al in 2004. Although the majority of published data appear to implicate ALA as a prostate cancer risk factor, it is worthy of note that none of the trials were interventional and many rely exclusively on food frequency questionnaires rather than independent biochemical indices of ALA. Other researchers have also presented sound arguments against this theory, such as those articulated by de Lorgeril and Salen (2004), which query the quality of evidence being considered, the exclusion of trials that demonstrated minor risk reduction with increased ALA intake (Schuurman et al 1999) and other weaknesses of the study designs. Additional criticisms include the lack of distinction in the sources of dietary ALA, with red meat, an independent risk factor for prostate cancer, being a major dietary source of ALA in some studies (Brouwer et al 2004). Until interventional trials are conducted, a resolution on the matter is not possible.

DOSAGE RANGE

- Anticlotting: 5.9 g/day ALA.
- Improved endothelial function: 2 g/day ALA.
- Lipid-lowering: 60 mL/day FSO.
- Reduced CHD mortality: 1–3 g/day ALA.

A key consideration with FSO supplementation is product quality. Due to the high potential for FSO to become oxidised, ingestion of inadequately manufactured or preserved FSO could result in higher intakes of peroxides. It is recommended that only refrigerated FSO packaged in opaque containers be used. Once opened, the product should be consumed within a few weeks of opening and kept stored in the fridge.

ADVERSE REACTIONS

FSO may cause loose stools and gastrointestinal distress in some individuals (Austria et al 2008). There is a report of an allergic reaction to FSO, with a 40-year-old woman experiencing ocular pruritis and weeping followed by generalised urticaria and nausea, and vomiting within 10 min of taking a spoonful of linseed oil. A subsequent skin prick test produced a positive response to linseed. It remains unclear, however, whether this patient consumed FSO or linseed oil, which is denatured and unfit for human consumption (Alonso et al 1996).

SIGNIFICANT INTERACTIONS

None known.

CONTRAINDICATIONS AND PRECAUTIONS

- Hypersensitivity to flaxseed/linseed
- Prostate cancer

There are a number of studies that link increased ALA intake with a higher risk of prostate or aggressive prostate cancer. Although the evidence is preliminary and widely debated, it is recommended that at-risk individuals avoid high-dose consumption of FSO and only consume FSO that is packaged in opaque containers and refrigerated.

PREGNANCY USE

There is no evidence to suggest safety concerns.

PRACTICE POINTS/PATIENT COUNSELLING

- Good quality, cold-pressed FSO is a good source of the essential fatty acid ALA, which is often deficient in the Western diet. Capsules are more stable than the bottled oil which must be stored in a dark bottle, refrigerated after opening and consumed within a few weeks.
- The polyunsaturated fatty acids found in FSO, particularly ALA, are precursors of eicosanoids and influence many important physiological processes. Additional actions may be attributed to the variable amount of lignan present in FSO, but which is found in higher concentrations in the actual seed.
- FSO has demonstrated anti-inflammatory, immunological, minor antiplatelet and chemopreventive effects and a range of beneficial actions within the cardiovascular system; however, large RCTs are still required to determine the role of FSO in clinical practice.
- FSO is not an adequate substitute for animal sources of n-3 EFAs. Most studies of oral FSO demonstrate only moderate increases in EPA, while DHA remains unchanged. Strict vegetarians and vegans using FSO as n-3 EFA substitute may be at risk of EPA and DHA deficiency.
- There is some evidence to suggest that daily ingestion of an additional 1–3 g of ALA (equivalent to 5 mL FSO) may reduce the incidence of some cancers and coronary heart disease mortality; however, this remains speculative.

PATIENTS' FAQs

What will this supplement do for me?

Regular consumption of flaxseed oil, in the presence of balanced linoleic acid (omega-6) intake, may reduce cardiovascular mortality and possibly reduce the risk of some cancers; however, this remains speculative.

When will it start to work?

This will depend on the dosage taken and indication for use.

Are there any safety issues?

Long-term high doses may compromise immune function in susceptible individuals.

Preliminary evidence suggests a possible link between high ALA intake and increased risk of prostate cancer; however, this is controversial.

Folate

HISTORICAL NOTE Folic acid was isolated from spinach leaves in 1941 and synthesised in 1946; hence, its name comes from the Latin *folium*, which means leaf.

BACKGROUND AND RELEVANT PHARMACOKINETICS and CHEMICAL COMPONENTS

Folate is the generic term for a large family of chemically similar trace compounds that fall within the vitamin B group. Folate, also known as folacin and vitamin B_9, is frequently referred to as folic acid (pteroylmonoglutamic acid or PGA). This is the most oxidised and stable form and the one characteristically used in supplements and food fortification. Folate found in animal sources is present in a 'free form' and is readily absorbed; however, aside

Clinical note — A challenge to the perceived safety and superiority of synthetic folic acid?

Given its relative stability in processing and enhanced bioavailability, synthetic folic acid in food fortificants and supplements has long been regarded as more reliable than natural dietary sources for ensuring folate adequacy (Kelly 1998). This, in turn, has led to widening implementation of mandatory folate fortification programs aimed at the prevention of neural tube defects (NTDs). Recently, however, the safety of increased exposure to synthetic folic acid has been thrown into question. Individuals who consume high doses (≥ 400 μg/day) exhibit unmetabolised folic acid in their blood, a form that does not naturally occur in human physiology (Kelly 1998, Lucock 2004, Lucock 2006, Sauer et al 2009, Smith et al 2008, Sweeney et al 2007, Troen et al 2006, Wright et al 2007). While this will eventually be hepatically converted into a natural folate derivative, there is speculation regarding the interim effects, with evidence of competition between the unmetabolised folic acid and the main active folate form methyl-THF at receptors and their subsequent down-regulation on cell surfaces (Sauer et al 2009, Smith et al 2008). Particular at-risk groups identified by researchers include those individuals taking anti-folate medications, folate-replete cancer patients and elderly patients with B_{12} deficiency (Smith et al 2008, Wright et al 2007), while others question the long-term safety for the unborn fetus (Kelly 1998). Until further research is conducted in this area, the implications, however, remain unclear.

from the organ meats, animal products are notoriously poor sources. Folate found in plant foods exists in conjugated forms, which require deconjugation by zinc-dependent enzymes in the gut prior to absorption. (Kelly 1998). This step is inhibited by chronic alcohol ingestion and some foods, including oranges and legumes (Gropper et al 2009). Secondary to this difference, the average bioavailability of natural folate is half that of the synthetic form (e.g. 55–66% versus ≈ 100% (Carmel et al 2006, Kelly 1998). Small amounts of folate are endogenously produced by bacteria in the intestines, but this appears to be predominantly lost via the faeces (Gropper et al 2009).

Dietary folate and synthetic folic acid, alike, then undergo complex conversion into folate's active forms, e.g. tetrahydrofolate (THF). This occurs via a multistep pathway now proposed to occur solely within the liver (Wright et al 2007). In contrast, a less common supplemental form of folate — folinic acid (5-formyltetrahydrofolate or 5-formylTHF), as an intermediate folate metabolite, bypasses some of these steps to readily form 5,10-methylenetetrohydrofolate (5,10-formylTHF) (Kelly 1998, McGuire et al 1987, Priest et al 1991).

Secretion into the bile of the THF derivatives and their subsequent reabsorption through the enterohepatic circulation enable redistribution throughout the body. Distribution of folate appears to be regulated via an unknown mechanism, ensuring increased availability to those tissues demonstrating rapid cell division (Gropper et al 2009). Although many of the biochemical pathways in which folate is involved act to regenerate the nutrient, there is still a significant amount that is broken down and eliminated, chiefly in the urine.

FOOD SOURCES

Good dietary sources are fresh green leafy vegetables, such as cabbage and spinach, asparagus, broccoli, sprouts, mushrooms, legumes, nuts and fortified cereals and organ meats.

Food preparation and processing can destroy up to 100% of the naturally occurring folate, as it is sensitive to light and air but especially heat; therefore, raw foods, as well as fortified foods,

Clinical note — Food fortification with folate: still not enough for pregnant women?

In 1997, voluntary folic acid fortification of foods was introduced in Australia and New Zealand to improve the folate status, particularly of pregnant women. Following this, a study evaluating mean serum folate levels in over 20,000 Australian women aged 14–45 years found that although concentrations had increased by 19%, the prevalence of poor folate status in this age group had only reduced from 8.5% to 4.1% (Metz et al 2002). Several state-based studies since 1997 have shown a variety of improvements in a range of measures, including folate awareness and supplementation rates amongst Australian women (Chan et al 2008, du Plessis et al 2008, Hickling et al 2005) and corresponding reductions in NTD births have varied from 17% to 40%; however, some researchers suggest that this decrease occurred in the first 2 years following fortification and the launch of awareness campaigns, and that there has been no further reduction since this time (du Plessis et al 2008).

Although fortification programs, including the recently introduced mandatory fortification of bread flour in Australia and New Zealand (FSANZ 2007), provide some measure of protection for women of reproductive age, supplementation is still required. Unfortunately, widespread public health campaigns have had limited success and many women remain unaware of the need to take supplements prior to pregnancy, or are aware but still fail to use supplements (du Plessis et al 2008, Metz et al 2002). In Australia, only 36% and 46% of new mothers in Victoria and New South Wales, respectively, took folate supplements in 2006, with even lower rates reported for women of low socio-economic or non-English speaking backgrounds (Watson et al 2006) and women aged 20–24 years. The last group also experiences the highest rate of NTD births (du Plessis et al 2008).

are considered superior sources, which in Australia provide 100 μg per serve (Gropper et al 2009, Hickling et al 2005).

DEFICIENCY

Folate deficiency is not uncommon and can develop within only 4 months of an inadequate diet (Carmel et al 2006, Gropper et al 2009, Wilson et al 1991).

In light of folate's fundamental role in DNA synthesis, deficiency of this nutrient will predictably impact most on those cells and tissues that exhibit a high turnover (e.g. blood and the cells in the gastrointestinal tract), which also applies to those stages of development with increased rates of growth, such as pregnancy and fetal tissue development.

Signs and symptoms of deficiency

- Macrocytic/megaloblastic anaemia
- Fatigue
- Psychological symptoms such as irritability and depression (Reynolds 2002)
- Headache
- Hair loss
- Nausea
- Insomnia (Pelton et al 2000)
- Peripheral neuropathy
- Tendon hyperreflexivity
- Diarrhoea
- Weight loss
- Cerebral disturbances (Botez 1976), cerebral cortex atrophy and cognitive decline
- Increased blood levels of homocysteine

Primary deficiency

This develops in response to inadequate dietary intake and can be caused by a diet generally lacking in fresh, lightly cooked vegetables. Risk is increased in patients with *MTHFR* gene polymorphisms, in people receiving total parenteral nutrition (TPN), chronic alcoholics, phenylketonuria patients on restricted diets, patients with sickle cell anaemia and the institutionalised elderly (Carmel et al 2006, Wahlqvist 2002).

Folate enzyme polymorphisms

Single allele substitution in the gene encoding for the *N*5,10-methylenetetrahydrofolate reductase enzyme, responsible for converting folate into its methylated 'active' form, results in several possible polymorphisms. Individuals who are homozygous for the *MTHFR* C677T polymorphism (2–16% white populations) convert the active folate form at only 30% of the normal capacity, while the *MTHFR* A1298C genotype produces an enzyme with 60% of the unaffected enzyme activity (Gilbody et al 2007). Homozygotes for either polymorphism are at a significantly increased risk of folate deficiency and cannot maintain adequacy with recommended dietary intake levels (NHMRC 2006).

Secondary deficiency

Secondary deficiency is caused by compromised absorption, increased excretion or increased demands or losses. Inadequate absorption can occur in malabsorption syndromes such as coeliac and Crohn's disease, with long-term use of certain medications such as phenytoin, sulfasalazine, cimetidine, antacids and oral contraceptive pill (OCP), in congenital malabsorption states and in blind loop syndrome (Beers & Berkow 2003), especially when combined with suboptimal dietary intake (Carmel et al 2006). Significantly impaired absorption has also been observed in HIV patients (Revell et al 1991).

Besides impaired absorption, inadequate use can occur with concurrent vitamin B12 or C deficiency, smoking (Gabriel et al 2006) or acute or chronic alcoholism (Hamid & Kaur 2007). A genetic variation in folate requirement has also been identified, as a congenital enzyme deficiency exists in approximately 13% of the Western population (Ma et al 1996). In these cases, total or partial absence of the enzyme responsible for the final step in converting folate to its major active metabolite (methylenetetrahydrofolate reductase) results in decreased plasma levels (Kumar & Clarke 2002). Therefore, these individuals have a higher folate requirement than others without this congenital enzyme deficiency and display increased susceptibility to folate deficiency.

A number of pharmaceutical drugs, such as folic acid antagonists (e.g. methotrexate), can affect status by interfering with absorption, use and conversion to its active forms. In such cases, oral folic acid supplements are sometimes given to reduce side effects, although it may marginally reduce drug efficacy (Kumar & Clarke 2002, Strober & Menon 2005).

Additionally, there are several subpopulations with increased demands for folic acid, such as pregnant and lactating women, the elderly and patients with malignancies, haemolytic anaemias such as sickle cell disease, chronic exfoliative skin disorders, or achlorhydria (Gropper et al 2009). Extra losses have also been reported in haemodialysis patients.

MAIN ACTIONS

Folate's actions are all secondary to its ability to donate methyl groups and its central role, therefore, in one-carbon metabolism.

Coenzyme

As a key methyl donor, folate is involved in a variety of reactions important for the metabolism of amino acids and nucleic acids.

DNA and RNA synthesis

Folate plays an essential part in the production of purines and pyrimidines that make up DNA, making it a critical nutrient in relation to cell division and repair of genetic material, and is generally required for genomic stability. Subsequently, folate plays an indirect role in the synthesis of transfer RNA.

Production of the active form of B_{12}

Folate and B_{12} are intrinsically linked; for example, the conversion of B_{12} into methylcobalamin is dependent upon the presence of a THF derivative.

Reduction of homocysteine levels

Folate, via B_{12} activation, donates a methyl group to homocysteine facilitating its recycling back to methionine. Together with vitamin B_6, necessary for homocysteine catabolism, folate effectively lowers homocysteine levels.

Synthesis of S-adenosyl-l-methionine (SAMe)

Following regeneration of methionine from homocysteine, the methyl group donated by folate is then taken up by SAMe, enabling it to become a carbon donor in multiple transmethylation reactions throughout the body, including neurotransmitter synthesis (Hendler & Rorvik 2001).

Amino acid metabolism

Folate is involved in the synthesis of some of the non-essential amino acids such as serine and glycine. It is also required for the conversion of histidine into glutamate (Gropper et al 2009).

CLINICAL USE

The conditions for which folate is indicated as a potential treatment are primarily due to an existing deficiency, through either primary or secondary pathways. Research has focused particularly on those conditions in which folate deficiency is a consequence of medication use and the benefits of improved folate status.

Prevention and treatment of deficiency

Commonly, folic acid supplements are used to correct identifiable deficiency states, such as macrocytic anaemia, or given as preventative treatment to those patients at risk of deficiency, such as in malabsorption syndromes or taking long-term folate antagonist medication. Increased oral intake of folate has been found to be effective even in cases of malabsorption due to the passive diffusion evident with pharmacological doses (Carmel et al 2006).

Preconception and during pregnancy

Poor folate status either 1 month before conception or during the first pregnancy trimester is an independent risk factor for NTD in the newborn. One study has suggested that the increased risk could be as high as 10-fold (Daly et al 1995).

Intervention trials for pregnancy have routinely used 400 μg folic acid/day; however, there is some suggestion that routine ingestion of only 100 μg folate from fortified food would prevent the majority of NTDs. Studies have also been conducted on women with a previous NTD birth, with benefits demonstrated at doses of 4 mg/day. There is a general consensus among researchers and health authorities that due to the inconsistent nature of natural food sources, taking a supplement or incorporating fortified foods is the most reliable way to increase levels sufficiently (Cuskelly et al 1996). A maternal red blood cell folate concentration > 906 nmol/L is thought to be optimal for lowering risk (Pietrzik et al 2007).

Our understanding of the consequences of folate inadequacy during pregnancy has progressed significantly recently, with the ongoing attribution of other birth defects including Down syndrome (Eskes 2006) and cleft lip and/or palate (CL/P) (Blieka et al 2006, Badovinac et al 2007, Boyles et al 2008, Chevrier et al 2007, Johnson & Little 2008). While increased dietary folate does not appear to convey protection against CL/P (Johnson & Little 2008), one meta-analysis of five prospective studies revealed that folic acid supplementation resulted in risk reduction of 0.55 for all types of cleft presentations (Badovinac et al 2007). Interestingly, several studies have failed to demonstrate a significant relationship between the *MTHFR* C677T genotype and CL/P (Boyles et al 2008, Chevrier et al 2007); however, this may be confounded by concurrent folic acid supplementation in some individuals.

Higher folate levels are linked to the prevention of miscarriages, decreased risk of intrauterine growth retardation, increased birth weight in the offspring of smoking mothers (Sram et al 2005) and increased rates of twin pregnancies, from both natural and in vitro fertilisation (IVF) conception (Haggarty et al 2006).

OCP-induced folate deficiency

Long-term use of the oral contraceptive pill (OCP) (>5 years) has historically been associated with a progressive decrease in serum folate levels, of up to 40%, which could feasibly result in changes to cognition and mood, increased risk of macrocytic anaemia and increased risk of NTD in newborns once use has ceased. Results from recent studies suggest this last concern may be unfounded (Lussanaa et al 2003, Sütterlin et al 2003).

There are a number of proposed mechanisms for folate depletion with OCP use, including concurrent depletion of B_{12}, which is involved in the regeneration pathway of THF (Bielenberg 1991), and impaired folate resorption (Sütterlin et al 2003).

Hyperhomocysteinaemia

Together with vitamins B_{12} and B_6, folic acid has been shown to reduce high plasma levels of homocysteine (Hcy). Of the three, folate appears to have the strongest effect (Voutilainen et al 2001). Although elevated Hcy has been implicated as a risk for cardiovascular disease (including atherosclerosis and coronary artery disease), cerebrovascular disease, peripheral vascular disease and venous thromboembolism (Clarke et al 1991, den Heijer et al 1996, Malinow et al 1989, Selhub et al 1995), exudative age-related macular degeneration (Nowak et al 2005), noise-related hearing loss (Gok et al 2004), cognitive dysfunction, posttraumatic stress disorder (Jendricko et al 2008), breast cancer incidence in post-menopausal women (Gatt et al 2007) and adverse pregnancy outcomes (Bjorke Monsen & Ueland 2003) including postnatal depression (Behzadi et al 2008), clinical trials are ongoing to determine the clinical relevance of these associations.

Bone health and fracture risk

Elevated Hcy has been identified as a strong risk factor for osteoporotic fractures (Abrahamsen et al 2006, Green et al 2007, McLean et al 2008, Rejnmark

et al 2008). While a significant association between the *MTHFR* C677T polymorphism and fractures has also been demonstrated, this is only significant when coupled with low reported intake of folate, B_{12}, B_2 and B_6 (Abrahamsen et al 2006). This has led some researchers to conclude that the response rate to folate treatment amongst an osteoporotic population is likely to be as little as 2% (Abrahamsen et al 2006). This may explain the lack of positive effect on bone turnover seen in a randomised controlled trial (RCT) of hyperhomocysteinaemic (> 15 mmol/L) older patients treated with 1 mg folate, 500 μg B_{12} and 10 mg B_6 treated for 2 years, in spite of significant Hcy lowering (Green et al 2007).

Cardiovascular protection and treatment

In spite of two early meta-analyses which concluded that risk of ischaemic heart disease could be reduced by 16% following a decrease in Hcy of 3 mmol/L (Homocysteine Study Collaboration 2002, Wald et al 2002), there are few folate interventional studies in established hyperhomocysteinaemic cardiovascular populations and recent studies have produced mixed findings. An interesting trial investigating the benefits of combined B vitamins (5 mg folic acid and high-dose B complex, both administered twice weekly) to patients with a history of cardiovascular events has revealed that those participants whose Hcy decreased within the first 3 months demonstrated significantly reduced cardiovascular risk over the next 5 years; however, no protection was conveyed for slower responders (Siragusa et al 2007). While another small study of B vitamins in hyperhomocysteinaemic elderly subjects failed to improve blood pressure (McMahon et al 2007), elevated Hcy secondary to impaired kidney function in this population group cannot be excluded as a confounding variable.

Alzheimer's dementia and impaired cognitive function in the elderly

Findings such as the prevalence of folate deficiency in the elderly, increasing Hcy levels with age, evidence of an inverse relationship between total plasma Hcy levels and cognitive function, and preliminary evidence of correlation between Hcy and plasma amyloid peptides levels in Alzheimer patients (Aisen et al 2008) have attracted attempts to link the phenomena, providing an explanation for neurodegenerative disorders.

In spite of this, and a large number of investigations of B vitamins, very few have restricted participation to only hyperhomocysteinaemic individuals, which may partly explain their negative findings. The Folic acid and carotid intima-media thickness (FACIT) trial, however, administered 800 μg/day over 3 years to participants with elevated baseline Hcy (≥ 13 mmol/L), producing a mean increase in serum folate of 576% and 26% reduction in plasma Hcy (Durga et al 2007). Treated subjects demonstrated significant improvements in three of the six cognitive testing domains (memory; information processing speed and sensorimotor speed), leading the authors to conclude that folic acid is an effective agent for improving cognitive function that tends to decline with age.

In patients with organic brain disease including Alzheimer's and vascular dementia, again only one study has restricted participation to hyperhomocysteinaemic individuals, administering 5 mg folic acid together with 1 mg B_{12} daily over 2 months (Nilsson et al 2001). As this stands alone in its positive findings, it is suggestive that Hcy is a key indicator of likelihood for response to B vitamin supplementation (Nilsson et al 2001)

It is important to note that hyperhomocysteinaemic patients suffering dementia do not typically co-present with macrocytic anaemia, as might be expected (McCaddon et al 2004). Therefore, the neurological and haematological features of B_{12} and folate deficiency are often unrelated in these patients.

Renal transplant recipients

Combination vitamin B treatment (folate, B_{12} and B_6) may be of benefit in renal transplant patients, according to an RCT of 56 renal transplant patients, which found that vitamin supplementation with folic acid (5 mg/day), vitamin B_6 (50 mg/day) and vitamin B_{12} (400 μg/day) for 6 months reduced the progression of atherosclerosis, as evidenced by a significant decrease in carotid intima-media thickness. Additionally, a significant decrease in homocysteine levels was observed (Marcucci et al 2003).

Restenosis after percutaneous coronary intervention

An RCT found that treatment with vitamin B_{12} (cyanocobalamin 400 μg/day), folic acid (1 mg/day) and vitamin B_6 (pyridoxine hydrochloride 10 mg/day) for 6 months significantly decreased the incidence of major adverse events, including restenosis, after percutaneous coronary intervention (Schnyder et al 2002). In contrast, a more recent trial demonstrated an increased risk of in-stent restenosis in those patients intravenously administered 1 mg of folic acid, 5 mg of vitamin B_6 and 1 mg of vitamin B_{12} followed by daily oral doses of 1.2 mg of folic acid, 48 mg of vitamin B_6 and 60 μg of vitamin B_{12} for 6 months (Lange et al 2004). Further research with more consistent study designs is required to elucidate the true effects.

Idiopathic recurrent miscarriage (IRM)

Maternal hyperhomocysteinaemia and poor folate status are risk factors for recurrent embryo loss and for first early embryo loss (George et al 2002). There has also been conflicting evidence in relation to the role of *MTHFR* polymorphisms and pregnancy, although many studies point towards increased risk of recurrent spontaneous abortion. One explanation for the discrepant results may be that the numbers of study participants have been relatively small (Zetterberg 2004). Although researchers encourage the periconceptional use of both folate and B12 to reduce these risks, there is a lack of interventional studies in this area other than one investigation of combined aspirin (100 mg/day) and folic acid

Clinical note—Homocysteine lowering an ineffective treatment?

In spite of confirmation that elevated Hcy is an independent risk factor for cardiovascular disease, dementia and a range of other chronic conditions and the consistent finding that folic acid and B_{12}, in particular, can reduce these levels, a large number of studies examining the effect of supplementation have failed to produce clinical benefits. While this has led some researchers and clinicians to abandon Hcy-lowering strategies, including folic acid supplementation, others have reflected on possible reasons for this discrepancy. Study design critique in these trials, including the largest cardiovascular trials e.g. NORVIT and HOPE2, has identified several confounding variables and weaknesses including the following (Antoniades et al 2007, Marcus et al 2007, Maron & Loscalzo 2008):

- Samples were generally composed of individuals with only mildly elevated Hcy.
- In cardiovascular studies, patients typically had advanced pathology, e.g. recent myocardial infarction (MI) in the NORVIT study.
- Concomitant initiation of polypharmacy with B vitamins.
- The cardiovascular benefits may have been too small for the studies to detect due to incorrect powering.
- Study participants have been included even when taking B vitamins prior to commencement of and during study.
- Some study participants consumed folate-fortified diets.

Accordingly, these researchers conclude that more positive outcomes are likely if future study designs control for these confounding variables and select more suitable subjects, e.g. marked hyperhomocysteinaemia patients who are prediagnostic or in the early stages of their condition. Until the results of such trials emerge, they recommend the ongoing treatment of elevated Hcy with folate and B vitamins.

F

(5 mg/alternate days) throughout gestation, on top of initial (12 weeks) prednisone and progesterone treatment (Tempfer et al 2006). This treatment yielded higher live birth rate compared with no treatment in women with IRM.

Cardiovascular disease protection and treatment independent of homocysteine status

In the absence of a causal relationship between Hcy and cardiovascular disease, what remains most promising for folate are studies illustrating its protective effects, mediated through other mechanisms. This has led some researchers to suggest that folate deficiency may be the primary cause of an increased vascular risk and that elevated Hcy levels should principally be considered an indicator of low folate status rather than a pathogenetic marker (Verhaar et al 2002). Demonstrations of in vitro antioxidant activity, effects on co-factor availability and direct and indirect interactions with the endothelial NO synthase enzyme have been proposed as plausible mechanisms, through which folate may prevent endothelial dysfunction (Antoniades et al 2007, Das 2003, Verhaar et al 2002).

Several studies show the cardiovascular protective effects of folic acid, including the predictive value of low folate status on stroke risk (Bazzano et al 2002, Verhaar et al 2002); however, on the whole, interventional studies using folate (800 μg to 2.5 mg daily) either alone or in combination with the other B vitamins have been disappointing. Two meta-analyses from 2006 assessing the impact of folate alone or in combination on cardiovascular and all-cause mortality in individuals with pre-existing cardiovascular or kidney disease concluded that the treatments conveyed no significant benefits (Bazzano et al 2002, Bleys et al 2006). More recent studies have produced equivocal results. Combined B vitamins failed to reduce cardiovascular risk in high-risk women (Albert et al 2008), improve mortality and cardiovascular event frequency in patients with coronary artery disease (Ebbing et al 2008), failed to protect against cardiovascular events over 40 months (Bønaa et al 2006) and failed to prevent vascular events in patients with a stroke history after 3.9 years (Potter et al 2008).

On a more promising note, 51 heart transplant recipients who took 15 mg/day of methyltetrahydrofolate for 1 year following transplantation were found at their 7-year follow-up to have reduced all-cause mortality with a relative risk (RR) 0.53 when compared to the placebo group (Potena et al 2008). Another small study, employing high-dose folate (10 mg/day) in patients with a recent history of acute myocardial infarction, demonstrated improved endothelial function (Moens et al 2007). These positive findings were independent of Hcy levels at baseline or changes to Hcy throughout the trial.

Cognitive decline, dementia and Alzheimer's disease prevention or treatment independent of homocysteine status

Independent of Hcy, folate is implicated in cognition and neurodegeneration due to its ability to improve nitric oxide levels in the brain and facilitate synthesis of neurotransmitters (Malouf & Grimley Evans 2008). Additionally, atrophy of the cerebral cortex results from folate deficiency. Currently, an abundance of epidemiological evidence and a limited number of studies have shown a positive correlation between folate status and dementia. For example, a 2002 review has estimated that 71% of acute hospital admissions with severe folate deficiency have organic brain syndrome, compared with 31% of controls (Reynolds 2002). Low baseline serum folate also predicted dementia in a sample of 625 individuals followed over 2.4 years (Kim et al 2008), with onset of dementia significantly associated with exaggerated declines in folate, B_{12} and increases in Hcy, which may, however, have been the result of concomitant weight loss. In spite of

this knowledge, the results of studies investigating supplemental folic acid have been equivocal and warrant closer examination of the disparate methodologies.

A review by Balk in 2007, which sub-analysed folic-acid-only treatments (three RCTs, using 750 μg to 15 mg/day over 5–10 weeks) in elderly patients who were either healthy or cognitively impaired, found that, while folic acid was not universally effective, there was evidence to suggest that patients with low baseline folate (< 3 ng/mL) may significantly benefit. In contrast, a 2008 Cochrane review examining the effects of folic acid supplementation, with or without vitamin B_{12}, including some of the same trials, concluded that folate was an ineffective treatment (Malouf & Grimley Evans 2008).

Several studies investigating folic acid, either alone or in combination with other B vitamins, for slowing cognitive decline in Alzheimer's disease have failed to demonstrate an effect, independent of the hyperhomocysteinaemic population (Aisen et al 2008). One small study using 1 mg folic acid/day in conjunction with cholinesterase inhibitors over 6 months did, however, point towards an additive effect on patients' function (rather than cognition per se) regardless of Hcy (Connelly et al 2008); however, a similar study using higher doses of combined B vitamins failed to produce any statistically significant benefits (Sun et al 2007).

Anticonvulsant-induced folate deficiency

Anticonvulsant medications such as phenytoin, carbamazepine and valproate reduce serum ftolate status. Individual studies have estimated an incidence of 15% folate deficiency in this group, compared with 2% for control groups (Froscher et al 1995). However, the figure may be as high as 97% with long-term phenytoin therapy (Rivey et al 1984). This may be due to increased use of folate in drug metabolism and/or decreased mucosal absorption (Berg et al 1992, Pelton et al 2000). Often, folic acid supplements are recommended to avoid deficiency, but this requires close supervision to ensure drug efficacy is not substantially reduced (Rivey et al 1984), and a recent series of published case reports documenting NTD births to women supplemented with folic acid 5 mg/day while on anticonvulsants has thrown into question whether this commonly recommended dose is sufficient or whether concomitant administration of other B vitamins, especially B_6, may be necessary (Candito et al 2007).

Psychiatric illness

Over the past three decades, a vast number of case reports, open studies and, to a lesser extent, case–control studies have been published on the topic of psychopathology and folate deficiency. Many report a high incidence of serum folate deficiency in patients with symptoms of depression and various psychiatric disorders, particularly in geriatric populations (Reynolds 2002). For instance, one review identified that rates of deficiency varied between 8% and 50% in patients with various psychiatric disorders including depression and schizophrenia (Young & Ghadirian 1989). Two large studies involving over 350 patients diagnosed with acute psychiatric presentations identified low folate levels or frank deficiency (31% and 12% respectively). The patients with the most marked deficiency were also the group with the highest percentage of inpatients (Carney et al 1990). Recently, another study of similar design found that 30% of 224 newly admitted psychiatric patients had low serum folate (< 3.5 ng/mL) compared to only 2.4% of controls, and that patients with low folate were 3.5-fold more likely to present with depressive features (Lerner et al 2006). Disturbingly, the researchers also identified a significant trend between folate deficiency and hospital readmissions.

Depression

Aetiological role

It has been estimated that 15–38% of depressed people are folate deficient (Alpert & Fava 1997, Lerner et al 2006). Studies have also demonstrated that low dietary folate consumption (< 256 μg/day) (Tolmunen et al 2004), low serum folate (< 3.5 ng/mL) (typically co-occurring with B_{12} deficiency) (Gilbody et al 2007, Lerner et al 2006) and an *MTHFR* C677T genotype (OR 1.36) are all independently associated with an increased risk of depression (Gilbody et al 2007, Kelly et al 2004). The lesser-studied *MTHFR* A1298C genotype (although more active than the C677T genotype, but still 40% underactive) also demonstrates a weak positive relationship with depression incidence; however, more studies are required (Gilbody et al 2007). Following on from these findings, serum folate has also been negatively correlated with depression severity and duration, in some, but not all, studies (Kim et al 2008). One proposed explanation for these inconsistencies is that low folate and elevated Hcy are only found in a sub-group of depressed patients; in particular, those who experience increased anger and hostility as part of their depression (Fraguas et al 2006).

Additional studies also highlight an association between antenatal and postnatal depression and elevated Hcy or low folate levels but not serum B_{12} nor dietary intake of these two nutrients (Abou-Saleh et al 1999, Miyake et al 2006) and depression in antenatal and postnatal patients, with Hcy naturally peaking in the 3rd trimester (Abou-Saleh et al 1999, Behzadi et al 2008). The link between folate and B_{12} and depression has been hypothesised to be via Hcy and independent of this, due to its methylation role generally (Bottiglieri 2005, Coppen & Bolander-Gouaille 2005, Das 2008, Lerner et al 2006, Gilbody et al 2007, Roberts et al 2007, Tiemeier et al 2002).

Therapeutic role

Given the volume of evidence linking folate with depression, it is surprising that so few clinical trials have been conducted. A Cochrane systematic review of three RCTs involving 247 depressed people suggested that, on the limited evidence available, folate shows potential as an augmenting

agent, but speculated that its effectiveness might be restricted to folate-deficient patients (Taylor et al 2003). The studies included in this review used 500 μg folic acid, 15 mg or 50 mg of methyltetrahydrofolate once daily and lasted from 8 weeks to 6 months.

More recent studies, particularly in the elderly, who exhibit high rates of both folate deficiency and depression, have investigated the effects of broad-scale nutritional supplementation (meeting recommended daily intakes (RDIs) for all essential micronutrients) over a 6-month period with promising results. Red cell folate and serum B_{12} values rose in supplemented individuals in accord with significantly reduced scores on depression scales (Gariballa & Forster 2007). Prophylactic treatment of non-depressed elderly men with 2 mg folic acid, 25 mg B_6 and 400 μg B_{12}, in another study, however, failed to reduce depression incidence over 2 years (Ford et al 2008).

Improves response to standard antidepressants

Research investigating folate's adjunctive role in depression treatment has escalated in recent years and there is now evidence of an impaired fluoxetine response in patients with low folate levels, with response rates dropping from 44.7% in subjects with normal serum folate to only 7.1% of deficient patients (< 2.5 ng/mL) (Papakostas et al 2004a, 2004b), as well as a potentiating effect when only 500 μg/day of folic acid is added to fluoxetine (Coppen & Bailey 2000). Reduced folate levels have also been associated with reduced response to sertraline (Alpert et al 2003). Poor folate status negatively impacts response time (+1.5 weeks) (Papakostas et al 2005) and relapse rates during continuation of fluoxetine (42.9% relapse in patients with low folate levels versus 3.2%) (Papakostas et al 2004a, 2004b), independent of B_{12} and Hcy levels.

Schizophrenia

Folate has been implicated in schizophrenic aetiology since the 1950s with one-carbon metabolism abnormalities proposed as a distinct hypothesis at a similar time (Regland 2005). With current knowledge linking the two, there has been renewed interest in the role of folate in this disorder. In particular, folate deficiency fits with the neurodevelopmental theory, implicating malnutrition amongst other environmental stressors during gestation in the subsequent susceptibility to neurological disorders of offspring (Applebaum et al 2004, Gilbody et al 2007, Haidemenos et al 2007, Muntjewerff & Blom 2005). Specifically, elevated Hcy in the third trimester has been associated with significantly elevated risk. This theory is supported in part by the parallel increases in NTD births and schizophrenia incidence in populations affected by famine (Muntjewerff & Blom 2005). Further evidence of folate's role comes from elevated Hcy and a high incidence of the *MTHFR* C677T genotype which are frequently, but not consistently, found in this patient group (Kemperman et al 2006, Regland 2005). A recent meta-analysis of links between this folate polymorphism and schizophrenia found an odds ratio of 1.44 (Gilbody et al 2007).

Several studies in adult schizophrenic patients have reported increased rates of active folate deficiency. One, in addition to this, demonstrated an inverse relationship between serum folate and degree of negative symptoms and a positive association between Hcy and extra-pyramidal symptoms (Goff et al 2004). There have been several case reports of successful treatment using 15–30 mg folate together with B_{12} injections (1 mg every 10 days) and *N*-acetylcysteine (200 mg twice daily) (Regland 2005) and a more recent study which administered a combination of 2 mg folic acid, 25 mg B_6 and 400 μg B_{12} to schizophrenic patients with baseline Hcy > 15 mmol, which produced improvements in both clinical features and neuropsychological test performance (Levine et al 2006).

Other psychiatric presentations

Significantly decreased red cell folate (not serum) has been documented in both phases of bipolar disorder (Hasanah et al 1997), as well as frequently found in patients chronically treated with lithium (Coppen & Bolander-Gouaille 2005). There is also preliminary evidence of mildly elevated Hcy in post traumatic stress disorder (PTSD) sufferers; however, more thorough investigation is required to confirm this tentative association (Jendricko et al 2008).

Chemopreventative role

Epidemiological, animal and human studies all suggest that folate status affects the risk of developing cancers in selected tissues; however, the exact nature of this relationship continues to elude researchers (Bollheimer et al 2005, Powers 2005). One current theory points to the negative synergism between ageing and folate inadequacy, producing aberrations in one-carbon transfer such as gene hypomethylation, implicated in potentially carcinogenic genomic changes (Jang et al 2005).

Previously, high folate intake was purported to have an almost universally protective effect. An extensive review of the role of the *MTHFR* C677T polymorphism in cancer risk concluded that, in spite of the poor folate status associated with this polymorphism, however, many studies identify it as protective against a range of cancers (Sharp & Little 2004). In addition to this, a group of Swedish researchers have demonstrated that the relationship between serum folate and colorectal cancer follows a bell-shaped curve distribution (Van Guelpen et al 2006). Speculation regarding the role of additional co-factors involved in folate activity has also emerged (Powers 2005).

Folate's actions, however, still constitute a plausible cancer risk modulator, due to its critical role in the production, methylation and repair of DNA, regulation of cell turnover and suppression of excessive proliferation (Choi & Mason 2000, 2002).

Colon cancer

The link between folate status and colorectal cancer was first suggested as a result of 1990s epidemiological findings. Subsequent rodent studies further

strengthened the theory, when chemically induced colorectal carcinogenesis was shown to be enhanced under dietary folate deprivation and reduced with folate administration (Cravo et al 1992, Kim et al 1996). Recently the *MTHFR* C677T genotype has been identified as a risk factor (OR 1.34), compounded by dietary folate below median intakes (Murphy et al 2008).

In 2005, a major review of in vitro, animal and various clinical and epidemiological studies concluded that high folate intake does not possess an independent, overall chemopreventative effect on colorectal carcinogenesis, irrespective of two large studies that suggest that folate deficiency might have a particular impact on proximal colon cancer in females (Bollheimer et al 2005). In fact, over the previous few years, the evidence pertaining to a relationship between folate and colorectal cancer derived from studies using folic acid supplementation (≈ 1 mg/day) has swung more towards one of increased risks (Cole et al 2007, Luebeck et al 2008). Consistent with this, researchers have speculated that a rise in colorectal cancer diagnoses in the US between 1996 and 1998 may be the result of mandatory fortification, which occurred during the same period (Mason et al 2007). A study based on a mathematical model, designed to investigate the effect of folic acid supplementation on colorectal cancer incidence in the general population, has concluded that folic acid would convey protective benefits only when initiated prior to 20 years of age and when initiated after this time, may in fact increase risk (Luebeck et al 2008). In spite of this, a recent study of two large prospective cohorts failed to demonstrate a relationship between prediagnostic (3–5 years) higher plasma folate and increased risk (Wolpin et al 2008).

Recent research is also taking into account a possible role for other B vitamins in the folate and colorectal cancer equation, with preliminary evidence of superior protective effects when folate is used in combination with B2 as a minimum (5–10 mg/day) (Mason et al 2008, Powers 2005).

Breast cancer

While the epidemiological evidence with respect to dietary folate and breast cancer risk has produced equivocal results, more consistent evidence points to low folate intake as a risk factor only when combined with increased alcohol consumption (Larsson et al 2007, Mahoney et al 2007). This negative synergy is further supported by evidence that maintaining adequate folate intake, usually via supplementation, can reduce or eliminate the excess risk due to increased alcohol consumption (Mahoney et al 2007). A comparable detrimental additive effect has been demonstrated between the *MTHFR* genotype and low folate intake (OR 2.80) (Suzuki et al 2008).

Cervical cancer

Folate deficiency may increase the risk of cervical cancer in individuals infected with high risk human papiloma virus (HR-HPV) (Piyathilake et al 2004). Recent evidence suggests a diet rich in fruit and vegetables generally (OR 0.52), and folate independently (OR 0.55) reduces the risk of developing cervical cancer (Ghosh et al 2008); however, much of the other evidence pertaining to a protective relationship has been ambiguous and results from intervention studies on cervical cancer have been inconsistent (Henao et al 2005, Kwanbunjan et al 2005, Sedjo et al 2003). The most surprising finding recently is that the *MTHFR* genotype appears protective against cervical cancer (Shekari et al 2008), enhanced further by a concomitant low intake of B2 (Piyathilake et al 2007).

The most promising RCT involved 47 patients taking an OCP who demonstrated mild to moderate intraepithelial dysplasia. A dose of 10 mg folic acid daily over 3 months resulted in significantly lower biopsy scores in the treatment group and a significant reduction in cytology scores from baseline (Butterworth et al 1982). Other studies have shown that folic acid treatment does not alter the course of disease in patients with pre-established cervical dysplasia (Childers et al 1995).

Other cancers

A protective role for folate in the prevention of a growing number of other cancers, e.g. prostate (Marchal et al 2008), lung (Suzuki et al 2007), pancreas (Suzuki et al 2008) and nervous system cancers (Sirachainan et al 2008), has been tentatively made, often in combination with increased alcohol consumption; however, more research is required to validate these preliminary findings.

Periodontal disease

A series of RCTs have shown that rinsing with a solution of folate (5 mg/dose) twice daily alleviates gingival inflammation in all age groups and in pregnant and non-pregnant women (Pack 1984, Thomson & Pack 1982). Treatment results in a significant reduction in inflammation without altering plaque levels or folate serum status and appears to be more successful than oral supplements (Vogel et al 1976).

Preliminary evidence suggests that topical folate may also have a role in controlling gingival hyperplasia associated with long-term phenytoin use (Drew et al 1987).

Methotrexate toxicity

Methotrexate is a cytotoxic drug with folate antagonist properties. In part, its efficacy is dependent on this effect, but severe deficiency symptoms such as macrocytic anaemia are sometimes induced (Lambie & Johnson 1985). Co-administration of folic acid or folinic acid has been investigated as preventative treatment, with both forms capable of reducing drug side effects (Ortiz et al 1998, Strober & Menon 2005).

Sickle cell anaemia

In the past, folate supplements were recommended to patients with sickle cell anaemia, but more recent studies show that clinically significant folate deficiency occurs in a very small percentage of these

patients and other nutrients may be indicated (Reed et al 1987).

Vitiligo

Although a number of uncontrolled studies testing combination treatments have been promising, folate has never been assessed as a sole treatment. As such, it is difficult to determine its role in the treatment of this condition. In previous studies, a combination of oral folic acid and vitamin B_{12}, together with increased sun exposure, has produced response rates in the vicinity of 50% (Juhlin & Olsson 1997). A more recent controlled study by a different group of researchers found that exposure to a specific band width of UV radiation produced repigmentation in 92% of subjects, irrespective of vitamin supplementation (Tjioe et al 2002).

DOSAGE RANGE

Australian RDI (NHMRC 2006).

- 400 μg/day for adults; up to 1 mg/day in deficiency states.
- Up to 600 μg/day is recommended as the Suggested Dietary Target to reduce chronic disease risk in adults.
- 600 μg/day in pregnancy.
- 500 μg/day during lactation.

According to clinical studies

- Preconception care or early pregnancy supplementation: 400–600 μg/day.
- Preconception and pregnancy supplementation in women with a previous NTD birth: 4 mg/day.
- Idiopathic recurring miscarriage: aspirin (100 mg/day) and folic acid (5 mg/alternate days) throughout gestation plus prednisone and progesterone treatment for first 12 weeks.
- Anticonvulsant-induced deficiency: 15 mg/day (under supervision).
- Prevention of cervical cancer: 800–10,000 μg/day.
- Prevention of breast cancer in high alcohol consumers: 400 μg/day.
- Alzheimer's dementia in the presence of elevated Hcy: 800 μg/day.
- Alzheimer's dementia with normal Hcy: 1 mg/day in combination with cholinesterase inhibitors.
- Cognitive decline in elderly with folate deficiency: 750 μg/day.
- Depression: minimum of 2 mg or sufficient dose to reduce elevated homocysteine as stand-alone treatment.
- Depression as an augmenting agent with standard antidepressants: 500 μg/day.
- Acute psychiatric presentation: 15–30 mg methylfolate daily in combination with standard psychotropic treatment.
- Hyperhomocysteinaemia: 500–5000 μg/day.
- Cardiovascular protection in patients with elevated Hcy: 5 mg/day with high-dose B complex.
- Cardiovascular protection in heart transplant recipients or patients with recent history of MI: 10–15 mg/day.
- Methotrexate toxicity: 5 mg/week.
- OCP-induced folate deficiency: 2 mg/day.
- Periodontal disease: rinse mouth with a solution of folate (5 mg/dose) twice daily.
- Prevention of restenosis after percutaneous coronary intervention: 1 mg in combination with vitamin B_{12} (400 μg) and vitamin B_6 (10 mg) daily.
- Schizophrenia with marked negative symptoms: 2 mg/day in combination with 25 mg/day B_6 and 400 μg/day B_{12}.
- Sickle cell anaemia: 1 mg/day.
- Ulcerative colitis: 15 mg/day.
- Vitiligo: 2–10 mg/day.

ADVERSE REACTIONS

Adverse reactions appear to be limited to oral doses greater than 5 mg/day. Reactions include a generalised urticaria associated with an allergic response, nausea, flatulence and bitter taste in the mouth, irritability and excitability.

SIGNIFICANT INTERACTIONS

Antacids

Reduce folic acid absorption — separate doses by 2–3 hours.

Anticonvulsants (phenytoin)

Reduced folate levels frequently develop with long-term use, but macrocytic anaemia is rare (Lambie & Johnson 1985). Supplementation can reduce toxicity, which is a beneficial interaction, although medical supervision is advised.

Cholestyramine (e.g. Questran)

Reduced folate absorption — observe patient for signs and symptoms of folate deficiency and separate doses by at least 4 hours.

Gastric acid inhibitors (proton-pump inhibitors)

Reduced folic acid absorption — separate doses by 2–3 hours.

Methotrexate

Methotrexate is a folate antagonist drug. Folate supplementation can reduce toxicity, which is a beneficial interaction; however, it may reduce the efficacy of methotrexate — medical supervision advised.

Oral contraceptives

Folate levels are reduced with long-term use of the OCP, particularly those with high oestrogen content; therefore, increased intakes may be required for women undertaking long-term use.

Pancreatin

Reduced folate absorption (Kelly 1998) — separate doses by 2–3 hours.

Pyrimethamine (e.g. maloprim)

Impairs the use of folate and, as such, supplementation with folinic acid may be beneficial.

Sulfasalazine

Folic acid can reduce drug absorption — separate doses by 2–3 hours.

Trimethoprim
Trimethoprim is a folate antagonist drug. Supplementation can reduce toxicity, which is a beneficial interaction — medical supervision advised.

Zinc
At high doses (>15 mg/day), minor zinc depletion may develop (Carmel et al 2006, Kelly 1998) — observe patients for signs and symptoms of zinc deficiency.

CONTRAINDICATIONS AND PRECAUTIONS
Use of folate supplements may mask a B_{12} deficiency state by correcting an apparent macrocytic anaemia without altering progression of neurological damage. It is recommended that patients be screened for vitamin B_{12} deficiency.

PREGNANCY USE
According to the Australian Drug Evaluation Committee (1999), folate is considered to be safe to take during both pregnancy and lactation. Retrospective analysis of a trial of folate in pregnancy in the 1960s has suggested a possible increase in all-cause mortality and breast cancer in pregnant women taking 5 mg/day folate; however, this finding could be due to a number of factors unrelated to folate (Bland 2005, Charles et al 2004). The only context requiring special consideration is those pregnant women taking anticonvulsant medication (see *Significant interactions*).

PRACTICE POINTS/PATIENT COUNSELLING
- Folate is involved in a number of important biochemical pathways required for health and wellbeing, in particular development and cell growth.
- Folate supplements are often given to correct deficiencies or prevent deficiency in people at risk, such as those with malabsorption syndromes (e.g. coeliac disease and Crohn's disease), long-term use of certain medications such as phenytoin, sulfasalazine, cimetidine, antacids and the OCP, in congenital malabsorption states and blind loop syndrome, chronic alcoholism, the institutionalised elderly, pregnant and lactating women and HIV infection.
- It is considered to be the most important supplement to be taken by women in the weeks leading up to conception and during the first 12 weeks of pregnancy, in order to significantly reduce the risk of NTD in newborns. Food fortification is not considered sufficient.
- Other uses for folic acid supplements include reducing homocysteine levels (often in combination with vitamins B_{12} and B_6), reducing primary cardiovascular disease risk and cancer risk in general, periodontal disease (as a topical application), depression, schizophrenia and other psychiatric presentations and vitiligo.

PATIENTS' FAQs
What will this supplement do for me?
Folic acid is essential for health and wellbeing. Supplements have a critical role in preventing NTD in newborns and may also reduce the risk of primary cardiovascular disease and improve brain function in Alzheimer's dementia and non-Alzheimer's dementia and depression. It can also reduce the toxic effects of some medicines and may reduce the risk of developing some forms of cancer.

When will it start to work?
This depends on the indication.

Are there any safety issues?
The major concern with high doses of folate is that they may mask an underlying vitamin B_{12} deficiency and allow it to progress unnoticed, which means that a vitamin B_{12} deficiency should be excluded. It also interacts with some drugs in both a potentially harmful and a beneficial way. High doses should not be used in patients with a history of bowel polyps or adenomas.

Garlic

HISTORICAL NOTE Garlic has been used as both a food and a medicine since antiquity. Legend has it that garlic was used in ancient Egypt to increase workers' resistance to infection and later used externally to prevent wound infection. Other ancient civilisations have also used it medicinally. Sanskrit records document the use of garlic approximately 5000 years ago and the Chinese have been using it for over 3000 years. One of the uses of garlic was as a treatment for tumours, a use that extends back to the Egyptian Codex Ebers of 1550 BC (Hassan 2004). Louis Pasteur was one of the first scientists to confirm that garlic had antimicrobial properties. Garlic was used to prevent gangrene and treat infection in both world wars. Traditionally, garlic has been used as a warming and blood-cleansing herb to prevent and treat colds, flu, coughs and menstrual pain and expel worms and other parasites.

COMMON NAME
Garlic

OTHER NAMES
Ail, ajo, allium, camphor of the poor, da-suan, knoblauch, la-juan, poor man's treacle, rustic treacle, stinking rose

BOTANICAL NAME/FAMILY
Allium sativum (family Liliaceae)

PLANT PART USED
Bulb, and oil from the bulb

CHEMICAL COMPONENTS
Garlic bulbs contain organosulfur compounds (OSCs), protein (mainly alliinase), amino acids (such as arginine, lysine, threonine and tryptophan), fibre, lipids, phytic acid, saponins, beta-sitosterol and small quantities of vitamins and minerals such as vitamin C, vitamin E, beta-carotene, chromium, iron and selenium (Duke 2003). Of the numerous constituents present, it is the alliin component and resultant degradation products, such as allicin and ajoene, that produce much of the herb's pharmacological activity. These are formed when garlic is crushed or chewed and alliin is exposed to the enzyme alliinase. According to Commission E, 1 mg of alliin produces 0.458 mg of allicin (Blumenthal et al 2000). Allicin is unstable and degrades to various sulfides depending on the conditions. Steam distillation converts water-soluble thiosulfanates to lipid-soluble diallyl sulfides, whereas oil maceration results in the production of ajoenes and vinyldithines (Stargrove et al 2008).

The pharmacological actions of the herb are due to its organosulfur components: alliin, allyl cysteine, allyl disulfide, and allicin (Chung 2006). In garlic oil, there are three major OSCs: diallyl trisulfide (DATS), diallyl sulfide (DAS) and diallyl disulfide (DADS) (Liu et al 2006).

MAIN ACTIONS

Antioxidant
Garlic and many of its constituents have strong antioxidant activity and is capable of directly scavenging free radicals, and indirectly by enhancing endogenous antioxidant systems such as glutathione, superoxide dismutase, catalase and glutathione peroxidase (Arhan et al 2009). This has been demonstrated in vitro and in vivo (Arhan et al 2009).

When tested individually, the four main chemical classes of garlic, allyl disulfide, alliin, allicin and allyl cysteine, have been shown to exhibit different patterns of antioxidant activity. Alliin scavenges superoxide via the oxanthine oxidase system, alliin, allyl cysteine and allyl disulfide act as hydroxyl scavengers and allyl disulfide prevents lipid peroxidation (Chung 2006). S-allylcysteine has also been shown to scavenge reactive oxygen and nitrogen species, including superoxide anion, hydrogen peroxide, hydroxyl radical and peroxynitrite anion (Medina-Campos et al 2007).

According to in vitro tests, garlic prevents cadmium- and arsenic-induced oxidative damage by inducing endogenous antioxidant defence mechanisms (Chowdhury et al 2008, Ola-Mudathir et al 2008, Suru 2008).

Antioxidant activity and lower levels of oxidative stress has further been demonstrated in several clinical studies for garlic supplementation. One study used a dose of garlic 0.1 g/kg/day for 1 month, which was shown to induce a significant reduction in erythrocyte malondialdehyde (an indicator of oxidative stress) and significantly increase levels of superoxide dismutase (SOD) and glutathione peroxidase (GSH-Px) (Avci et al 2008). Similarly, oral garlic (250 mg/day) taken for 2 months caused a significant reduction in markers of lipid peroxidation in people with essential hypertension compared to normotensive controls (Dhawan & Jain 2005).

Protection against ischaemic and reperfusion injury
Prophylactic administration of garlic protects against renal and hepatic ischaemia/reperfusion injury in vitro and in a rat model (Kabasakal et al 2005, Sener et al 2005) prevents ischaemic and perfusion injuries after testicular torsion and detorsion in rats (Unsal et al 2006).

Anti-inflammatory activity
Fresh garlic extracts and garlic oil exert anti-inflammatory action in various models. Mechanisms of action identified to date include a direct action upon toll-like receptor-mediated signalling pathway inhibiting NF-kappa activation (Youn et al 2008), modification of the expression of cyclo-oxygenase (COX) activity (Thomson et al 2000), and suppression of iNOS and NO production (Liu et al 2006).

Lee et al investigated the anti-inflammatory action of DAS in articular chondrocytes and synovial fibroblasts harvested from patients undergoing joint replacement for osteoarthritis. Incubation with DAS inhibited the up-regulation of COX-2 expression in synovial cells and chondrocytes and ameliorated crystal-induced synovitis through the inhibition of NF-kappaB (Lee et al 2009).

Inhibits platelet aggregation and antithrombotic effects

In vitro studies indicate that garlic inhibits platelet aggregation through multiple mechanisms, including inhibition of COX activity, and as such, thromboxane A2 formation, via the suppression of intraplatelet Ca^{2+} mobilisation and by increasing cAMP and cGMP levels. The antioxidant action of garlic also increased platelet-derived NO, and interaction with GPIIb/IIIa receptors reduces platelets' ability to bind to fibrinogen (Allison et al 2006, Chan et al 2007, Rahman 2007).

Importantly, the method of garlic preparation can influence its antiplatelet activity in humans (Lawson et al 1992, Rahman & Billington 2000) yet microwaving, oven heating at 200°C or submersion in boiling water for 3 min has shown no reduction in inhibition of platelet aggregation as compared to raw garlic (Cavagnaro et al 2007).

A recent double-blind, placebo-controlled crossover study of 14 volunteers concluded that solvent-extracted garlic oil had minimal or no effect on platelet aggregation. Researchers found that administration of garlic 9.9 g over 4 h exerted little or no effect on both collagen and adenosine 5'-diphosphate (ADP)-induced aggregation. Adrenaline-induced aggregation did, however, exert a slight but significant ($P < 0.05$; 12) reduction (Wojcikowski et al 2007).

Stimulates fibrinolysis

A significant increase in fibrinolysis has been observed in several clinical tests for both raw and fried garlic, which appears to be dose-dependent (Bordia et al 1998, Chutani & Bordia 1981, Gadkari & Joshi 1991). A recent controlled animal study found a statistically significant decrease in plasma fibrinogen and increase in clotting time in treatment groups receiving doses of raw garlic 750 and 1000 mg/kg, respectively, in comparison to that of 500 mg/kg (Gorinstein et al 2006). Odourless garlic has been shown to stimulate fibrinolytic activity via accelerated tissue plasminogen activator (t-PA)-mediated plasminogen activation and to inhibit the formation of thrombin, leading to suppression of coagulation (Fukao et al 2007).

Anti-atherosclerotic activity

Evidence from in vitro, animal and human research has shown that garlic supplementation significantly reduces the atherosclerotic process (Campbell et al 2001, Durak et al 2002, Ferri et al 2003, Koscielny et al 1999, Kwon et al 2003, Orekhov et al 1995). More specifically, garlic significantly decreases accumulation of aortic tissue cholesterol, fatty streak formation and the size of atherosclerotic plaque in vivo (Campbell et al 2001).

The adherence of leucocytes/monocytes to endothelium is also implicated in early stage atherogenesis. In vitro studies have shown that incubation with garlic compounds significantly inhibits the oxidation of low-density lipoprotein (LDL) (Lau 2006), prevents adhesion of monocytes to IL-1alpha-stimulated endothelial cells (Rassoul et al 2006) and suppresses oxidised LDL-mediated leucocyte adhesion to human endothelial cells (Lei et al 2008). A critical review conducted on in vitro studies has confirmed that garlic inhibits enzymes involved in lipid synthesis, platelet aggregation, oxidisation of LDL while increasing antioxidant status (Rahman et al 2006).

Results from several published animal studies further confirm antiatherogenic effects and have investigated the mechanisms responsible (Durak et al 2002, Ferri et al 2003, Kwon et al 2003). One in vivo study found that garlic activated antioxidant systems and decreased peroxidation in aortic tissue (Durak et al 2002), whereas ajoene inhibited smooth muscle cell proliferation in another (Ferri et al 2003). The administration of 9 mg/kg of pure allicin in an animal model was found to reduce atherosclerotic plaque, Cu^{2+} binding to LDL, macrophages and the inhibition of LDL and oxidised LDL degradation. Allicin was also found to directly bind to lipoproteins, suggesting a further mechanism of action (Gonen et al 2005).

Similar results have been obtained using ultrasound techniques in a randomised, double-blind, placebo-controlled clinical trial, involving 152 people (Koscielny et al 1999). Not only did high-dose garlic powder significantly reduce arteriosclerotic plaque volume, it also induced a slight regression in plaque spread within the 4-year test period. Later, these results were found to be significant only in females.

In a multifactor prognostic evaluation of high-risk patients assessing risk of coronary heart disease (CHD), myocardial infarction (MI) and sudden death, prolonged administration of Allicor significantly reduced multifactor risk of CHD in both genders. However, reduced risk of MI and sudden death was achieved significantly in men but not in women (Sobenin et al 2005). A pilot study suggests that incremental benefits were identified when evaluating the role of garlic therapy in coronary artery calcification with patients also on concomitant statin therapy (Budoff 2006).

A recently published review suggested that the anti-atherosclerotic action of garlic, while dose dependent, is a valuable component in an atherosclerosis-preventing diet (Gorinstein et al 2007). A need for the standardisation of garlic products has been called for, to enable the opportunity to evaluate and draw conclusions from research findings (El-Sabban & Abouazra 2008).

A possible role for garlic in the prevention of cerebrovascular damage has been postulated through a reduction in levels of beta-amyloid (Abeta) and apoptosis, associated with the pathogenesis of Alzheimer's disease (Borek 2006). Aged S-allyl-L-cysteine, an organosulfur compound purified from aged garlic extract, exerted an anti-amyloidogenic activity in

vitro protecting against amyloid-beta-induced neuronal cell death, inhibiting amyloid-beta fibril formation and defibrillating amyloid-beta preformed fibrils (Gupta & Rao 2007, Gupta et al 2009, Imai et al 2007, Ishige et al 2007).

Reduces serum cholesterol levels

A 2000 meta-analysis of 13 clinical trials concluded that garlic is superior to placebo in reducing total cholesterol levels, exerting a modest effect (Stevinson et al 2001). In addition, a critical review published in 2006 suggests that garlic and its constituents exert a capacity to inhibit the enzymes involved in cholesterol and fatty acid synthesis, particularly mono-oxygenase and 3-hydroxy-3-methylglutaryl-CoA (HMG-CoA) reductase (Rahman et al 2006).

A 75% inhibition of cholesterol synthesis was achieved in garlic-treated human hepatoma cells without any evidence of cytotoxicity. Results indicated that compounds containing allyl-disulfide or allyl-sulfhydryl have the strongest inhibitory effect, likely through mediation of sterol 4-alpha-methyl oxidase (Singh et al 2006). Administration of high-dose (500 mg/kg) raw garlic extract to rats showed a significant (38%) reduction in triglycerides and cholesterol (Thomson et al 2006).

The capacity for modulating lipids may be attributed to the release of allicin through enzyme activation. A clinical crossover study involving 50 renal transplant patients involved the ingestion of one garlic clove daily for 2 months, either by swallowing or chewing. The swallowing route achieved a significant reduction in systolic blood pressure (SBP) and malondialdehyde (MDA) but no change in lipid parameters. However, chewing garlic achieved a reduction in cholesterol and a significant reduction in triglycerides, MDA and systolic and diastolic blood pressures, but no changes in HDL or LDL (Jabbari et al 2005).

Garlic's beneficial effects on serum lipids have been shown to decline following cessation of treatment, suggesting that long-term supplementation is required. A reduction in cholesterol and triglycerides and increase in HDL was achieved in 30 participants with elevated blood cholesterol ingesting 5 g of raw garlic twice daily for 42 days. However, following a 42-day washout period, cholesterol and triglycerides increased and HDL decreased (Mahmoodi et al 2006). Clinical evidence also suggests that it raises HDL levels and reduces triglyceride levels (Bordia et al 1998, Sobenin et al 2005).

Hypoglycaemic activity

Animal studies have shown that garlic and its constituents exhibit a hypoglycaemic action (Jelodar et al 2005, Hattori et al 2005) and produce significant changes in glucose tolerance and insulin secretion (Liu et al 2005). An antioxidant isolated from garlic, S-allyl cysteine sulfoxide, was found to stimulate insulin secretion from beta cells in rats (Augusti & Sheela 1996). Oral administration of garlic extract for 14 days significantly decreased serum glucose in streptozotocin-induced diabetic rats but not in normal rats. The garlic extract was also compared to that of glibenclamide, a known antidiabetic drug, and was found to be more effective (Eidi et al 2006). A similar study using garlic oil found no effect on oral glucose tolerance, but did report significantly improved oral glucose tolerance at 4, 8, 12 and 16 weeks, respectively (Liu et al 2006). A recently published animal investigation suggests that garlic is insulinotropic rather that hypoglycaemic (Islam & Choi 2008).

One double-blind study reported that 800 mg garlic powder taken daily for a period of 4 weeks reduced blood glucose concentrations by 11.6% (Kiesewetter et al 1993). However, a more recent study using a higher dose of 3 g/day over 26 weeks found no effects (Ali & Thomson 1995).

The metabolic action of Allicor was investigated in a 4-week, double-blind, placebo-controlled study of 60 type 2 diabetic patients, resulting in better metabolic control due to the lowering of fasting blood glucose, serum fructosamine and serum triglyceride levels (Sobenin et al 2008). A review suggests the need for large-scale clinical studies with diabetic patients to elucidate garlic's possible role in prevention and treatment of diabetes (Liu et al 2007).

Antihypertensive activity

Numerous clinical studies have identified antihypertensive activity with garlic (Andrianova et al 2002, Dhawan & Jain 2005, Silagy & Neil 1994). Although the mechanism of action has not been fully elucidated, evidence from in vivo research suggests that both the renin–angiotensin system and the NO system are responsible for this activity (Al-Qattan et al 2006, Mohamadi et al 2000). A controlled animal study found that both raw and aged garlic produced a reduction in induced elevated SBP compared to control. A reduction in pulse pressure was also achieved in the aged garlic-treated group (Harauma & Moriguchi 2006). Rats receiving a conjugate of allicin and captopril (allylmercaptocaptopril) showed a greater reduction in blood pressure and improved cardiac hypertrophy than those receiving captopril alone. Allylmercaptocaptopril improved, whereas captopril impaired fasting glucose tolerance (Ernsberger et al 2007).

In a controlled human study, hypertensive and normotensive patients received 250 mg daily for 2 months. A moderate reduction in blood pressure and a significant reduction in NO levels were observed in the hypotensive patients compared to controls (Dhawan & Jain 2005).

Enhances microcirculation

Jung et al (1991) found that 5 h after the administration of garlic powder (Kwai: total dose 900 mg garlic powder), a significant increase in capillary skin perfusion (55%) occurred in the healthy volunteers, whereas Kiesewetter et al (1993) showed a 48% increase with a dose of 800 mg garlic.

Antimicrobial and immune-enhancing activities

Garlic and its components have been demonstrated in vitro to exert a direct and indirect activity against various pathogens, including bacteria

(both gram-negative and gram-positive), fungi and parasites. Antimicrobial sensitivity tests conducted on *Escherichia coli*, *Shigella* spp, *Salmonella* spp and *Proteus mirabilis* found that no isolates were resistant to garlic; moreover, gram-negative isolates were found to be highly sensitive to garlic in comparison to ciprofloxacin and ampicillin (Eja et al 2007).

Allicin was initially believed to be chiefly responsible for the antimicrobial activity of garlic. Research found it to exert antibacterial activity against a wide range of gram-negative and gram-positive bacteria, including multidrug-resistant enterotoxicogenic strains of *Escherichia coli*, *Staphylococcus aureus*, *Mycobacterium tuberculosis*, *Proteus* spp, *Streptococcus faecalis* and *Pseudomonas aeruginosa*; antifungal activity, particularly against *Candida albicans*; antiparasitic activity against some of the major human intestinal protozoan parasites such as *Entamoeba histolytica* and *Giardia lamblia* and antiviral activity (Ankri & Mirelman 1999, Davis 2005, Tessema et al 2006). Allicin has been found to exert an antimalarial action in vitro and in vivo (Coppi et al 2006). Recent in vitro investigations have identified the capacity of allicin to activate macrophage activity (Ghazanfari et al 2006) and inhibit macrophage apoptosis (Cho et al 2006). Allicin has also been found to significantly enhance the effect of amphotericin B against *Candida albicans* in vitro and in vivo, mediated through oxidative damage to *C. albicans* (An et al 2008).

Ajoene, another important antimicrobial constituent, has been attributed to more biological activities in vitro and in vivo, including antifungal and antiparasitic actions (Ledezma & Apitz-Castro 2006) with greater antiviral activity than that of allicin, according to one in vitro test (Weber et al 1992).

The role of garlic in oral hygiene and the pathogenesis of dental disease has been investigated. All isolates of *Streptococcus mutans* identified in human carious teeth were sensitive to garlic extract, suggesting a role for garlic in mouthwashes for the prevention of dental caries (Fani et al 2007). This antimicrobial effect against Streptococci was found to continue for 2 weeks post treatment (Groppo et al 2007). Garlic extract was also found to significantly kill *P. gingivalis* and its protease enzymes, indicating a role in the treatment of periodontitis (Bakri & Douglas 2005). A randomised trial of 56 patients found garlic paste to be as effective as that of clotrimazole solution in suppressing signs of oral candidiasis (Sabitha et al 2005).

Helicobacter pylori infection

Several in vitro and in vivo tests have shown that garlic has activity against *H. pylori* (Chung et al 1998, Jonkers et al 1999, O'Gara et al 2000); however, results from clinical studies are equivocal. Two studies found that a combination of garlic and omeprazole produced synergistic effects against *H. pylori* (Cellini et al 1996, Jonkers et al 1999). Recently, rapid anti-*H. pylori* action of garlic oil was observed in artificial gastric juice, suggesting it as a useful treatment (O'Gara et al 2008).

Antineoplastic and chemopreventative effects

Garlic was first used over 3500 years ago in Egypt for the treatment of cancer. Garlic, and, in particular, its OSCs, including allicin, DAS, DADS, DATS and ajoene, have been investigated for their chemoprotective actions (Shukla & Kalra 2007). Recent review articles have identified the multiple mechanisms by which garlic's compounds exert anticarcinogenic properties.

Garlic OSCs demonstrate a capacity to modulate detoxification enzyme systems often responsible for the activation of carcinogens (Yang et al 2001); for example, DAS and its metabolites have been found to competitively inhibit the metabolism of cytochrome P450 2E1 substrates in vitro (Brady et al 1991). This inhibitory activity has been shown in rat nasal mucosa (Hong et al 1991) and hepatocytes (Brady et al 1991).

In addition, garlic OSCs increase the expression of phase II enzymes by enhancement of detoxification of activated carcinogenic intermediates such as quinine reductase and glutathione transferases (Bianchini & Vainio 2001, Rose et al 2005). Phase II enzyme modulation by OSCs has been reported in forestomach and lung cancer in mice (Singh et al 1998), and hepatoma cells (Chen et al 2004). Further investigations have established garlic OSCs' capacity to up-regulate gene expression of glutathione S-transferase.

Garlic OSCs have been shown to suppress neoplastic cell formation by inhibition of cell cycle progression, leading to cellular accumulation in the G2/M phase (Frantz et al 2000, Zheng et al 1997). Human colon cancer cells treated with DADS have not only been seen to arrest the G2/M phase, concomitant alterations were also seen to DNA repair and cellular adhesion factors (Knowles & Milner 2003), with increases in cyclin B1 expression and p53 expression leading to cellular apoptosis (Jo et al 2008, Song et al 2009). Treatment with DATS was reported to be more effective in arresting the G2/M phase of the cell cycle than DADS or DAS in human prostate cells (Xiao et al 2005).

Treatment with garlic and its compounds has been shown to display characteristics of mitotic arrest, exhibiting alterations to tubulin network and chromatin condensation (Herman-Anstosiewicz & Singh 2005). Treatment of human colon cells with garlic-derived compound s-allylmercaptocysteine (SAMC) resulted in depolymerisation of microtubules and cytoskeleton disruption (Xiao et al 2005). Similarly, DATS treatment induced rapid microtubule disassembly and cell cycle arrest in human colon cancer cells (Hosono et al 2008).

Garlic and its constituents have demonstrated actions that modify apoptopic pathways mostly through regulation of antiapoptotic Bcl-2 and pro-apoptotic Bax and Bac proteins (Herman-Antosiewicz et al 2007). For example, modification to transcription ratios of Bax/Bc1-2 proteins following treatment with OSCs has induced apoptosis in neuroblastoma and lung cancer cells (Hong et al 2000), breast cancer cell lines (Nakagawa et al 2001) and prostate cancer cells (Xiao et al 2004). Other mechanisms shown to induce

cellular apoptosis following treatment with OSCs include the induction of reactive oxygen species (ROS) generation (Song et al 2009, Sriram et al 2008), regulation of Akt-Bad (protein kinase B) pathway (Xiao & Singh 2006) and increased free intracellular calcium (Lin et al 2006). Malignant cells appear to be more sensitive to OSC-mediated apoptosis than normal cells (Powolny & Singh 2008).

Garlic OSCs' protective qualities include increased histone acetylation by the inhibition of histone deacetylase (HDAC), leading to cancer cell growth inhibition; for example, treatment of rodent erythroleukaemia and human leukaemia cells with DADS increases H4 and H3 histone acetylations (Lea & Randolph 2001). Increased acetylation has also been reported with treatment of OSCs in human colon cancer cells (Druesne et al 2004) and prostate cancer cells (Arunkumar et al 2007).

Finally, in vitro studies in human and animal cell lines indicate garlic and/or its constituents' ability to inhibit angiogenesis and metastasis. In human colon cancer cells, aged garlic extract was shown to inhibit angiogenesis by reducing endothelial cell motility, inhibiting tube formation, proliferation and invasion (Matsuura et al 2006). Administration of alliin exerted a dose-dependent inhibition of fibroblast growth factor-2-induced human endothelial cell tube formation and angiogenesis (Mousa & Mousa et al 2005). Similarly, treatments with DATS, DADS and DAS have been shown to inhibit capillary-like tube formation, cellular proliferation and migration (Thejass & Kuttan 2007. DADS was also found to inhibit angiogenesis by inhibiting the activation of matrix metalloproteinase (Thejass & Kuttan 2007). In human breast tumour cells, S-allylcysteine (SAC) reduced cell adhesion and invasion through expression of E-cadherin and reduced expression of matrix metalloproteinase (MMP)-2 (Gapter et al 2008). In animal studies, IV administration of ajoene significantly inhibited lung metastasis of melanoma cells (Taylor et al 2006) and aged garlic extract inhibited sarcoma cell migration (Hu et al 2002).

A systematic review published in 2007 suggested that there is consistent scientific evidence derived from animal studies reporting the protective effects of garlic on colorectal cancer (Ngo et al 2007). There are many recently published reviews confirming garlic and its constituents' chemoprotective capacity in various human cancer cell lines (Herman-Antosiewicz et al 2007, Moriarty et al 2007, Nagini 2008, Powolny & Singh 2008, Seki et al 2008, Shukla 2007). It is suggested that future research should focus on pharmacokinetics and pharmacodynamics in humans (Powolny et al 2008).

OTHER ACTIONS

Hepatoprotective effects

Aged garlic extract has a glutathione-sparing effect in the liver and specifically elevates reduced glutathione content, thereby enhancing endogenous protective mechanisms, according to in vitro tests (Wang et al 1999). The protective effects of a single simultaneous dose of garlic oil have been demonstrated on acute ethanol-induced fatty liver in mice, by significantly inhibiting elevation of MDA levels, restoring GSH levels and enhancing SOD, glutathione reductase (GR) and GST activities (Zeng et al 2008).

Homocysteine-lowering action

Aged garlic extract exhibits homocysteine-lowering action that indicates its potential for treatment of cardiovascular disease (Yeh & Yeh 2006). A pilot study conducted in patients with cardiovascular disease showed that pretreatment for 6 weeks with aged garlic extract significantly reduced the effects of acute hyperhomocysteinemia (Weiss et al 2006). It is postulated that the homocysteine-lowering action of aged garlic extract is due to its ability to inhibit CD36 expression and OxLDL uptake in macrophages involved in the formation of atherosclerotic lesions (Ide et al 2006).

Modulates cytochrome P450

Garlic may alter CYP450 enzymes, according to in vitro and animal studies; however, the effect appears unlikely in humans, as clinical studies have not produced the same findings (Dalvi 1992, Foster et al 2001). An in vitro model showed that S-methyl-L-cysteine and S-allyl-L-cysteine (100 micromol/L) produced modest inhibition of CYP3A; however, it is suggested that this would not be the case in vivo (Greenblatt et al 2006). Garlic oil constituent DAS was shown to activate CAR and Nrf2 to induce the drug-metabolising enzymes CYP2B and NAD(P)H quinone oxidoreductase 1 (Fisher et al 2007). In one study, garlic was also shown to have no in vitro inhibiting effects of cytochrome P-450 3A4 (CYP3A4) metabolism (Engdal et al 2009). Recently, an interaction between saquinavir and garlic has been reported, suggestive of a CYP induction effect, but human tests do not support this theory (Piscitelli et al 2002).

Researchers using human volunteers found that garlic oil reduced CYP2E1 activity by 39%, but had no effect on CYP1A2, CYP2D6 or CYP3A4 activity (Gurley et al 2002). The lack of a clinically significant effect on CYP1A2, CYP2D6 and CYP3A4 activity was confirmed in a later study of 12 elderly healthy volunteers receiving garlic oil for 28 days, followed by a 30-day washout period. Garlic oil had a mild inhibitory effect on CYP2E1 activity (by approximately 22%) (Gurley et al 2005). Additionally, tests with allicin also found no effect on CYP 3A4 in women receiving docetaxel treatment (Cox et al 2006).

CLINICAL USE

The use of garlic to treat a variety of conditions is supported by several authorities. Treatment of atherosclerosis, arterial vascular disease, blood lipids, respiratory tract infections and catarrhal conditions has been indicated by The European Scientific Cooperative on Phytotherapy (ESCOP). Treatment of hyperlipidaemia and age-related vascular changes with garlic are supported by the expert

German panel, the Commission E, while the World Health Organisation (WHO) also reports that there is sufficient clinical data to indicate the use of garlic in hyperlipidaemia, age-dependent atherosclerosis and mild hypertension.

Most studies have used a non-enteric coated dehydrated garlic powder preparation standardised to 1.3% alliin content (Kwai, Lichtwer Pharma) or an aged garlic extract (Kyolic, Wakunaga of America).

Cardiovascular disease (CVD)

Epidemiological studies show an inverse correlation between garlic consumption and progression of CVD in general (Rahman & Lowe 2006). A double-blind, placebo-controlled study of 167 patients with hyperlipidaemia demonstrated that Allicor was effective in reducing the 10-year absolute multifactorial risk of cardiovascular diseases (Sobenin et al 2005). Garlic was also found to reduce the 10-year risk of acute myocardial infarction and sudden death in a double-blind, placebo-controlled study of 51 patients with coronary artery disease receiving Allicor for a 12-month period (Sobenin et al 2007).

Hypertension

A meta-analysis of seven clinical trials using a garlic preparation, produced commercially as Kwai, found that three showed a significant reduction in SBP and four in DBP (Silagy & Neil 1994). Kwai was used in these studies in the dosage of 600–900 mg daily. Garlic treatment resulted in a mean reduction in SBP of 7.7 mmHg and 5.0 mmHg in DBP compared with placebo.

In 2000, the Agency for Health Care Research and Quality analysed results from 27 randomised, placebo-controlled trials and reported that results were mixed (Mulrow et al 2000). When significant reductions in blood pressure were observed, these were small.

Several newer trials have since been published, further confirming that the effect on blood pressure is small and sometimes non-significant (Andrianova et al 2002, McMahon & Vargas 1993, Zhang et al 2001a). A recent meta-analysis of 10 clinical trials found that garlic reduces blood pressure in patients with an elevated SBP, but not in those with normal SBP (Reinhart et al 2008). Another meta-analysis of randomised controlled trials with placebo groups, using garlic-only preparations and reporting mean systolic and/or diastolic blood pressure and standard deviations, suggested that garlic preparations are superior to placebo in reducing blood pressure in individuals with hypertension (Ried et al 2008).

Atherosclerosis and arteriosclerosis

Garlic indirectly affects atherosclerosis by reduction of hyperlipidaemia, hypertension and prevention of thrombus formation.

Koscielny et al conducted a randomised, double-blind, placebo-controlled clinical trial involving 152 volunteers to determine whether garlic powder supplements (Kwai 900 mg daily) directly alter plaque volumes in carotid and/or femoral arteries (Koscielny et al 1999). After 4 years' treatment, garlic intake significantly reduced the expected increase in arteriosclerotic plaque volume by 5–18%, with a slight regression also observed. A subsequent re-evaluation of the results found that significant effects were limited to women only (Siegel & Klussendorf 2000).

Hyperlipidaemia

In 2000, a meta-analysis of 13 clinical trials concluded that garlic reduces total cholesterol levels significantly more than placebo; however, the effects can only be described as modest (Stevinson et al 2001). The same year, a systematic review and meta-analysis were published by the Agency for Health Care Research and Quality, which analysed results from 44 studies with lipid outcomes (Mulrow et al 2000). Most studies involved fewer than 100 volunteers and randomisation techniques were unclear in 82% of the studies. Pooled data from the placebo-controlled trials reporting changes in total cholesterol levels found a significant average reduction in total cholesterol levels of 7.2 mg/dL after 4–6 weeks, using any form of garlic, and a reduction of 17.1 mg/dL at 8–12 weeks. Results at 20–24 weeks were not significant and thought to be due to low statistical power, fewer long-term studies or a time-dependent effect of garlic.

Since then, several new studies have been published, with most showing no significant reduction in total cholesterol levels (Gardner et al 2001, Kannar et al 2001, Peleg et al 2003, Turner et al 2004, Zhang et al 2001b, Ziaei et al 2001). In a parallel design trial of 192 patients with LDL cholesterol, treatment with either raw garlic, aged garlic extract or powdered garlic supplement, no significant effects on cholesterol, triglycerides or lipid concentrations were found (Gardner et al 2007). According to one review, non-enteric coated tablets containing dehydrated garlic powder (standardised to 1.3% allicin) produce the most consistent results (Ulbricht & Basch 2005). However, a single-blind, placebo-controlled study of lipid profiles in 150 hyperlipidaemic patients showed that treatment with enteric coated garlic powder (equal to 400 mg garlic, 1 mg allicin) twice daily showed statistically significant decreases in cholesterol and LDL cholesterol, and an increase in HDL cholesterol (Kojuri et al 2007). Moreover, the lipid-lowering effect of time-released garlic powder tablets Allicor (600 mg daily), investigated in a double-blind, placebo-controlled, randomised study of 42 men with mild hypercholesterolaemia, was shown to exert significant reductions in total cholesterol and LDL cholesterol and increased HDL cholesterol as compared to placebo after 8–12 weeks of treatment (Sobenin et al 2008).

Comparative studies

Two clinical studies have compared different garlic preparations with pharmaceutical cholesterol-lowering medicines. Garlic taken as 300 mg three times daily (Kwai) produced similar lipid-lowering effects to 200 mg bezafibrate (a hypolipidaemic fibrate) three times daily in subjects with primary hyperlipidaemia (Holzgartner et al 1992), whereas clofibrate 500 mg was more effective than

an essential oil extract of 50 g raw garlic (Arora & Arora 1981). The administration of 600 mg of fish oil with 500 mg of garlic pearls (garlic oil) per day to 16 hypercholesterolaemic subjects with a total cholesterol above 220 mg/dL for 60 days was found to reduce total cholesterol, LDL, serum triglyceride and very low-density lipoprotein (Jeyaraj et al 2005).

Commission E approves the use of garlic as an adjunct to dietary changes in the treatment of hyperlipidaemia (Blumenthal et al 2000).

Diabetics with hyperlipidaemia

A 12-week, placebo-controlled, single-blind, randomised study of 70 patients with type 2 diabetes and newly diagnosed dyslipidaemia found that treatment with a garlic tablet (Garlex-Bosch Pharmaceuticals: 300 mg, containing 1.3% allicin) twice daily, together with a diet and exercise plan, resulted in a significant reduction in total cholesterol of 28 mg/dL (12.03%) compared to placebo (Ashraf et al 2005). A 12-week, randomised, single-blind, placebo-controlled study of 70 type 2 diabetic patients with newly diagnosed dyslipidaemia demonstrated that garlic (300 mg) twice daily significantly reduced serum total cholesterol and LDL cholesterol and raised HDL cholesterol as compared to placebo (Ashraf et al 2005).

Over a decade ago, one double-blind study reported that 800 mg garlic powder taken daily for a period of 4 weeks reduced blood glucose concentrations by 11.6% (Kiesewetter et al 1993). However, a study using a higher dose of 3 g/day over 26 weeks found no effects (Ali & Thomson 1995).

The metabolic action of Allicor was investigated in a 4-week, double-blind, placebo-controlled study of 60 type 2 diabetic patients, resulting in better metabolic control due to the lowering of fasting blood glucose, serum fructosamine and serum triglyceride levels (Sobenin et al 2008). A review suggests the need for large-scale clinical studies with diabetic patients to elucidate garlic's possible role in prevention and treatment of diabetes (Liu et al 2007).

Antiplatelet effects

Antiplatelet effects of garlic are well recognised, but the dose at which this becomes significant remains uncertain. Results from a 2001 double-blind study have identified a dose of 7.2 g/day of aged garlic extract as significantly inhibiting platelet aggregation and adhesion (Steiner et al 1996).

Peripheral arterial occlusive disease

In 2000, Mulrow et al reported on two double-blind placebo-controlled trials in participants with atherosclerotic lower extremity disease (Mulrow et al 2000). One study of 64 participants showed that pain-free walking distance increased by approximately 40 m with standardised dehydrated garlic (Kwai 800 mg daily), compared with approximately 30 m with placebo over 12 weeks. Cochrane reviewers report that the effect was not significant (Jepson et al 2000). The other study of 100 participants (Mulrow et al 2000) showed that a combination treatment of garlic oil macerate/soya lecithin/hawthorn oil/wheat germ oil significantly increased the maximum walking distance (114%) compared to placebo (17%) ($P < 0.05$).

Infection

Garlic oil is effective against numerous bacteria, viruses and fungi, including *Staphylococcus aureus*, methicillin-resistant *Staphylococcus aureus* (MRSA), and several species of *Candida*, *Aspergillus* and *Cryptococcus neoformans* in vitro (Davis et al 1994, Tsao & Yin 2001, Yoshida et al 1987). As such, it has been used both internally and externally to treat various infections and prevent wound infection.

Tinea pedis, Tinea corporis, Tinea cruris

A trial comparing the effects of three different strengths of ajoene cream (0.4%, 0.6% and 1%) with 1% terbinafine applied twice daily found the cure rate to be 72% for 0.6% ajoene, 100% for 1% ajoene and 94% for 1% terbinafine after 60 days (Ledezma et al 2000).

Vaginitis

Taken internally as a 'natural antibiotic' or applied topically in a cream base, garlic is used to treat vaginitis. The considerable antibacterial activity of garlic provides a theoretical basis for its use in this condition, but controlled studies are not available to determine its effectiveness.

Common cold prevention

A 12-week, double-blind, randomised study involving 146 people demonstrated that allicin-containing garlic preparations significantly reduce the incidence

Clinical Note — Not all garlic preparations are the same

One of the difficulties encountered when interpreting the research available for garlic is comparing the effects of different preparations, which often have not been tested for the presence of important constituents or allicin-releasing potential. It is known that fresh garlic and dried garlic powder contain alliin. When cut, crushed, chewed or dehydrated, the enzyme allinase is rapidly released, which allows the biotransformation of allinin to active organo-sulfur compounds. Some other forms may only contain alliin, and not the necessary alliinase component, thus compromising allicin-releasing potential. An example of the manufacturing process affecting potency has been suggested for a commercial garlic product known as Kwai, which has often been used in cholesterol research (Lawson et al 2001). According to a 2001 experiment, substantial differences were found between tablets manufactured before 1993 (the years when all but one of the positive trials were conducted) and those manufactured after 1993 (the years when all of the negative trials were conducted). Kwai products manufactured after 1993 released only one-third as much allicin as older preparations. Those preparations from before 1993 disintegrated more slowly, protecting alliinase from acid exposure and inactivation.

of colds and accelerate recovery compared with placebo (Josling 2001). More specifically, the number of symptom days in the placebo group was 5.01 compared with 1.52 days in the garlic-treated group. Additionally, garlic reduced the incidence of developing a second cold, whereas placebo did not.

Helicobacter pylori infection

It has been suggested that gastrointestinal lesions, such as gastric ulcers, duodenal ulcers and gastric cancers, are strongly associated with *H. pylori* infection (Scheiman & Cutler 1999). Medical treatment consisting of 'triple therapy' has a high eradication rate; yet, is associated with side effects and has started to give rise to antibiotic resistance. Since garlic intake has been associated with a lowered incidence of stomach cancer, researchers have started investigating whether garlic has activity against *H. pylori*. Several in vitro and in vivo tests have shown garlic to be effective against *H. pylori* (see *Main actions*). However, to date only a few small clinical trials have been conducted, with disappointing and controversial results (Aydin et al 2000, Graham et al 1999, McNulty et al 2001).

A small pilot study of dyspeptic patients with confirmed *H. pylori* infection found that treatment with 4 mg garlic oil capsules taken four times daily with meals for 14 days did not alter symptoms or lead to *H. pylori* eradication (McNulty et al 2001). Another small study using garlic oil 275 mg three times a day (allicin 800 microgram/capsule) either as stand-alone treatment or in combination with omeprazole (20 mg twice daily) found that both treatments produced similar results (Aydin et al 2000). These results were confirmed in another small clinical study (Graham et al 1999).

Protective effects against cancer

A 2001 critical review of the epidemiological evidence suggests a preventive effect for garlic consumption in stomach and colorectal cancers, but not other cancers (Fleischauer & Arab 2001). With regard to gastric cancer protection, case-control studies suggested a protective effect for raw and/or cooked garlic when eaten at least once a week, whereas protective effects against colorectal cancer seem to require at least two servings of garlic per week. A similar view was reported in a 2003 review by Ernst, which stated that the weight of evidence to support the use of allium vegetables, such as garlic, in cancer is clearly positive. However, a recently published review of 19 human studies evaluated the evidence supporting a relationship between garlic intake and a reduction in risk of different cancers with respect to food labelling. No evidence was found to suggest that garlic consumption reduced the risk of gastric, breast, lung or endometrial cancer, with very limited evidence supporting a reduction in risk of colon, prostate, oesophageal, larynx, oral, ovary or renal cell cancers due to garlic consumption (Kim & Kwon 2009).

Intervention study in colorectal cancer

A preliminary double-blind, randomised clinical trial in patients with colorectal adenomas — precancerous lesions of the large bowel — produced promising results with the use of high-dose aged garlic extract (AGE 2.4 mL/day) (Tanaka et al 2006). The study of 51 patients measured the number and size of adenomas at baseline and at 6 and 12 months and found that AGE significantly suppressed both the size and the number of colon adenomas in patients after 1 year of treatment ($P = 0.04$). In comparison, the number of adenomas increased linearly in the control group from the beginning. A systematic review of scientific evidence from all studies conducted over the last decade that examined the effects of garlic on colorectal cancer (CRC) was conducted. One randomised controlled trial (RCT) reported, for CRC patients taking AGE, a statistically significant 29% reduction in both size and number of colon adenomas and a meta-analysis confirmed protective effect, with a 30% reduction in relative risk. Five of eight case-control/cohort studies suggested that high intake of raw/cooked garlic produced a chemoprotective effect. Review of 11 animal studies showed a significant anticarcinogenic effect of garlic. Overall, the authors concluded that there was consistent scientific evidence derived from RCT animal studies, despite heterogeneity of human epidemiological studies (Ngo et al 2007).

Analysis of data from a multicentre, case-control study of 454 endometrial cancer cases and 908 controls found a moderate protective role for allium vegetables on the risk of endometrial cancer, with a significant inverse trend identified for high intakes of garlic (Galeone et al 2008). Topical application of garlic-derived ajoene to tumours of 21 patients with either nodular or superficial basal cell carcinoma resulted in reduction in tumour size in 17 patients. Chemical assays prior to and posttreatment showed a significant decrease in the expression of the apoptosis-suppression protein Bcl-2 (Tilli et al 2003).

OTHER USES

Some early research suggests that garlic may prevent the incidence of altitude sickness (Fallon et al 1998, Kim-Park & Ku 2000) and reduce mosquito numbers (Jarial 2001). It has also been used to assist in heavy metal detoxification. Studies with experimental animal models provide some support for its use in this way (Bone & Morgan 2005).

DOSAGE RANGE

General guide

- Fresh garlic: 2–5 g/day (ensure it is bruised, crushed or chewed).
- Dried powder: 0.4–1.2 g/day.
- AGEs have been studied in amounts ranging from 2.4 to 7.2 g/day.
- Oil: 2–5 mg/day.
- Garlic preparations that will provide 4–12 mg alliin daily.
- Fluid extract (1:1): 0.5–2 mL three times daily.

According to clinical studies

- Hypertension: 600–900 mg/day in divided doses (delivering approximately 5000–6000 microgram allicin potential).
- Hyperlipidaemia: 600–9000 mg/day.

- Fungal infection: topical 0.4–0.6% ajoene cream applied twice daily.
- Occlusive arterial disease: 600–800 mg/day.

It is important to be aware of the thiosulfinate content, in particular allicin-releasing ability, of any commercial product to ensure efficacy.

ADVERSE REACTIONS

Internal use

Breath and body odour, allergic reactions, nausea, heartburn, flatulence, abdominal discomfort and diarrhoea have been reported (Berthold et al 1998). These side effects are more common when garlic is taken on an empty stomach.

Headache, myalgia and fatigue were reported in one study using a dose of 900 mg garlic powder (standardised to 1.3% alliin) (Holzgartner et al 1992).

Topical use

An ajoene 0.6% gel produces a transient burning sensation after application, according to one study (Ledezma et al 1999). Contact dermatitis can occur — one study using patch testing found that 5.2% of volunteers had contact sensitisation (Lembo et al 1991).

SIGNIFICANT INTERACTIONS

Saquinavir and ritonavir

A clinical study showed that garlic powder reduced blood levels of saquinavir and ritonavir due to stimulation of P450 isoenzymes, and therefore may reduce efficacy of drug — avoid using concurrently (Piscitelli et al 2002). However, in a clinical study of 10 participants, 10 mg of odourless garlic had no significant effect on the pharmacokinetics of ritonavir (Gallicano et al 2003).

Anticoagulants

Theoretically, a pharmacodynamic interaction is possible when using garlic at high doses (> 7 g), in excess of usual dietary amounts; however, results from clinical studies cast doubt on this proposition. Published clinical studies have identified no significant action of enteric-coated or aged garlic on warfarin pharmacodynamics or pharmacokinetics. A double-blind, randomised, placebo-controlled pilot study of 48 patients demonstrated that the concomitant use of garlic containing 14.7 mg/day of *S*-allylcysteine and warfarin showed no adverse effects (Macan et al 2006). An open-label, three-treatment, randomised, crossover clinical trial involving 12 healthy males, investigating potential effects of garlic and cranberry on warfarin (25 mg single dose), found that two garlic tablets daily containing 2000 mg of fresh garlic bulb equivalent to 3.71 mg of allicin per tablet did not significantly alter warfarin's pharmacokinetics or pharmacodynamics (Mohammed Abdul et al 2008). Use caution with doses > 7 g/day.

Antiplatelet drugs

Theoretically, a pharmacodynamic interaction is possible when using garlic at high doses in excess of usual dietary amounts, although a small clinical study involving 10 adult participants showed garlic had no effect on platelet function (Beckert et al 2007). Observe.

Antihypertensive agents

Theoretically, potentiation effects are possible when using garlic at high doses in excess of usual dietary amounts — this can be used as adjunctive therapy to produce beneficial results.

Antihyperlipidaemic agents

Theoretically, potentiation effects are possible when using garlic at high doses in excess of usual dietary amounts — this can be used as adjunctive therapy to produce beneficial results — observe.

Helicobacter pylori triple therapy

Additive effects are theoretically possible. While it is prudent to observe the patient for adverse reactions, the interaction may be beneficial.

Hepatotoxic drugs

Garlic may exert hepatoprotective activity against liver damage induced by drugs, according to in vitro tests, which suggests a beneficial interaction.

Paracetamol

In vivo protection from garlic and ajoene on paracetamol-induced hepatotoxicity has been observed (Hsu et al 2006) — beneficial interaction.

CONTRAINDICATIONS AND PRECAUTIONS

Patients with bleeding abnormalities should avoid therapeutic doses of garlic. Although usual dietary intakes are likely to be safe prior to major surgery, suspend the use of high-dose garlic supplements 1 week before, as there is a theoretical increased risk of bleeding.

If being used as part of a topical application, a test patch is advised before more widespread application.

PRACTICE POINTS/PATIENT COUNSELLING

- Garlic is both a food and a therapeutic medicine capable of significant and varied pharmacological activity.
- It has antioxidant, antimicrobial, antiplatelet, antithrombotic, antihypertensive, lipid-lowering, anti-atherosclerotic and vasoprotective activities.
- It also enhances microcirculation and may have hypoglycaemic, anti-inflammatory and immunostimulant activities.
- Garlic is used as a treatment for many common infections, to reduce the incidence of colds, to improve peripheral circulation and to manage hyperlipidaemia and hypertension.
  - Topical garlic preparations have been used to treat common fungal infections.
- Increased consumption of garlic has been associated with a decreased risk of stomach and colorectal cancers, according to a review of the epidemiological evidence.
- Several important drug interactions are possible with garlic (refer to significant interactions).

PREGNANCY USE

Garlic is not recommended at doses greater than usual dietary intakes.

PATIENTS' FAQs

What will this herb do for me?

Garlic has many different actions in the body and is used to treat conditions such as elevated blood pressure, cholesterol levels, poor peripheral circulation and common infections such as the common cold, flu and athlete's foot. Research suggests that it may be effective in all of these conditions; however, in some cases, the effect is small.

When will it start to work?

This varies greatly, depending on the reason for use. For example, garlic has been shown to improve microcirculation within 5 h of ingestion, whereas slowing down of the atherosclerotic process or cancer-protective effects are likely to require several years' continuous use.

Are there any safety issues?

When garlic is taken at doses above the usual dietary levels, it may interact with a number of medications. Also, it should not be taken by people with bleeding disorders.

Gentian

HISTORICAL NOTE The genus *Gentiana* is derived from Gentius, king of ancient Ilyra who is attributed with the discovery of its therapeutic effects (Blumenthal 2000). In ancient Greece and Rome it was used to relieve common gastrointestinal symptoms, much as it is used today. It was first noted in the Chinese medical literature in 50 BC (Willard 1991).

OTHER NAMES
Gentiana, yellow gentian, wild gentian

BOTANICAL NAME/FAMILY
Gentiana lutea (family Gentianaceae)

PLANT PARTS USED
Root and rhizome

CHEMICAL COMPONENTS
Secoiridoid bitter glycosides, oligosaccharides, phenolic acids, phytosterols, polysaccharides (inulin and pectin), tannin, lupeol, beta-amyrin triterpenes, xanthones and essential oil. Analysis of several commercially available *G. lutea* samples showed that gentiopicroside is the most prevalent bioactive compound (4.46–9.53%), followed by loganic acid (0.10–0.76%), swertiamarin (0.21–0.45%) and the xanthone glycosides. Gentisin and isogentisin were found in much lower concentrations between 0.02 and 0.11%, respectively (Aberham et al 2007).

MAIN ACTIONS
The active principals in gentian root are the bitter constituents, gentiopicroside and amarogentin.

Digestive stimulant
The bitter principals induce reflex excitation of taste receptors and increased saliva, gastric juice and bile secretion thereby stimulating appetite and digestion according to in vivo experiments. The small human study confirmed that oral administration of gentian root extract increases gastric juice secretion and emptying of the gall bladder (ESCOP 2003).

Antioxidant
This has been demonstrated in vivo (Amin 2008).

Promotes wound healing
The gentiopicroside, sweroside and swertiamarine constituents from *Gentiana lutea* demonstrate wound healing properties in animal models, which seems to be mainly due to increased stimulation of collagen production and mitotic activity (Ozturk et al 2006).

OTHER ACTIONS
A gentian root preparation inhibited *Helicobacter pylori* in vitro (Mahady et al 2005).

Antioxidant activity has been observed in vitro for the ethyl acetate and chloroform fractions of gentian (Calliste et al 2001). Animal studies with amarogentin have identified antileishmanial properties (Medda et al 1999). An orally administered crude extract of *Gentiana lutea* (1 g/kg b wt/day) prevented both the reproductive toxicity and oxidative damage induced in rat testes in response to a high acute dose of ketoconazole.

Traditionally, gentian is considered to have stomachic, anthelmintic, antiseptic, anti-inflammatory and tonic activity (Willard 1991).

CLINICAL USE
Gentian root preparations have not been significantly investigated under clinical trial conditions, so evidence is mainly derived from traditional, in vitro and animal studies. It is a popular remedy amongst naturopaths and herbalists.

Dyspepsia and flatulence
The considerable bitter taste of gentian provides a theoretical basis for its use in dyspepsia and flatulence for which increased saliva and gastric acid secretion would be beneficial. Commission E and ESCOP approve its use for this indication (Blumenthal 2000, ESCOP 2003).

Loss of appetite
The considerable bitter taste of gentian provides a theoretical basis for its use in anorexia when increased saliva and gastric acid secretions would be beneficial. Commission E and ESCOP approve its use for this indication (Blumenthal 2000, ESCOP 2003).

OTHER USES
Traditionally, gentian has also been used for gout, amenorrhoea, diarrhoea and worms in the stomach and bowel (Willard 1991). Gentian is also used in

Clinical note — Herbs in alcoholic drinks
The maceration of herbs and spices in wine was common practice in antiquity, and the invention of aromatised wine, the ancestor of vermouth, has been attributed to Hippocrates (Liddle & Boero 2003). Herbs are still commonly used in alcoholic drink production today, either as flavourings, or as both fermentation substrates and flavouring agents. The volatile components of a herb will provide its distinctive odour, whereas non-volatile constituents can affect some gustatory reactions and produce a physiological effect. Bitter herbs such as gentian are used for flavour, but also because they contain a significant amount of fermentable sugars that can be converted by strains of yeast into ethanol in an alcoholic fermentation process. Examples of other herbs that are used in brandies, flavoured spirits, liqueurs, medicinal wines and vermouth are anise, caraway, cardamom, coriander, dandelion, sage and yarrow (Veljkovic & Stankovic 2003).

alcoholic drinks such as brandy, medicinal wines and vermouth.

DOSAGE RANGE

General guide

- Cut root or dried extract: 2–4 g/day.
- Fluid extract (1:1): 1–2 mL taken 1 hour before meals up to three times daily.
- Tincture (1:5): 3–12 mL/day.
- Infusion: 1–2 g in 150 mL boiled water taken 1 hour before meals and up to three times daily.

ADVERSE REACTIONS

Headaches have been reported (ESCOP 2003) and nausea and vomiting with high doses.

SIGNIFICANT INTERACTIONS

Interactions are unknown.

CONTRAINDICATIONS AND PRECAUTIONS

Contraindicated in gastric or duodenal ulcers and hyperacidity according to Commission E (Blumenthal 2000).

PREGNANCY USE

There is insufficient reliable information available to make a recommendation.

PRACTICE POINTS/PATIENT COUNSELLING

- Gentian root and its preparations are extremely bitter.
- Gentian preparations stimulate salivation, gastric juice and bile secretion.
- They are used to improve digestion, relieve flatulence and stimulate appetite.
- Little clinical investigation has been undertaken with the herb, so evidence of efficacy relies on traditional and animal studies.
- It should not be used in cases of gastric or duodenal ulcer or hyperacidity.

PATIENTS' FAQs

What will this herb do for me?

Gentian preparations stimulate taste buds when taken orally, and increase gastric juice secretion, thereby improving digestion.

When will it start to work?

Effects are expected within several minutes of ingestion.

Are there any safety issues?

It should not be used by people with gastric or duodenal ulcers or with gastric hyperacidity.

Ginger

HISTORICAL NOTE Ginger has been used as both a food and a medicine since ancient times. Confucius wrote about it in his Analects, the Greek physician, Dioscorides, listed ginger as an antidote to poisoning, as a digestive, and as being warming to the stomach in De Materia Medica, and the Koran, the Talmud and the Bible all mention ginger. Records suggest that ginger was highly valued as an article of trade and in 13th and 14th century England, one pound of ginger was worth the same as a sheep (Rosengarten 1969). Ginger is still extremely popular in the practice of phytotherapy, particularly in traditional Chinese medicine (TCM), which distinguishes between the dried and fresh roots. It is widely used to stimulate circulation, treat various gastrointestinal disorders and as a stimulant heating agent.

OTHER NAMES

African ginger, Indian ginger, Jamaica ginger, common ginger, rhizoma zingiberis, shokyo (Japanese).

BOTANICAL NAME/FAMILY

Zingiber officinale Roscoe (family Zingiberaceae)

PLANT PART USED

Rhizome

CHEMICAL COMPONENTS

The ginger rhizome contains an essential oil and resin known collectively as oleoresin. The composition of the essential oil varies according to

the geographical origin, but the chief constituents, sesquiterpene hydrocarbons, which are responsible for the characteristic aroma, are fairly constant.

The oleoresin contains:

- Sesquiterpenes: zingiberene, ar-curcumene, beta-sesquiphellandrene and beta-bisabolene.
- Pungent phenolic compounds: gingerols and their corresponding degradation products, shogaols, zingerone and paradol. Zingerone and shogaols are found in small amounts in fresh ginger and in larger amounts in dried or extracted products (Govindarajan 1982).
- Other constituents: diarylheptanoids galanolactone (diterpenoid), 6-gingesulfonic acid, monoacyldigalactosylglycerols (Awang 1992, Bhattarai et al 2001, Charles et al 2000, Govindarajan 1982, Kikuzaki et al 1991, WHO 2003, Yamahara et al 1992, Yoshikawa et al 1992, 1993).

MAIN ACTIONS

Anti-emetic

Ginger has demonstrated anti-emetic activity in both experimental models and human studies. It appears that several key constituents are responsible which exert several different mechanisms. In vivo studies have demonstrated [6]-, [8]- and [10]-gingerol as well as [6]-shogaol exert anti-emetic activity (Kawai et al 1994, Abdel-Aziz et al 2006), most likely by acting on the 5-HT(3) receptor ion-channel complex either by binding directly to a modulatory site distinct from the serotonin binding site or indirectly via underlying muscarinic receptors. Specific constituents of ginger volatile oil including terpinolene, beta-pinene and alpha-phellandrene were also found to induce an anti-spasmodic effect via interaction with the 5-HT(3) receptor channel system in rat ileum (Riyazi et al 2007). Galactone has also been identified as a serotonin-receptor antagonist (Huang et al 1991, Mustafa et al 1993, Yamahara et al 1990). Such mechanisms of action also explain the inhibitory effect of ginger on serotonin-induced diarrhoea and antispasmodic effect on visceral and vascular smooth muscle.

Ginger has been shown to blunt gastric dysrhythmias and nausea evoked by acute hyperglycaemia in humans. The anti-arrhythmic and anti-emetic effects are thought to be due to a blockade of prostaglandins rather than inhibition of their release (Gonlachanvit 2001. Ginger has also been shown to reduce radiation-induced gastrointestinal distress and emesis in rat models, which is thought to be due at least in part to its antioxidant properties and the ability to scavenge free radicals and inhibit lipid peroxidation (Sharma et al 2005). Ginger extract displayed comparable radioprotection against radiation-induced taste aversion (CTA) when compared to dexamethasone and ondansetron in male and female rats. The most effective concentration was 1000 microgram/mL of ginger extract, which exerted free radial scavenging of hydroxyl ions and nitric oxide and modulation of CTA (Haksar et al 2006).

Gastrointestinal activity

Ginger exerts several effects in the gastrointestinal tract, which lead to an improvement in gastrointestinal symptoms. It stimulates the flow of saliva, bile and gastric secretions (Platel & Srinivasan 1996, 2001, Yamahara et al 1985) and has been shown to increase gastrointestinal motility in several animal models and human studies (Gupta & Sharma 2001, Micklefield et al 1999, Phillips et al 1993). In a recent randomised double-blind study involving 24 healthy volunteers, ginger was found to accelerate gastric emptying and stimulate antral contractions (Wu et al 2008). Ginger has also been observed to have prokinetic activity in mice in vivo and anti-spasmodic activity in vitro (Ghayur & Gilani 2005). These findings appear to support the traditional use of ginger in the treatment of gastrointestinal discomfort, colic, diarrhoea and bloating and its use as a carminative agent. Further in vitro studies confirm cholinergic agonistic activity on postsynaptic M3 receptors, as well as suggesting an inhibitory effect on presynaptic muscarinic autoreceptors (Ghayur et al 2007). The [6]-gingerol constituent displayed the strongest antispasmodic activity (Ghayur et al 2008).

Anti-ulcer activity

A number of in vivo studies have identified anti-ulcer activity for ginger extract and several of its isolated constituents. The orally administered acetone extract of ginger at a dose of 1000 mg/kg and zingiberene, the main terpenoid in this extract, at 100 mg/kg significantly inhibited gastric lesions by 97.5% and 53.6%, respectively. Additionally, the pungent principle, [6]-gingerol at 100 mg/kg, significantly inhibited gastric lesions by 54.5%. These results suggest that both zingiberene and [6]-gingerol are important constituents responsible for ginger's anti-ulcer activity (Yamahara et al 1988). Other constituents demonstrating anti-ulcer properties in gastric ulcer models in rats include beta-sesquiphellandrene, beta-bisabolene, ar-curcumene and shogaol (Sertie et al 1992, Yoshikawa et al 1994).

Helicobacter pylori has been identified as a major causative factor in gastric ulcer. In vitro studies have established ginger extract containing gingerols effectively inhibited the growth of 19 strains of *H. pylori* including CagA+ strains (Mahady et al 2003, 2005). While ginger is effective in inhibiting *H. pylori*, its ability to prevent bacterial adhesion to the stomach tissue is limited (O'Mahoney et al 2005).

In addition to direct anti-ulcer activity, ginger exerts synergistic effects with the antibiotic clarithromycin in inhibiting different *H. pylori* isolates independent of the organisms' susceptibility to clarithromycin (Nostro et al 2006). Ginger-free phenolic and ginger hydrolysed phenolic fractions were found to be potent inhibitors of gastric cell proton potassium ATPase and *H. pylori*, exhibiting a six-to-eight-fold better potency over lansoprazole (Siddaraju & Dharmesh 2007).

Hypolipidaemic

Ginger demonstrates significant lipid lowering activity in several animal models and, more recently, a double-blind clinical trial.

High doses of an aqueous extract of ginger (500 mg/kg) significantly reduced serum cholesterol according to an animal study that used oral doses of a raw aqueous extract of ginger administered daily for a period of 4 weeks (Thomson et al 2002). Treatment with ginger methanol and ethyl acetate extracts (250 mg/kg) for 8 weeks also resulted in a significant reduction in lipid levels in vivo (Goyal & Kadnur 2006). Similarly, methanolic and ethyl acetate extracts of dried ginger rhizome significantly reduced fructose elevated lipid levels and body weight in vivo (Kadnur & Goyal 2005). Reductions in lipid levels were further reported for ethanolic extract of ginger (200 mg/kg for 20 days) by using a streptozocin-induced diabetic rat model. In addition, herbal treatment effectively reduced serum glucose (Bhandari et al 2005).

Effects on triglyceride levels are more difficult to determine, as one study demonstrated that 250 microgram ginger extract/day reduced serum triglyceride levels by 27% in mice (Fuhrman et al 2000), whereas another study using a high dose of 500 mg/kg found no significant effects (Thomson et al 2002).

An ex vivo study found that 250 microgram/day of a standardised ginger extract significantly reduced plasma cholesterol, triglycerides and LDL cholesterol levels, the LDL basal oxidative state, as well as LDL cholesterol and serum cholesterol's susceptibility to oxidation and aggregation, compared with placebo. Ginger also reduced aortic atherosclerotic lesions by 44% in atherosclerotic mouse aorta (Fuhrman et al 2000).

According to a double-blind controlled clinical trial study of 85 volunteers, ginger (3 g/day) demonstrates clinically significant lipid lowering effects compared to controls. After 45 days of treatment, triglyceride and cholesterol levels were reduced as well as a reduction in LDL levels and an increase in HDL levels (Alizadeh-Navaei et al 2008).

Glycaemic response

Tests conducted with various animal models indicate hypoglycaemic activity for ginger.

One study tested 500 mg/kg of raw ginger administered to streptozotocin-induced diabetic rats, which proved to significantly lower serum glucose. Treatment with ginger also resulted in a significant reduction in proteinuria, enuresis, thirst and sustained maintenance of initial weights (Al-Amin et al 2006).

Researchers postulate that ginger improves insulin sensitivity resulting in a reduction in elevated glucose levels (Goyal & Kandur 2006). The results of one in vivo study suggest that ginger is insulinotropic rather than hypoglycaemic (Islam & Choi 2008).

Gingerols have been identified as the main constituent group responsible for improving insulin sensitivity. In an assay for aldose reductase inhibitors within ginger, five active compounds were isolated and two were found to be inhibitors of recombinant human aldose reductase (Kato et al 2006).

Anti-inflammatory and analgesic

The anti-inflammatory and analgesic effects reported for ginger are attributed to multiple constituents exerting several different mechanisms.

An acetone extract containing gingerols, shogaols and minor compounds like gingerenone A, [6]-gingerdiol, hexahydrocurcumin and zingerone have been shown synergistically to produce dose-dependent anti-inflammatory effects (Schuhbaum & Franz 2000). Other studies have identified the gingerols and diarylheptanoids and gingerdione as the key compounds responsible (Flynn et al 1986, Kiuchi et al 1992).

Investigations on macrophages in vitro found that [6]-shogaol and [6]-gingerol inhibit the expression of inflammatory iNOS and COX-2 proteins (Pan et al 2008). [6]-Gingerol has also been shown to inhibit catalytic activity of iNOS in murine macrophages via attenuation of NF-kappaB-mediated iNOS gene expression (Aktan et al 2006). [6]-Gingerol proved to be useful in treatment of inflammation by selectively inhibiting the production of inflammatory cytokines of murine peritoneal macrophages without interfering with the antigen presenting function of the macrophages (Tripathi et al 2007). Ginger extract inhibited interleukin (IL)-12, tumour necrosis factor (TNF)-alpha, IL-1-beta in lipopolysaccharide-stimulated macrophages and significantly reduced T-cell proliferation (Tripathi et al 2008).

Ginger has been found to modulate the arachidonic acid cascade, as COX-1 and -2 and lipoxygenase inhibition has been shown in vitro (Kobayashi et al 1987) and high oral doses of an aqueous extract of ginger (500 mg/kg) significantly lowered serum PGE2 and thromboxane B2 levels in rats (Thomson et al 2002). A hydroalcoholic extract of ginger exerted anti-inflammatory and attenuated COX metabolites in rat trachea hyperactivity for 90 minutes and 48 hours after exposure to lipopolysaccharide (LPS). Ginger reduced serum levels of prostaglandin (PGE2) and thromboxane (TXA2) post LPS exposure (Aimbire et al 2007). Ginger also suppresses leukotriene biosynthesis by inhibiting 5-lipoxygenase, thus distinguishing ginger from non-steroidal anti-inflammatory drugs (NSAIDs). Additionally, ginger extract has been shown to inhibit thromboxane synthase (Langner et al 1998) and a ginger extract (EV.EXT 77) has been found to inhibit the induction of several genes involved in the inflammatory response. These include genes encoding cytokines, chemokines and the inducible enzyme COX-2, thus providing evidence that ginger modulates biochemical pathways activated in chronic inflammation (Grzanna et al 2005).

Gingerol and [8]-gingerol have been found to evoke capsaicin-like intracellular Ca^{2+} transients and ion currents in vitro and it has been suggested that gingerols represent a novel class of naturally occurring vanilloid receptor agonists that contribute to ginger's medicinal properties (Dedov et al 2002). This is supported by the finding that topical application of ginger creams or compresses produce an analgesic capsaicin-like effect on the release of the immunoreactive substance P from primary afferent neurons (Onogi et al 1992). In an animal study of chemically induced inflammation, ginger

extract reduced oedema that was partly caused by serotonin-receptor antagonism (Penna et al 2003). Additionally, ginger oil has shown anti-inflammatory activity, significantly suppressing both paw and joint swelling in severe adjuvant arthritis in rats (Sharma et al 1994).

In an animal model of rheumatoid arthritis both crude ginger extract and gingerols were efficacious in preventing streptococcal cell wall-induced arthritis. However, the crude ginger extract, which also contained essential oils, was more effective in preventing both joint inflammation and attenuating cellular destruction (Funk et al 2009).

Antiplatelet

It has been suggested that gingerols and their derivatives represent a potential new class of platelet activation inhibitors, with synthetic gingerols being found to inhibit the arachidonic acid-induced platelet release reaction in vitro in a similar dose range as aspirin possibly due to an effect on COX activity in platelets (Koo et al 2001, Lu 2005, Nurtjahja-Tjendraputra et al 2003, Tjendraputra et al 2001).

Powdered ginger exerted an antiplatelet activity when taken in very high doses of at least 10 g, according to one human study (Bordia et al 1997). A randomised double-blind study found that doses up to 2 g of dried ginger had no effect on bleeding time, platelet aggregation or platelet count (Lumb 1994). This lack of effect has been demonstrated in healthy volunteers (Janssen et al 1996) and those with type 1 diabetes mellitus or coronary artery disease (Bordia et al 1997).

Antimicrobial and antiparasitic

Ginger extract, several of its main constituents and essential oil of ginger exhibit antimicrobial activity in vitro and in vivo. Ginger extract has been shown to have an antibacterial effect against *Staphylococcus aureus*, *Streptococcus pyogenes*, *Streptococcus pneumoniae* and *Haemophilus* collected from throat swaps of infected individuals. The minimum inhibitory concentration of ginger ranged from 0.0003 to 0.7 microgram/mL, and the minimum bactericidal concentration ranged from 0.135 to 2.04 microgram/mL (Akoachere et al 2002). The anti-*H. pylori* effects of ginger have also been shown to inhibit *H. pylori* CagA+ strains in vitro (Mahady et al 2003). Essential oils of ginger have also been shown to have antimicrobial activity against gram-positive and gram-negative bacteria in vitro (Martins et al 2001).

Ginger constituents

[10]-Gingerol and [12]-gingerol successfully inhibited oral bacteria associated with periodontitis. Ethanol and *n*-hexane extracts of ginger have demonstrated antibacterial activities against the bacteria *Porphyromonas gingivalis*, *Porphyromonas endodontalis* and *Prevotella intermedia*, associated with periodontal disease effectively inhibited the growth of these anaerobic gram-negative bacteria (Park et al 2008). Intraperitoneally administered ginger exerted a dose-dependent antimicrobial activity against *Pseudomonas aeruginosa*, *Salmonella typhimurium*, *Escherichia coli* and *Candida albicans* (Jagetia et al 2003).

Gingerols demonstrated antibacterial activity against *Bacillus subtilis* and *Escherichia coli* in vitro (Yamada et al 1992). [10]-Gingerol was found to potentiate the antibacterial actions of aminoglycosides in vancomycin-resistant enterococci, bacitracin and polymixin B suggesting [10]-gingerol increases membrane permeability of enterococcal cells promoting an enhanced influx of aminoglycosides (Nagoshi et al 2006).

Ginger has also shown antischistosomal activity. Gingerol (5.0 ppm) completely abolished the infectivity of *Schistosoma* spp (blood flukes) in animal studies (Adewunmi et al 1990). Gingerol and shogaol exhibited potent molluscicidal activity in vivo. Shogaol and gingerol have demonstrated antinematode activities; 6.25 microgram/mL 6-shogaol destroyed *Anisakis* larvae within 16 hours in vitro, whereas the anti-nematodal medication pyrantel pamoate had no lethal effect at 1 mg/mL (Goto et al 1990).

Antifungal and antiviral

Ginger constituents have demonstrated antifungal and antiviral activity. Shogaol and zingerone strongly inhibited *Salmonella typhi*, *Vibrio cholerae* and *Tricophyton violaceum*. Aqueous extracts have also been shown to be effective against *Trichomonas vaginalis* (Henry & Piggott 1987). Several sesquiterpenes, but especially beta-sesquiphellandrene, isolated from ginger have also been shown to have antirhinoviral activity in vitro (Denyer et al 1994).

Essential oils of ginger have been shown to have activity yeasts and filamentous fungi in vitro (Martins et al 2001). Such oils have exhibited virucidal activity against acyclovir-sensitive and resistant strains of herpes simplex-1 reducing plaque formation significantly (Schnitzler et al 2007). A further in vitro study has indicated a dose-dependent virucidal activity against herpes simplex-2 is possible by interaction with the viral envelope (Koch et al 2008).

Antioxidant

Clinical investigations have confirmed that ginger displays strong in vitro and in vivo antioxidant properties. Orally administered ginger significantly lowered levels of free radicals and raised the activities of endogenous antioxidants, superoxide dismutase and catalase and had a sparing effect on vitamins C and E (Jeyakumar et al 1999). Ginger has been found to protect against lipid peroxidation in the liver (Ahmed et al 2008) and kidney (Asani & Verma 2007). An in vivo and in vitro research has proved [6]-gingerol to be effective in reducing ultraviolet B (UVB)-induced intracellular reactive oxygen species (ROS), UVB-induced expression of COX-2 and inhibited the translocation of NF-kappaB from cytosol to cell nucleus. Moreover, topical application of [6]-gingerol prior to UVB exposure on hairless mice inhibited COX-2 mRNA, and protein and NF-kappaB translocation (Kim et al 2007).

Immunomodulation

In vitro and in vivo research suggests that ginger extract exerts some degree of immunomodulatory activity (Ahui et al 2008, Imanishi et al 2006, Tripathi et al 2008).

Ginger exerted an immunosuppressive in vitro lymphocyte proliferation analysis, an effect modulated through IL-2 production (Wilasrusmee et al 2002). Ginger oil has also been shown to have immunomodulatory activity in mice, with dose-dependent inhibition of T lymphocyte proliferation and IL-1-alpha secretion and reduced delayed type of hypersensitivity response in vivo (Zhou et al 2006).

Hepatoprotective

Ginger has significant hepatoprotective effects comparable to those of silymarin, according to a research with experimental models of alcohol-induced liver damage (Bhandari et al 2003). The effect appears to be mediated by an antioxidative mechanism. Reversal of ethanol-induced liver damage was achieved following the treatment with 1% ginger for 4 weeks. The hepatoprotective action was mediated by preventing a decline in antioxidant status (Mallikarjuna et al 2008). Pretreatment with an ethanol extract of ginger exerted a protective effect against carbon tetrachloride and acetaminophen induced acute liver damage in rats, with attenuation of serum and liver marker enzymes (Yemitan & Izegbu 2006). In a similar study ginger exerted significant declines in the activities of serum transaminases and alkaline phosphatase and restoration of hepatic oxidative status post administration of a single dose (Ajith et al 2007).

Nephroprotection

Ginger prevented the decline in renal antioxidant status by increasing glutathione-s-transferase activity in an experimental model of nephrotoxicity (Ajith et al 2008). Ginger exhibited a significant dose-dependent nephroprotective role in experimentally induced acute renal damage when administered as a stand-alone treatment (250 mg/kg) and when used in combination with vitamin E (Ajith et al 2007).

Chemoprotective

The inhibitory effects of ginger in tumour development have been demonstrated in animal models and human cell lines. Antitumour properties have been isolated to several key constituents of ginger including [6]-gingerol, [6]-paradol, shogaols, zerumbone and zingerone and are partly due to an antioxidative and anti-inflammatory mechanism (Kim et al 2005).

Application of ginger or its constituents achieved induction of apoptosis in cancerous cells resulting in suppression of proliferation (Lee & Surh 1998) and apoptosis resulting in cell transformation (Bode et al 2001). The apoptotic effect of ginger constituents was also demonstrated in human promyelocytic leukaemia cells (Wei et al 2005). The modulation of proteins involved in apoptosis has also been demonstrated in vivo and in vitro prostate cancer models (Shukla et al 2007). [6]-Gingerol administration exerted actions of cell cycle arrest and induction of apoptosis in suppression of hepatoma cells (Yagihashi et al 2008). [6]-Gingerol was also found to exert a direct suppressive effect on colon cancer cell growth and inhibit angiogenesis by reduction in tumour blood supply (Brown et al 2008). [6]-Shogaol has been found to effectively induce apoptotic cell death in human hepatoma p53 mutant cells by way of an intracellular oxidative stress mediated cascade which ultimately leads to cell death (Chen et al 2007).

Reduction of lipid peroxidation and increased antioxidant activity was attributed to suppression of colon carcinogenesis by ginger in male Wistar rats (Manju & Nalini 2005). Differing types of tumours exhibit high NF-kappaB activity sustaining angiogenesis and cell proliferation gingerols were found to display properties inhibiting the activation of NF-kappaB (Kim et al 2009, Takada et al 2005).

Human cell studies show that ginger and its constituents have a potential therapeutic role in the treatment and prevention of human breast cancer (Lee et al 2008), ovarian cancer (Rhode et al 2007), gastric cancer (Ishiguro et al 2007) and pancreatic cancer (Park et al 2006). It has been suggested that future studies investigating chemoprotective roles of ginger constituents in human cancers should include human intervention trials (Shukla & Singh 2007).

Ginger and moxibustion — a clinical perspective

Moxibustion as a part of acupuncture has been well noted in TCM and is widely accepted as a useful complementary and alternative medicine therapy (Okada & Kawakita 2009). Indirect moxibustion utilises ginger slices placed at specific acupuncture points to insulate the skin from burning moxa sticks and provides therapeutic effects via thermal stimulation and sympathetic vibration (Shen et al 2006).

A review of 587 acupuncture and moxibustion randomised controlled papers from 1978 to 2007 conducted by Du et al 2009 demonstrated the growing indications for, and applications of, the use of moxibustion and acupuncture. Clinical trials have shown ginger partitioned moxibustion to be therapeutically effective in the treatment of child diarrhoea (Liu et al 2003), cervical vertigo (Xiaoxiang 2006), poststroke urination disorders (Liu & Wang 2006), leukopenia induced by chemotherapy (Zhao et al 2007) and rheumatoid arthritis (Xie & Lei 2008).

OTHER ACTIONS

Antihistamine

Shogaols and certain gingerols exhibit dose-dependent inhibition of drug-induced histamine release from rat peritoneal mast cells in vitro (Yamahara et al 1995).

Anxiolytic

A combination of ginger and *Ginkgo biloba* has been shown to reduce anxiety in an animal model (elevated plus-maze test). The effect was similar to

diazepam (Hasenohrl et al 1996). A highly non-polar fraction of a ginger extract has been shown to possess anticonvulsant, anxiolytic and antiemetic activities in animals (Vishwakarma et al 2002).

Antifibrotic

Supplementation with 5 g ginger not only prevented a decrease, but also significantly increased fibrinolytic activity in 30 healthy adult volunteers who consumed 50 g fat in a meal in an open clinical study (Verma & Bordia 2001).

Positive inotrope

Gingerols and shogaols isolated from ginger have positive inotropic activity, as demonstrated on isolated heart muscle (Shoji et al 1982, Yamahara et al 1995). The effect of gingerol seems to be rather specific to SR Ca^{2+}–ATPase activity (Kobayashi et al 1987).

Thermogenic

Ginger helps to maintain body temperature and inhibit serotonin-induced hypothermia in vivo (Huang et al 1991, Kano et al 1991). However, the addition of a ginger-based sauce to a meal did not produce any significant effect on metabolic rate in humans (Henry & Piggott 1987).

Hypotensive

Aqueous ginger extract has been shown to lower blood pressure via stimulation of muscarinic receptors and blockade of Ca^{2+} channels in guinea pig atria (Ghayur et al 2005). The calcium channel blocking effect of ginger has been demonstrated in acetycholine (ACh) induced airway constriction of mouse lung tissue. Pretreatment with a 70% aqueous methanolic crude extract of ginger 30 min prior to ACh administration achieved significant reduction in airway contraction and Ca^{2+}. Similar results were achieved with verapamil, indicating comparable modes of action. Concomitant use of both ginger extract and verapamil achieved the same outcome as when each was used alone (Ghayur et al 2008).

CLINICAL USE

Although ginger is used in many forms, including fresh ginger used in cooking or chai (Indian spicy tea), pickled or glazed ginger, ethanol extracts and concentrated powdered extracts, preparations made with the root are used medicinally. Depending on the specific solvent used, the resultant preparation will contain different concentrations of the active constituents and may differ markedly from crude ginger. Although the great majority of research refer specifically to the species *Zingiber officinale*, there is the potential for confusion with other species or even with other genera (Canter 2004). Furthermore, there are reported to be wide variations in the quality of commercial ginger supplements with concentrations of gingerols ranging from 0.0 to 9.43 mg/g. As such, the results of specific extracts cannot necessarily be extrapolated to different preparations (Schwertner et al 2006).

Prevention of nausea and vomiting

Many clinical studies have investigated the effects of ginger in the prevention and treatment of nausea and vomiting associated with different circumstances, including pregnancy (Fischer-Rasmussen et al 1990, Keating & Chez 2002, Portnoi et al 2003, Smith et al 2004, Sripramote & Lekhyananda 2003, Vutyavanich et al 2001, Willetts et al 2003), the postoperative period (Arfeen et al 1995, Bone et al 1990, Meyer et al 1995, Phillips et al 1993, Visalyaputra et al 1998), motion sickness (Grontved & Hentzer 1986, Lien et al 2003, Mowrey & Clayson 1982, Schmid et al 1994, Stewart et al 1991) and chemotherapy (Manusirivithaya et al 2004, Meyer et al 1995, Sontakke et al 2003).

A systematic review of 24 randomised controlled trials (RCTs) covering 1073 patients suggests that results for the treatment of nausea and vomiting in pregnancy are encouraging and generally supportive; however, results for postoperative nausea and vomiting and motion sickness are unclear and daily doses of up to 6 g of ginger seem to have few side effects (Betz et al 2005). More reviews provide further encouragement and suggest that ginger may indeed be effective in nausea associated with pregnancy (Boone & Shields 2005) and the postoperative period (Chaiyakunapruk et al 2006). Similarly a review of four well-controlled, double-blind, randomised clinical studies concluded there was convincing evidence for application of ginger in the treatment of nausea and vomiting of pregnancy (Bryer 2005).

Nausea and vomiting in pregnancy

There is supportive evidence from clinical studies that ginger preparations in pregnancy reduce the duration and severity of nausea and vomiting.

Nausea of pregnancy

There are many studies, including an observational study (Portnoi et al 2003) and at least six RCTs (Fischer-Rasmussen et al 1990, Keating & Chez 2002, Portnoi et al 2003, Smith et al 2004, Sripramote & Lekhyananda 2003, Vutyavanich et al 2001, Willetts et al 2003), as well as multiple systematic reviews, including a Cochrane review, that suggest that ginger powder or extract may be safe and effective in treating nausea and vomiting of pregnancy (Boone & Shields 2005, Borrelli et al 2005, Bryer 2005, Dib & El-Saddik 2004, Ernst & Pittler 2000, Jewell 2003). A subsequent review, considering six

> ***Clinical note — Morning sickness***
>
> Nausea and vomiting are the most common symptoms experienced in early pregnancy, with nausea affecting between 70% and 85% of women. About half of pregnant women experience vomiting (Jewell & Young 2002). Hyperemesis gravidarum is more severe and affects between 0.3% and 2% of all pregnant women. It is a multifactorial disease in which pregnancy-induced hormonal changes associated with concurrent gastrointestinal dysmotility and possible *Helicobacter pylori* infection function as contributing factors (Eliakim et al 2000).

double-blind RCTs with a total of 675 participants, and a prospective observational cohort study of 187 women, suggest that ginger is superior to placebo and as effective as vitamin B_6 in relieving pregnancy-related nausea and vomiting and that there is an absence of significant side effects and adverse pregnancy outcomes (Borrelli et al 2005).

In three double-blind, placebo-controlled, randomised trials of ginger for pregnancy-related nausea and vomiting, including one trial on hyperemesis gravidarum, 1 g ginger in divided doses was significantly more effective than placebo in reducing nausea and vomiting (Fischer-Rasmussen et al 1990, Keating & Chez 2002, Vutyavanich et al 2001). In a further double-blind trial of 120 women, 25 mg of the ginger extract EV.EXT 35 (equivalent to 1.5 g of dried ginger) four times daily was useful in patients experiencing nausea and retching, although no significant result was seen for vomiting (Willetts et al 2003).

Comparative studies

More recently, a comparative double-blind randomised controlled trial of 170 pregnant women who attended an antenatal clinic with the symptoms of nausea and vomiting in pregnancy found one capsule of ginger (0.5 g ginger powder) twice daily was identical in efficacy to treatment with 50 mg dimenhydrinate twice daily. In addition, ginger treatment resulted in fewer side effects (Pongrojpaw et al 2007). Initial comparative randomised, double-blind controlled trials found ginger to be equivalent to vitamin B_6 in helping to reduce pregnancy-related nausea, dry retching and vomiting (Smith et al 2004, Sripramote & Lekhyananda 2003). However, ginger (650 mg qid) proved more effective than vitamin B_6 (25 mg qid) in a randomised double-blind controlled trial involving 126 pregnant women, with a gestational age of ≤ 16 weeks who had nausea and vomiting (Chittumma et al 2007). Investigations over a 3-month duration into the efficacy of ginger compared to vitamin B_6 of 70 pregnant women with nausea, a gestational age of ≤ 17 weeks were randomised to receive either ginger 1 g/day or vitamin B_6 40 mg/day for 4 days. Treatment with ginger was found to be more effective than vitamin B_6 for relieving the severity of nausea, as well as equally effective in decreasing the episodes of vomiting (Ensiyeh & Sakineh 2008).

Postoperative nausea

Ginger may be useful for the prevention of postoperative nausea; however, not all studies have produced positive results and as the ginger preparations used have not been standardised, it is difficult to directly compare studies. A recent meta-analysis of five randomised trials, however, including a total of 363 patients found that a fixed dose of at least 1 g of ginger was more effective than placebo for the prevention of postoperative nausea and vomiting (Chaiyakunapruk et al 2006).

Most of the studies on postoperative nausea and vomiting have been done on patients undergoing gynaecological surgery. In two such randomised, placebo-controlled, double-blind studies, ginger significantly reduced the incidence of postoperative nausea and vomiting (Bone et al 1990, Phillips et al 1993), although two further studies failed to show any benefit with ginger (Arfeen et al 1995, Eberhart et al 2003). A fifth study of 80 women undergoing gynaecological laparoscopy found that 1 g of ginger taken 1 hour before surgery was significantly superior to placebo in reducing the incidence of nausea 2–4 hours afterwards; however, it failed to show statistical significance for an observed reduction in the incidence and frequency of vomiting (Pongrojpaw & Chiamchanya 2003).

A double-blind randomised controlled trial of 120 patients who underwent major gynaecological surgery found that a pretreatment with ginger powder (0.5 g) as compared to placebo resulted in lower incidence and frequency of vomiting in the treatment group. Frequency of vomiting was evaluated at 0, 2, 6, 12, and 24 hours postoperatively with the most statistically significant differences between ginger and placebo occurring at the 2- and 6-hour time intervals (Nanthakomon & Pongrojpaw 2006). Similarly a randomised study of 60 inpatients who underwent laparoscopic operations for non-cancer gynaecological conditions found that pretreatment 1 hour prior to surgery with three capsules of ginger (0.5 g of ginger powder per capsule) when compared to placebo significantly prevented vomiting at 6 hours postoperation. The effect was not apparent at 2 hours postoperation (Apariman et al 2006).

Although other types of surgery have not been as extensively studied as gynaecological surgery, there is a report on 6 months of clinical anaesthetic experience that suggests that a nasocutaneously administered 5% solution of essential oil of ginger given pre-operatively, together with conventional therapies, to general anaesthesia patients at high risk for postoperative nausea and vomiting is a safe and cost-effective way of reducing nausea and vomiting post anaesthesia (Geiger 2005).

In the only double-blind, placebo-controlled study of postoperative nausea and vomiting in patients undergoing middle ear surgery, ginger was ineffective and the use of 1 g of ginger 1 hour before surgery was associated with significantly more postoperative nausea and vomiting than the use of ondansetron or placebo (Gulhas et al 2003).

Motion sickness

Commission E approves the use of ginger root for the prevention of motion sickness (Blumenthal et al 2000) and several clinical studies have assessed its effects as either prophylaxis or treatment. An early double-blind, randomised, placebo-controlled study involving 80 naval cadets found that ginger was significantly superior to placebo in reducing symptoms of vomiting and cold sweats due to seasickness. Fewer symptoms of nausea and vertigo were also reported with ginger, but the difference was not statistically significant (Grontved & Hentzer 1986). In another randomised double-blind study of seasickness involving over 1700 tourists on a whale-watching safari 300 km north of the Arctic circle, 500 mg ginger was found to be as effective for the treatment of motion sickness as several

common antiemetic medications (cinnarizine, cyclizine, dimenhydrinate, domperidone, meclizine and scopolamine) with ginger preventing seasickness in 80% of the subjects during the 6-hour boat trip, although the incidence of severe vomiting did not differ significantly between treatment groups (Schmid et al 1994).

At least three studies have had mixed results from experimental models of motion sickness whereby subjects are seated in a rotating chair. The first study involving 28 volunteers found no significant protective effects for powdered ginger (500 mg or 1000 mg) or fresh ginger root (1000 mg) (Stewart et al 1991), whereas a second study involving 36 undergraduate men and women who reported very high susceptibility to motion sickness found that ginger was superior to dimenhydrinate (Mowrey & Clayson 1982). Another double-blind, randomised, placebo-controlled crossover study showed positive benefits with ginger pretreatment on prolonging time before nausea, shortening recovery time and effectively reducing nausea (Lien et al 2003). This study used pretreatment doses of 1000 mg and 2000 mg, which were also shown to reduce tachygastria and plasma vasopressin.

Chemotherapy-induced nausea

In an open study, 1.5 g ginger was found to decrease psoralen-induced nausea in 11 patients treated with photopheresis for cutaneous T-cell lymphoma (Meyer et al 1995).

Powdered ginger root effectively reduced cyclophosphamide-induced nausea and vomiting in a randomised, prospective, crossover double-blind study, with the antiemetic effect of ginger being equal to metoclopramide (Sontakke et al 2003). Ginger was found to have similar efficacy to metoclopramide in reducing cisplatin-induced emesis in a randomised, double-blinded, crossover study of 48 gynaecological cancer patients receiving chemotherapy (Manusirivithaya et al 2004). In a study of 28 cancer patients receiving chemotherapy for the first time, patients receiving high protein meals with ginger for 3 days beginning the day after chemotherapy were found to experience a reduction in delayed nausea and a reduced need for antiemetic medications compared to control groups (Levine et al 2008). However, a randomised, double-blind, placebo-controlled trial in 162 patients with cancer receiving chemotherapy and a previous experience of chemotherapy-induced nausea and vomiting found ginger (either 1 g or 2 g daily) provided no additional benefits for nausea prevention when given with 5-HT(3) receptor antagonists and/or aprepitant (Zick et al 2009).

Musculoskeletal disorders

Ginger is described in Ayurvedic (traditional Indian) and Tibb (traditional Arabian) systems of medicine to be useful in inflammation and rheumatism and this traditional use is supported by modern studies demonstrating ginger's anti-inflammatory activity.

A randomised, double-blind, placebo-controlled, multicentre, parallel-group 6-week study of 261 patients found that a highly purified and standardised ginger extract (EV.EXT 77) moderately reduced the symptoms of osteoarthritis (OA) of the knee (Altman & Marcussen 2001). Similarly, 250 mg of the ginger extract (Zintona EC) four times daily for 6 months was shown to be significantly more effective than placebo in reducing pain and disability in 29 OA patients in a double-blind, placebo-controlled, crossover study (Wigler et al 2003).

These studies are supported by an open retrospective study involving 56 patients (28 with RA, 18 with OA, 10 with muscular discomfort) that revealed that more than three quarters experienced varying degrees of relief of pain and swelling from the long-term use of powdered ginger (Srivastava & Mustafa 1992). Further support comes from studies comparing ginger to NSAIDs.

In one double-blind, randomised, placebo-controlled trial involving 120 patients, 30 mg of an ethanolic ginger extract equivalent to 1 g of ginger and prepared from fresh ginger purchased from a local market in India was found to be significantly more effective than placebo and was as effective as 1.2 g of ibuprofen in the symptomatic treatment of OA (Haghighi et al 2005). In another double-blind crossover study, 170 mg of the ginger extract EV.EXT 33 with a standardised content of hydroxy-methoxy-phenyl compounds given twice daily was found to be significantly more effective than placebo but not as effective as ibuprofen in reducing pain and disability in 75 patients with OA before the crossover period, whereas no statistical difference was seen between ginger and placebo in the analysis after the crossover period. The authors commented that the washout period may have been insufficient and that ginger might need to be administered for longer than 3 weeks, and possibly in a higher dosage, to be clinically effective (Bliddal et al 2000).

Dysmenorrhoea

Ginger has been used orally to treat dysmenorrhoea. Due to its ability to inhibit thromboxane synthetase and activate endorphin receptors, the use of ginger has been suggested in treatment of dysmenorrhoea (Backon 1991). A double-blind comparative clinical trial involving 150 participants demonstrated that ginger (250 mg ginger rhizome powder qid for 3 days from the start of their menstrual period) was just as effective as 250 mg mefenamic acid or 400 mg ibuprofen capsules in relieving pain in women with primary dysmenorrhoea (Ozgoli et al 2009).

Dyspepsia

Ginger stimulates the flow of saliva, bile and gastric secretions and therefore is traditionally used to stimulate appetite, reduce flatulence and colic, gastrointestinal spasms and generally act as a digestive aid. Commission E approves the use of ginger root for the treatment of dyspepsia (Blumenthal et al 2000).

Hyperlipidaemia

A double-blind controlled clinical trial of 85 volunteers with hyperlipidaemia showed ginger treatment (3 g/day) produced a significant lipid lowering

effect compared to controls. Measurement of lipid concentrations before and after 45 days of treatment showed significantly higher mean changes in triglyceride and cholesterol levels for ginger compared to control ($P < 0.05$) as well as significant mean reduction in LDL level and increase in HDL levels compared to controls (Alizadeh-Navaei et al 2008). This initial study shows promising results, however further controlled human trials are necessary to prove efficacy.

Migraine

Ginger is used to prevent and treat migraine headache. Its ability to inhibit thromboxane A2 and exert antihistamine, anti-inflammatory and gastric actions makes it a theoretically attractive choice (Mustafa & Srivastava 1990). This use is supported by an open-label study of 30 migraine sufferers that reported that treatment with a sublingual ginger and feverfew preparation (GelStat MigraineO) in the initial phase of a migraine resulted in most patients being satisfied with the therapy and being pain-free or only having mild headache post-treatment (Cady et al 2005).

OTHER USES

Ginger cream or compress is used externally for mastitis.

Diabetes

Ginger may also have potential benefits in the treatment of diabetes according to some promising animal studies indicating that ginger improves insulin sensitivity and reduces serum glucose levels. Clinical trials are required to confirm the significance of these findings in humans.

Weight loss

Further investigations in animal models suggest a potential role for ginger in weight loss. A significant reduction in body weight and parmetrial adipose tissue following oral administration of zingerone in ovariectomised rats indicated that by increasing norepinephrine-induced lipolysis in adipocytes, zingerone may prevent fat storage (Han et al 2008). The anti-obesity action of ginger may be a result of slowed intestinal absorption of dietary fat (Han et al 2005).

Asthma

A possible therapeutic role for gingerol in the treatment of asthma has been indicated through a recent animal model. An aqueous ginger extract enriched in *n*-gingerols was investigated in Th2-mediated pulmonary inflammation where gingerols were found to decrease recruitment of eosinophils to the lungs and suppress Th2 cell response to allergen. Serum IL-4, IL-5 and IgE titres were diminished in ginger-treated mice relative to controls (Ahui et al 2008).

Ulcerative colitis

Recent research has identified a potential role for ginger in attenuating inflammatory bowel disease. In an in vitro study involving ulcerated male wistar rats, ginger extract was found to be comparable to sulfasalazine in attenuating colonic mucosal injury. The effect of ginger against acetic acid-induced ulcerative colitis has been attributed to its anti-inflammatory and antioxidant properties (El-Abhar et al 2008). Clinical trials are required to determine the significance of this effect in humans.

DOSAGE RANGE

The recommended dose ranges widely from 500 mg to 9 g/day dried root or equivalent; however, a safe maximal dose is 4 g/day. As there are wide variations in the gingerol concentrations in commercial ginger supplements (Schwertner et al 2006), the effective dosage will depend on the preparation and the indication for use.

- Liquid extract (1:2): 0.7–4.0 mL/day.
- Dried root: 1–3 g daily in divided doses.
- Infusion: 4–6 slices of fresh ginger steeped in boiling water for 30 minutes.

According to clinical studies

- Dysmenorrhoea: 250 mg ginger rhizome powder taken four times daily for 3 days from the start of the menstrual period.
- Hyperlipidaemia: 3 g/day.
- Nausea and vomiting of pregnancy: 1–2 g taken daily in divided doses.
- Motion sickness: powdered ginger (500 mg or 1000 mg) or fresh ginger root (1000 mg) up to 2000 mg.
- Osteoarthritis: 250 mg of the ginger extract (Zintona EC) four times daily.
- Prevention of postoperative nausea: 1 g 1 hour prior to surgery.
- Rheumatoid arthritis: 1–2 g/day of powdered ginger.

ADVERSE REACTIONS

Gastric irritation, heartburn and bloating have been reported in clinical trials (Arfeen et al 1995). Contact dermatitis of the fingertips has also been reported (Seetharam & Pasricha 1987) with topical use.

SIGNIFICANT INTERACTIONS

Controlled studies are not available for many interactions; therefore they are based on evidence of activity and are largely theoretical and speculative.

Warfarin

Due to the herb's antiplatelet effects there is a theoretical risk of increased bleeding at high doses (> 10 g) although this is not evident clinically. There is no evidence of an interaction with warfarin at the usual dietary and therapeutic intakes (Jiang et al 2005, Stenton et al 2001, Vaes & Chyka 2000), and ginger has been shown not to alter prothrombin times in pooled human plasma collected from male volunteers between the ages of 18 and 57 years (Jones et al 2001). A standardised ginger extract, EV.EXT 33, has demonstrated no significant effect on coagulation parameters or on warfarin-induced changes in blood coagulation in rats (Weidner & Sigwart 2000) and ginger was found not to affect clotting status or the pharmacokinetics or pharmacodynamics of warfarin in healthy human subjects (Jiang et al 2005).

A study of 24 subjects found that ginger did not significantly affect clotting status or pharmacokinetics of warfarin in healthy subjects (Jiang et al 2006).

Due to the potential seriousness of the proposed interaction, people taking warfarin should use high-dose supplements (> 10 g/day) with caution.

Antiplatelet drugs

Theoretically, increased antiplatelet and anti-inflammatory effects may occur with high-dose ginger preparations, but the clinical significance of this is unknown. Caution should be exercised with doses > 10 g — possible beneficial effect.

Cisplatin

Pretreatment has restored testicular antioxidant parameters and sperm motility in cisplatin-induced damage in an animal model (Amin & Hamza 2006). Clinical implications are uncertain; however, potential benefits may be found upon further testing.

CONTRAINDICATIONS AND PRECAUTIONS

Ginger in high doses is not recommended for children under 6 years of age due to the pungent nature of ginger. However, if the benefits of ginger treatment outweigh the potential for gastric irritation, then it can be used. Alternatively, ginger lollies or ginger ale is sometimes used and a dose of 250 mg every 4 hours for motion sickness is safe.

Commission E suggests that people with gallstones consult with their physician before using ginger. People with gastric ulcers or reflux should use this herb with caution. Suspend use of high-dose supplements (> 10 g) 1 week before major surgery.

PREGNANCY USE

Although Commission E suggests that ginger is contraindicated in pregnancy, more recent research suggests that ginger is not contraindicated in pregnancy — doses up to 2 g/day of dried ginger root have been used safely.

No adverse effects on pregnancy were observed in multiple studies of ginger for nausea and vomiting (Boone & Shields 2005, Borrelli et al 2005, Bryer 2005, Dib & El-Saddik 2004, Ernst & Pittler 2000, Jewell 2002).

PRACTICE POINTS/PATIENT COUNSELLING

- Ginger is most often used for its antiemetic, anti-inflammatory and gastrointestinal effects.
- There is good clinical support for the use of ginger in the treatment of nausea and vomiting associated with pregnancy and some evidence for its use in motion sickness, the postoperative period and chemotherapy although this is less consistent.
- Ginger is traditionally used for gastrointestinal disorders including dyspepsia, poor appetite, flatulence, colic, vomiting, diarrhoea and spasms, as well as a diaphoretic in the treatment of the common cold and influenza.
- Ginger is also used as an anti-inflammatory agent for arthritis, although large controlled studies have yet to produce strong support for this use.
- Although antiplatelet effects have been reported, these require very large doses and are not likely to be significant in normal therapeutic doses or dietary intake levels.

PATIENTS' FAQs

What will this herb do for me?

Ginger is a useful treatment for nausea and vomiting associated with pregnancy and may also be of benefit in motion sickness, postoperative nausea and seasickness. It is also useful for treating symptoms of dyspepsia and may have symptom-relieving effects in arthritis, although this is less certain.

When will it start to work?

In the case of dyspepsia and motion sickness prevention, ginger will have an almost immediate effect, with improvement reported within 30 minutes. For motion sickness, 0.5–1.0 g ginger should be taken 30 minutes before travel and repeated 4 hourly. For nausea of pregnancy it should be taken for at least 4 days; however, symptoms should start to reduce within 1 hour of administration.

Are there any safety issues?

Ginger is well tolerated, although it should be used with caution by people with gallstones, gastric ulcers or reflux.

Ginkgo biloba

HISTORICAL NOTE *Ginkgo biloba* is one of the world's oldest living tree species, earning it the name 'living fossil'. Its existence can be traced back more than 200 million years and it was commonly found in North America and Europe before the Ice Age. Its place of origin is believed to be remote mountainous valleys of Zhejiang province of eastern China and up to 350 years ago, knowledge about this plant was restricted to China (Singh et al 2008). Ginkgo was first introduced into Europe in 1690 by the botanist Engelbert Kaempfer, who described it as the 'tree with duck feet'. Ginkgo has been used medicinally for decades and is now one of the most popular therapeutic agents prescribed in Europe by medical doctors. It has been estimated that in Germany and France, prescriptions for ginkgo make up 1% and 1.3%, respectively, of total prescription sales (Pizzorno & Murray 2006). Also popular in the United States, it was the top-selling herbal medicine in 1999 with sales of US$148 million.

Current estimates indicate that the use of *G. biloba* has been growing at a very rapid rate worldwide at 25% per year in the open world commercial market (Singh et al 2008). Germany, Switzerland and France have respectively 31%, 8% and 5% of the world commercial market. To meet the demand for ginkgo products, 50 million *G. biloba* trees are grown, especially in China, France and South Carolina, USA, producing 8000 tons of dried leaves each year.

COMMON NAME

Ginkgo

In England, it is known as 'Maidenhair tree' based on its resemblance to the foliage of the 'Maidenhair fern' (*Adiantum*). In Japan, it is known as 'Ginkyo' and in France, 'L'arbre aux Quarante ecus' and 'Noyer Du Japon' (Singh et al 2008).

OTHER NAMES

Adiantifolia, *Arbre aux quarante ecus*, bai guo ye, duck foot tree, fossil tree, gin-nan, icho, Japanese silver apricot, kew tree, maidenhair tree, salisburia, silver apricot, tempeltrae, temple balm, yinhsing

BOTANICAL NAME/FAMILY

Ginkgo biloba (family Ginkgoaceae)

PLANT PARTS USED

In modern times only the leaf is used, but traditionally the nut was also used.

CHEMICAL COMPONENTS

Important constituents present in the leaves are the terpene trilactones (i.e. ginkgolides A, B, C and J and bilobalide), many flavonol glycosides, biflavones, proanthocyanidins, alkylphenols, simple phenolic acids, 6-hydroxykynurenic acid, 4-O-methylpyridoxine and polyprenols (van Beek 2002). *G. biloba* contains more than 30 genuine flavonoids, of which the flavonol glycosides are the most abundant (Singh et al 2008).

There has been some interest in ginkgo alkylphenols (ginkgolic acids) because of their allergenic

Clinical note — Ginkgo extract used in practice
The standardised ginkgo extract is made from dried ginkgo leaves extracted in 60% acetone. Only a fraction of the leaf matter is extracted, 98% is not extracted. Of the 2% extracted, the flavones account for 25%, the ginkgolides 3% and the bilobalide 3%. The remaining 69% is not specified. The drug ratio may vary from 35:1 to 67:1 (average ratio 50:1). This means that, on average, it takes 50 kg dried leaf to produce 1 kg of extract. Standardised ginkgo extract (e.g. EGb 761) must be standardised to 22–27% flavone glycosides, 5–7% terpenes lactones (2.8–3.4% ginkgolides A, B and C, and 2.6–3.2% bilobalide). The content of ginkgolic acids must be less than 5 ppm (Blumenthal et al 2000). Although the standardisation is very specific, the compounds are considered to be marker compounds, as the active constituents of *G. biloba* have not been fully identified (unpubl. data: Keller K, Chair of the Herbal Medicinal Products Working Group, European Medicines Evaluation Agency. Quality Assurance of Herbal Medicines, March 2001).

properties, so most manufacturers limit the concentration of alkylphenols to 5 ppm.

MAIN ACTIONS

The many and varied pharmacological actions of ginkgo preparations are related to the presence of several classes of active constituents.

Antioxidant

G. biloba extract and several of its individual constituents, such as quercetin and kaempferol, have demonstrated significant antioxidant properties in vitro (Hibatallah et al 1999, Sloley et al 2000). Antioxidant activity has further been demonstrated in several different animal models.

Experimental models investigating the effects of ginkgo on reducing ischaemic injury have shown positive results, indicating that ginkgo reduces the damage caused by oxidative stress during reperfusion. One study using a model of myocardial infarction found that pretreatment with *G. biloba* extract EGb 761 reduced ischaemic myocardial injury compared to the untreated animals (Schneider et al 2008). Another in vivo study investigated the effects of *G. biloba* extract (EGb 761) on lung injury induced by intestinal ischaemia/reperfusion (II/R) (Liu et al 2007). The treated group received EGb 761 (100 mg/kg/day) via gastric tube for seven consecutive days prior to surgery, whereas the inactive group just received vehicle. Active treatment produced a significant protective effect on lung injury induced by II/R, which may be related to its antioxidant property and suppression of neutrophil accumulation and nitric oxide synthase (iNOS)-induced NO generation.

A novel study has investigated the effect of *G. biloba* on mobile phone-induced oxidative damage in brain tissue of rats (Ilhan et al 2004). Rats were exposed to the same amount of mobile phone-induced radiation for 7 days with some also pretreated with *G. biloba*. After exposure, oxidative damage was evident by the: (i) increase in malondialdehyde (MDA) and nitric oxide (NO) levels in brain tissue, (ii) decrease in brain superoxide dismutase (SOD) and glutathione peroxidase (GSH-Px) activities and (iii) increase in brain xanthine oxidase (XO) and adenosine deaminase (ADA) activities. *Gingko biloba* prevented these alterations and the mobile phone-induced cellular injury in brain tissue histopathologically.

Topical antioxidant effects have also been investigated. *G. biloba* has been shown to reduce the effects of UV radiation on skin (Aricioglu et al 2001, Hibatallah et al 1999, Kim 2001, Lin & Chang 1997). When applied topically, ginkgo increases the activity of SOD within skin, thereby enhancing the skin's natural defences.

Vascular effects

Vasodilation

Ginkgo promotes vasodilation and improves blood flow through arteries, veins and capillaries. Increases in microcirculatory blood flow occur rapidly and have been confirmed under randomised crossover test conditions 1 hour after administration (Jung et al 1990).

Several mechanisms of action are responsible. Currently, these are considered to be: inhibition of NO release, activation of Ca^{2+}-activated K^+ (K_{Ca}) channels, and increased prostacyclin release (Chen et al 1997, Koltermann et al 2007, Nishida & Satoh 2003). In 2008, a clinical study was published which provides further information about the mechanisms involved. Wu et al investigated the effects of *G. biloba* extract (GBE) on the distal left anterior descending coronary artery (LAD) blood flow and plasma nitric oxide (NO) and endothelin-1 (ET-1) levels (Wu et al 2008). The randomised study of 80 volunteers with coronary artery disease (CAD) used Doppler echocardiography to determine blood flow, which was measured at baseline and after 2 weeks of treatment. A significant improvement in maximal diastolic peak velocity, maximal systolic peak velocity and diastolic time velocity integral was observed for the group treated with GBE compared with controls ($P < 0.01$). Additionally, a significant increase in NO and decrease in ET-1 was observed, suggesting that the observed increase of LAD blood flow might be related to restoration of the delicate equilibrium between NO and ET-1.

Reduces oedema

Various flavonoids, including anthocyanosides and *G. biloba* extracts, have been shown to be effective against experimentally induced capillary hyperfiltration (Cohen-Boulakia et al 2000).

Antiplatelet and anticoagulant

There have been several case reports of *G. biloba* causing haemorrhage during or after surgery (Hauser et al 2002, Schneider et al 2002) and there is evidence that one of its components, ginkgolide

B, is a platelet-activating factor antagonist (Smith et al 1996). One clinical study demonstrated that EGb 761 (80 mg/day) produced a significant reduction in blood viscosity after 30 days' treatment (Galduroz et al 2007). When measured again 90 days after commencement of EGb 761 treatment, a further reduction was observed which appeared to stabilise, as no further reduction was observed after 180 days of use.

In contrast, at least 10 clinical studies have found no evidence of significant bleeding or platelet effects due to *G. biloba* ingestion (Aruna & Naidu 2007, Bal Dit et al 2003, Beckert et al 2007, Carlson et al 2007, Engelsen et al 2003, Gardner et al 2007, Jiang et al 2005, Kohler et al 2004, Lovera et al 2007, Wolf 2006). Studies have included young healthy volunteers, older adults, people with multiple sclerosis and people using warfarin or aspirin at the same time as *G. biloba*. An escalating dose study found that 120 mg, 240 mg or 480 mg given daily for 14 days did not alter platelet function or coagulation (Bal Dit et al 2003).

Alters neurotransmitters

Monoamine oxidase (MAO) inhibition

In vitro tests in rat brains suggest that EGb 761 may exert MAO-A and MAO-B inhibitor activity (Wu & Zhu 1999). Tests with isolated constituents, kaempferol, apigenin and chrysin, have demonstrated these to be potent MAO inhibitors, with greater effect on MAO-A than MAO-B (Sloley et al 2000).

Alternatively, one human study using positron emission tomography (PET) found that treatment with *G. biloba* (EGb 761: 120 mg/day) for 1 month did not produce significant changes in brain MAO-A or MAO-B in the 10 participating volunteers (Fowler et al 2000).

Serotonin

Another in vitro study found that oral EGb 761 significantly increases the uptake of serotonin, but not dopamine, in cerebral cortex samples from mice (Ramassamy et al 1992). Another in vivo study identified an antiaggressive effect mediated by 5-HT_{2A} receptors (Shih et al 2000).

Cholinergic effects

Considering that *G. biloba* appears to be as effective as anticholinesterase drugs, several researchers have investigated whether it exerts cholinergic effects. Evidence from behavioural, in vitro and ex vivo tests with *G. biloba* has shown both direct and indirect cholinergic activities (Das et al 2002, Nathan 2000). The extract appears to increase the rate of acetylcholine turnover and stimulate the binding activity of ligands to muscarinic receptors in the hippocampus (Muller 1989).

Gamma aminobutyric acid (GABA) receptors

Bilobalide in *G. biloba* is a competitive antagonist for GABA-A receptors according to in vitro tests (Huang et al 2003). The effect is almost as potent as bicuculline and pictrotoxinin.

Corticosterone

In vivo tests have found that EGb 761 has stress-alleviating properties mediated through its moderation of corticosterone levels (Puebla-Perez et al 2003).

Neuroprotection

G. biloba leaf extract (EGb 761) has demonstrated neuroprotective effects in a variety of studies ranging from molecular and cellular, to animal and human; however, the cellular and molecular mechanisms remain unclear (Ao et al 2006, Smith et al 2002). Of the constituents studied, it appears that the bilobalide constituent is chiefly responsible for this activity, although others are also involved (DeFeudis & Drieu 2000).

Until recently, it was believed that the antioxidant, membrane-stabilising and platelet-activating factor antagonist effects were chiefly responsible for neuroprotection, but effects at the mitochondria may also be important contributing mechanisms.

Beta-amyloid

G. biloba extract EGb 761 protects cells against toxicity induced by beta-amyloid in a concentration-dependent manner, according to in vitro tests (Bastianetto & Quirion 2002a, 2002b; Bastianetto et al 2000). In vivo studies have confirmed that ginkgo extract has an antiamyloid aggregation effect (Luo 2006). It appears that ginkgo increases transthyretin RNA levels in mouse hippocampus, which is noteworthy because transthyretin is involved in the transport of beta-amyloid and may provide a mechanism to reduce amyloid deposition in brain (Watanabe et al 2001). There is also evidence that *G. biloba* modulates alpha-secretase, the enzyme that cuts the amyloid precursor protein and prevents amyloidogenic fragments from being produced (Colciaghi et al 2004).

Cerebral ischaemia

There is evidence from experimental and clinical studies that *G. biloba* extract protects tissues from ischaemia/reperfusion damage (Janssens et al 2000). According to investigation with an experimental model, EGb 761 could prevent and treat acute cerebral ischaemia, but the effect was most pronounced when administered prophylactically (Peng et al 2003).

Stabilisation and protection of mitochondrial function

Several in vitro tests have demonstrated that EGb 761 stabilises and protects mitochondrial function (Eckert et al 2005, Janssens et al 2000). These observations are gaining the attention of researchers interested in neurodegenerative diseases, as it is suspected that the mitochondria and the phenomenon of mitochondrial permeability transition play a key role in neuronal cell death and the development of such diseases (Beal 2003, Shevtsova et al 2005).

Immunostimulant

Immunostimulatory activity has been demonstrated in several experimental models (Puebla-Perez et al 2003, Tian et al 2003, Villasenor-Garcia et al 2004).

The beneficial effects of EGb 761 on immune function are based on its antioxidant properties, as well as the cell proliferation-stimulating effect.

Anti-inflammatory

The anti-inflammatory activity of ginkgo has been investigated for the whole extract and an isolated biflavonoid component known as ginkgetin, with both forms demonstrating significant anti-inflammatory activity.

Ginkgo extract

Intravenously administered ginkgo extract produced an anti-inflammatory effect that was as strong as the same dose of prednisolone (i.e. 1 mg GBE = 1 mg prednisolone) in an experimental model. Ginkgo extract was also found to significantly reduce the concentration of PGE_2, TNF-alpha and NO production in vitro (Ilieva et al 2004).

Studies with subcutaneously administered *G. biloba* extract in experimental models have also identified significant anti-inflammatory activity, with the addition of antinociceptive effects (Abdel-Salam et al 2004).

Investigation with an animal model of colitis revealed that *G. biloba* (EGb 761) extract reduces markers of inflammation (iNOS, COX-2 and TNF-alpha) and inflammatory stress (p53 and p53-phospho-serine 15) (Kotakadi et al 2008).

Ginkgetin

Ginkgetin showed a stronger anti-inflammatory activity than prednisolone when administered by intraperitoneal injection in an animal model of arthritis. Histological examination of the knee joints confirmed the effect (Kim et al 1999). When used topically in an animal model of chronic skin inflammation and pro-inflammatory gene expression, it was found to inhibit ear oedema by approximately 26% and PGE_2 production by 30% (Lim et al 2006). Histological comparisons revealed that ginkgetin reduced epidermal hyperplasia, inhibited phospholipase A2, and suppressed COX-2 and iNOS expression (Lim et al 2006).

Anticancer

Studies conducted with various molecular, cellular and whole animal models have revealed that leaf extracts of *G. biloba* may have anticancer (chemopreventive) properties that are related to its antioxidant, antiangiogenic and gene regulatory actions (DeFeudis et al 2003). Both the flavonoid and terpenoid constituents are thought to be responsible for many of these mechanisms, meaning that the whole extract is required for activity. Studies in humans have found that ginkgo extracts inhibit the formation of radiation-induced (chromosome-damaging) clastogenic factors and UV-induced oxidative stress, both effects that may contribute to the overall chemopreventive activity. As a result of these observations, there has been a call by some academics for ginkgo to be more widely investigated and used in the prevention and treatment of cancer (Eli & Fasciano 2006).

OTHER ACTIONS

Activity on cytochromes and P-glycoprotein

Several studies have investigated *G. biloba* for effects on different cytochromes in vitro and with various animal models. Four human studies have also been conducted. Early in vitro tests demonstrated that *G. biloba* inhibits CYP 3A4; however, clinical studies have found no such effect (Budzinski et al 2000, Gurley et al 2002, 2005, Markowitz et al 2003). In vitro tests have suggested that the effect on cytochromes is biphasic, with low doses of ginkgo extract inducing CYP 1A2 and inhibiting 2D6 and higher doses exhibiting the opposite effect (Hellum et al 2007). Studies investigating ginkgo extract and its various constituents in animal models have identified induction of CYP 3A1, 1A2, 2E1, 2B½ for ginkgo which appears to be largely mediated by the bilobalide constituent, whereas no effect on CYP 2D6, 2C11 or 2C7 has been demonstrated (Deng et al 2008, Tang et al 2007a, Zhao et al 2006).

The question arises of clinical significance and whether the effects observed in animal models also occur in humans to an appreciable degree. To this end, four clinical studies have been conducted clarifying the issue (Duche et al 1989, Gurley et al 2002, 2005, Markowitz et al 2003, Tang et al 2007a). Tests with human volunteers have found no significant effect on CYP 3A4, 2D6 or 1A2 with *G. biloba* extract.

Little is known about the effects of ginkgo on the drug transporter molecule P-glycoprotein (P-gp). Two in vitro studies have identified induction of P-gp with ginkgo; however, tests with human subjects are required to determine whether the effect occurs in vivo and its clinical significance (Hellum & Nilsen 2008, Yeung et al 2008).

CLINICAL USE

G. biloba is a complex herb that contains many different active constituents and works by means of multiple mechanisms. In practice, its therapeutic effect is a result of interactions between constituents and mechanisms, giving it applications in many varied conditions. To date, most of the research conducted in Europe has used a standardised preparation known as EGb 761, available commercially as Rokan, Tanakan or Tebonin.

Dementia, memory impairment

G. biloba has been used and studied as a cognitive activator in a variety of populations, such as cognitively intact people, those with cerebral insufficiency, age-related memory impairment, Alzheimer's dementia or multi-infarct dementia (Itil et al 1998, Le Bars et al 2000, 2002, Oken et al 1998, Wettstein 1999). It has also been tested in healthy adults with no cognitive deficits to determine whether treatment can further improve memory (Kennedy et al 2007b). Overall, the evidence suggests that oral ginkgo extract may improve cognitive function in people with mild-to-moderate cognitive impairment, but it is less successful in people with normal cognitive function. Long-term use does not appear to protect against the development of dementia.

A 2002 Cochrane review of the scientific literature concluded that *G. biloba* produces benefits superior to placebo within 12 weeks' treatment in people with acquired cognitive impairment, including dementia, of any degree of severity (Birks et al 2002). Cognition, activities of daily living and measures of mood and emotional function show significant benefit for ginkgo compared with placebo.

The most recent Cochrane review analysed results from 35 double-blind, placebo-controlled trials (n = 4247) which lasted from 3 weeks to 52 weeks, with the majority being of 12 weeks duration (Birks et al 2007). Subjects enrolled in the studies were diagnosed with dementia of any type or age-related cognitive impairment. Older studies (> 20 years ago) generally used sign and symptom questionnaires, whereas more recent studies used modern diagnostic criteria and computerised tomographic (CT) scans for dementia. All except one study used a standardised extract and the daily dose tested ranged from 80 to 600 mg/day but was mostly less than 200 mg/day.

The final meta-analysis used results from 29 studies that the reviewers described as heterogeneous, not allowing a consistent pattern of results to emerge. This may be in part due to reviewers pooling all studies regardless of patient diagnoses, the myriad of different scales and measures used and the fact that some studies are over 20 years old and randomisation and blinding techniques have changed in recent years. As a result, the findings are not straightforward and deserve more detailed description to be better understood.

Using the CGIC scale whereby clinical global improvement is assessed by the physician, ginkgo treatment produced benefits at doses greater than 200 mg/day at 24 weeks compared with placebo, but showed no effects at the lower doses. Benefits were defined as clinical improvement or no further deterioration. Studies that used the Sandoz Clinical Assessment-Geriatric (SCAG) scale, which assesses global function, also found that *G. biloba* produced benefits compared to placebo at low dose (< 200 mg/day) before and after 12 weeks of treatment. One study found a significant difference between treatment and control groups in Geriatric Evaluation by Relative's Rating Instrument (GERRI) scores but not in Clinical Global Impression of Change (CGIC).

Studies testing cognitive function showed that treatment for less than 12 weeks produced no significant effect; however, longer treatment produced a significant difference between *G. biloba* and placebo in favour of *G. biloba*, but the treatment effect is very variable. Activities of daily living showed benefit at 12 weeks (dose < 200 mg/day), but not at 24 weeks as assessed by different methods.

With regard to adverse effects, *G. biloba* was well tolerated with no significant differences compared with placebo. Whilst positive results emerged in the meta-analysis, reviewers concluded that the evidence indicating ginkgo has predictable and clinically significant benefit for people with dementia or cognitive impairment is inconsistent and unconvincing.

Clinical note — What is cerebral insufficiency?
Cerebral insufficiency is a syndrome characterised by a collection of symptoms, although it is not associated with any clear pathological changes. The 12 symptoms associated with this condition are: difficulties of memory and concentration, being absent-minded, confusion, lack of energy, tiredness, decreased physical performance, depressive mood, anxiety, dizziness, tinnitus and headaches (Kleijnen & Knipschild 1992). Some of these symptoms are also described as early symptoms of dementia and appear to be associated with decreased cerebral blood flow, although frequently no explanation is found.

In 2008, several more placebo-controlled studies were published. One randomised, double-blind, parallel-group trial of 176 subjects with mild-to-moderate dementia compared a standardised extract of *G. biloba* (120 mg daily) to placebo over 6 months (McCarney et al 2008). At this low dose, ginkgo did not provide benefits. A larger double-blind randomised study of 400 patients with dementia associated with neuropsychiatric features tested a higher dose of EGb 761 extract (240 mg/day) (Scripnikov et al 2007). The study population included people with probable or possible Alzheimer's disease (AD) with cerebrovascular disease or vascular dementia. EGb 761 was significantly superior to placebo with respect to the primary (Specialty Knowledge Test [SKT] battery) and all secondary outcome variables. Whilst herbal treatment improved outcomes, the placebo group showed evidence of deterioration as measured by the mean composite score (frequency × severity) and the mean caregiver distress score ($P < 0.001$). The largest effects for EGb 761 were found for apathy/indifference, anxiety, irritability/lability, depression/dysphoria and sleep/nighttime behaviour.

Another double-blind study of 400 subjects with mild-to-moderate dementia (AD or vascular dementia) with neuropsychiatric features tested EGb 761 extract over 22 weeks (Napryeyenko & Borzenko 2007). Active treatment produced a mean −3.2-point improvement in the SKT with an average deterioration by +1.3 points on placebo ($P < 0.001$). EGb 761 was significantly superior to placebo on all secondary outcome measures, including the Neuro Psychiatric Inventory (NPI) and an activities-of-daily-living scale. Treatment results were essentially similar for AD or vascular dementia subgroups. The drug was well tolerated; adverse events were similar for ginkgo and placebo treatment.

Use in healthy subjects

Many double-blind studies have investigated the effects of *G. biloba* (120–600 mg/day) on cognitive function in younger and older healthy subjects. Some studies have evaluated the effects of a single dose, whereas others are long-term studies (2 days–13 weeks).

The most recent systematic review of placebo-controlled trials was published in 2007 and investigated whether *G. biloba* enhances cognitive function

in healthy subjects aged under 60 years (Canter & Ernst 2007). A number of the acute studies included in the analysis used multiple outcomes and reported positive effects on one or more of these at particular time points with particular doses, but these findings were either not replicated, or contradicted by other studies. The evidence from long-term studies is largely negative. Of those studies that measured subjective effects, only one of five acute studies and one of six long-term studies reported any significant positive results.

Since this review, several new studies have been published. Overall, tests with younger subjects taking *G. biloba* long term have failed to show positive effects on memory; however, short-term benefits after acute dosing may be possible for some aspects of memory. Healthy older adults with poorer cognitive performance appear to experience greater benefit than those with higher cognitive function levels, according to the latest studies, but more research is required to confirm this initial observation.

Carlson et al conducted a 4-month, randomised, double-blind, placebo-controlled study of 90 men and women (age range 65–84 years) (Carlson et al 2007). Treatment consisted of placebo or a *G. biloba*-based supplement containing 160 mg *G. biloba*, 68 mg gotu kola and 180 mg docosahexaenoic acid per day for 4 months. Of the group, 78 subjects completed the study that found no significant differences in quality of life or adverse events. Researchers commented that high baseline scores for cognitive function may have contributed to the null findings.

Tests with younger (18–43 years) and older volunteers (55–79 years) produced different results in a 12-week, double-blind, placebo-controlled study (Burns et al 2006). The effects of ginkgo (120 mg/day) were assessed for both groups on a wide range of cognitive abilities, executive function, attention and mood. The older group responded to treatment as long-term memory assessed by associational learning tasks showed significant improvement with ginkgo; however, no other significant differences were found on any other measure. The young adult group ($n = 104$) failed to respond on any measure, as no significant differences were observed for the treatment or placebo groups. Similarly, no significant effects on mood or any of the cognitive tests employed by Elsabagh et al were found for ginkgo (120 mg/day) taken over 6 weeks in a placebo-controlled study of 52 young adults (Elsabagh et al 2005a). In contrast, acute treatment of younger subjects with ginkgo (120 mg) significantly improved performance on the sustained-attention task and pattern-recognition memory task according to a randomised, double-blind study (Elsabagh et al 2005a). The study of 52 students found no further effects for ginkgo on working memory, planning, mental flexibility or mood.

Kennedy et al reported on a re-analysis of data from three methodologically identical, double-blind, crossover studies that each included a treatment of 120 mg ginkgo extract and matched placebo (Kennedy et al 2007b). The analysis found that 120 mg of ginkgo conferred a significant improvement on the 'quality of memory' factor and was most evident at 1 and 4 hours after single-dose treatment, but had a negative effect on performance on the 'speed of attention' factor, which was most evident at 1 and 6 hours after treatment.

Ginkgo complexed with phospholipids

Some recent data suggest that the complexation of standardised GBE with soy-derived phospholipids may enhance the bioavailability of active components, thereby producing better results. Kennedy et al tested two different ginkgo products complexed with either phosphatidylserine or phosphatidylcholine in a placebo-controlled study of younger volunteers (Kennedy et al 2007a). Test subjects were given an acute dose of ginkgo, one of the ginkgo combinations or placebo on separate days (7 days apart). Confirming earlier results, *G. biloba* (120 mg) as sole treatment was not associated with markedly improved performance on the primary outcomes in this younger population; however, administration of GBE complexed with phosphatidylserine resulted in improved secondary memory performance and significantly increased speed of memory task performance across all of the postdose testing sessions. Interestingly, all three herbal treatments were associated with improved calmness. Whether the superior effect obtained for this combination is due to the complexation of the extracts, their mere combination or the separate psychopharmacological actions of the two extracts remains to be tested.

Cognitive effects in postmenopausal women

One week of treatment with ginkgo (120 mg/day) significantly improved attention, memory and mental flexibility in postmenopausal women according to a double-blind, placebo-controlled study (Elsabagh et al 2005b). The study tested ginkgo (LI 1370, Lichtwer Pharma, Marlow, UK) over 6 weeks, which significantly improved mental flexibility in women who began the trial with poorer cognitive performance (Elsabagh et al 2005b). Younger subjects with better cognitive performance at baseline did not experience any significant effects compared to placebo.

Comparisons with anticholinesterase drugs

The type of CNS effects produced by EGb 761 in elderly dementia patients is similar to those induced in tacrine responders and those seen after the administration of other 'cognitive activators', according to a small randomised study involving 18 elderly people diagnosed with mild-to-moderate dementia (possible or probable AD) (Itil et al 1998). The results also demonstrated that 240 mg EGb produced typical cognitive activator ECG profiles (responders) in more subjects (8 of 18) than 40 mg tacrine (3 of 18 subjects). A later review concluded that ginkgo extract and second-generation cholinesterase inhibitors (donepezil, rivastigmine, metrifonate) should be considered equally effective in the treatment of mild-to-moderate Alzheimer's dementia (Wettstein 2000).

Commission E approves the use of standardised ginkgo extract in dementia syndromes, including

vascular, primary degenerative and mixed types (Blumenthal et al 2000).

Dementia prevention

The many mechanisms attributed to ginkgo make it an ideal candidate for the long-term prevention of many age-related diseases such as dementia. Two clinical trials were published in 2008, which investigated whether treatment with *G. biloba* could significantly reduce the incidence of dementia.

DeKosky et al compared the effectiveness of *G. biloba* to placebo in reducing the incidence of all-cause dementia and AD in elderly individuals with normal cognition and those with mild cognitive impairment (MCI) (DeKosky et al 2008). The large randomised, double-blind, placebo-controlled clinical trial involved 3069 community dwelling subjects aged 75 years or older with normal cognition (n = 2587) or MCI (n = 482). It was conducted at five academic medical centres in the United States between 2000 and 2008 with a median follow-up of 6.1 years. Treatment consisted of a twice-daily dose of 120-mg extract of *G. biloba* and was not shown to reduce either the overall incidence rate of dementia or AD incidence in elderly individuals. Treatment was well tolerated by this population, as the incidence of side effects was similar for both groups.

The same year, Dodge et al published the results of a double-blind study involving 118 cognitively intact older subjects (85 years or older) (Dodge et al 2008). In the intention-to-treat analysis, there was no reduced risk of progression to clinical dementia among the GBE group; however, in the secondary analysis, where medication adherence level was controlled, the GBE group had a significantly lower risk of progression and a smaller decline in memory scores. Importantly, more stroke and transient ischaemic attack (TIA) cases were observed among the GBE group, which require further investigation to confirm.

Currently, two large double-blind, placebo-controlled studies are underway testing whether *G. biloba* (120 mg twice daily) is effective in the prevention of dementia in normal elderly people and those with early cognitive decline (Williamson et al 2008). The complete results from these studies are not expected for another few years.

Acute ischaemic stroke

G. biloba extract is widely used in the treatment of acute ischaemic stroke in China. A Cochrane systematic review identified 14 trials, of which 10 (792 patients) were included (Zeng et al 2005). In those 10 trials, follow-up was performed at 14–35 days after stroke and in all studies, neurological outcome was assessed, but none of them reported on disability (activities of daily living function) or quality of life (QOL) and only three trials reported adverse events. Nine of the trials were considered to be of inferior quality. Overall results from the 10 studies found that *G. biloba* extract was associated with a significant increase in the number of improved patients. Of note, one placebo-controlled trial, assessed to be of good quality, failed to show an improvement of neurological deficit at the end of treatment. In view of the shortcomings of many trials and limited evidence, high-quality and large-scale randomised controlled trials are still required to determine its efficacy.

Depression

Although studies that have investigated the effects of *G. biloba* in cerebral insufficiency, a syndrome that is often characterised by depression, have shown positive results, no clinical studies are available that have investigated its use in clinical depression.

One randomised, double-blind, placebo-controlled study has investigated its effects in seasonal affective disorder (SAD). *G. biloba* extract PN246, in tablet form (Bio-Biloba), was tested in 27 patients with SAD over 10 weeks or until they developed symptoms, starting in a symptom-free phase about 1 month before symptoms were expected. In this trial, *G. biloba* failed to prevent the development of SAD (Lingaerde et al 1999).

Cieza et al (2003) tested EGb 761 (240 mg/day) on the subjective emotional wellbeing of healthy older subjects (50–65 years) in a randomised, double-blind study. Ginkgo treatment produced a statistically significant difference for the visual analogue scale (VAS) mental health and for QOL, as well as for the Subjective Intensity Score Mood in week 2 compared with placebo. At the end of the study, statistically significant improvement in the EGb 761 group was observed for the variables: depression, fatigue and anger.

Several recent studies investigating the effects of ginkgo on memory have also measured effects on mood. The double-blind studies found no significant effects for healthy older or younger volunteers (Burns et al 2006, Carlson et al 2007, Elsabagh et al 2005a). Whether ginkgo may have a mood enhancing effect in a population with diagnosed depression remains to be tested.

Generalised anxiety disorder (GAD)

EGb 761 has demonstrated stress-alleviating and anxiolytic-like activity in preclinical studies, and most recently in a randomised study of 107 patients with GAD (n = 82) or adjustment disorder with anxious mood (n = 25) (Woelk et al 2006). *G. biloba* was tested in two different doses (480 mg and 240 mg/day) against placebo over 4 weeks and found to be significantly superior with a dose-response trend being identified. Beneficial effects were observed after 4 days of treatment. Additionally, ginkgo treatment was safe and well tolerated.

Peripheral vascular diseases

Ginkgo has been used in the treatment of intermittent claudication, Raynaud's syndrome and chilblains (Mouren et al 1994, Pittler & Ernst 2000).

Intermittent claudication

In 2000, a meta-analysis of eight clinical trials found a significant difference in the increase in pain-free walking distance in favour of *G. biloba* over placebo in intermittent claudication (Pittler & Ernst 2000). An earlier randomised study measuring transcutaneous partial pressure of oxygen during exercise

Clinical note — Peripheral arterial disease
PAD is the chronic obstruction of the arteries supplying the lower extremities. The most frequent symptom is intermittent claudication, which results from poor oxygenation of the muscles of the lower extremities and is experienced typically as an aching pain, cramping or numbness in the calf, buttock, hip, thigh or arch of the foot. Symptoms are induced by walking or exercise and are relieved by rest. Presently, medical treatment revolves around lifestyle changes, such as increased exercise, and surgery as a final option.

showed that a dose of 320 mg/day EGb 761 taken for 4 weeks significantly decreased the amount of ischaemic area by 38%, compared with no change with placebo (Mouren et al 1994).

A more recent 2004 meta-analysis confirmed that ginkgo is more effective than placebo in intermittent claudication (Horsch & Walther 2004). Nine double-blind studies of EGb 761 for intermittent claudication were assessed in a total of 619 patients. A sensitivity analysis of a homogeneous sample in terms of design, treatment duration, inclusion and exclusion criteria and methods of measurement confirms these findings. Most studies have used a dose of 120 mg/day taken in divided doses, although one trial found that 240 mg/day gave better results. It should be recommended as long-term therapy and as an adjunct to exercise for the best results.

A year later, Pittler and Ernst conducted a systematic review of all complementary therapies which may be useful as a treatment for intermittent claudication and identified *G. biloba* as the only effective herbal medicine to show better results than placebo (Pittler & Ernst 2005).

Commission E approved the use of standardised ginkgo extract for intermittent claudication (Blumenthal et al 2000).

Two double-blind, placebo-controlled studies found no significant effects for *G. biloba* on maximal walking time in people with claudication (Gardner et al 2008, Wang et al 2007). One study compared the effects of an exercise program with and without the addition of ginkgo treatment in 22 subjects (Wang et al 2007). Ginkgo was administered for 24 weeks at a dose of 240 mg/day and no differences were seen between the exercise-only phase and the exercise and herbal treatment phase. The other placebo-controlled study used a higher dose of *G. biloba* (EGb 761; 300 mg/day), which was administered for 4 months (Gardner et al 2008). Active treatment resulted in a modest but insignificant increase in maximal treadmill walking time and flow-mediated vasodilation in older people with peripheral arterial disease (PAD). The study included 62 adults, aged 70 ± 8 years (mean ± SD).

Raynaud's syndrome

A standardised *G. biloba* extract (Seredrin) taken over a 10-week period significantly reduced the number of attacks per week (from 13.2 to 5.8) compared with placebo, according to a randomised study (Muir et al 2002).

Vertigo, tinnitus and sudden deafness

Ginkgo is used to treat these and other symptoms of vestibule-cochlear disorders.

In 1999, a systematic review of five RCTs testing standardised *G. biloba* extracts in people whose primary complaint was tinnitus concluded that treatment with *G. biloba* may result in significant improvements in tinnitus (Ernst & Stevinson 1999). Three years later, a review of eight controlled trials in tinnitus confirmed these findings, stating that ginkgo is significantly superior to placebo or reference drugs when used for periods of 1–3 months (Holstein 2001).

However, results of two double-blind studies conducted more recently have shifted the evidence against the use of *G. biloba* in tinnitus. The first was a large, double-blind, placebo-controlled study involving 1121 people aged between 18 and 70 years with tinnitus and 978 matched controls, which found that 12 weeks of treatment with ginkgo extract, LI 1370 (Lichtwer Pharma, Berlin, Germany), 50 mg, three times daily resulted in no significant differences when subjects assessed their tinnitus in terms of loudness and how troublesome it was (Drew & Davies 2001). A more recent double-blind, placebo-controlled, randomised study of 66 subjects with tinnitus failed to show benefits with active treatment using a dose of 120 mg extract daily over 12 weeks (Rejali et al 2004). The primary outcome measures used were the Tinnitus Handicap Inventory, The Glasgow Health Status Inventory and the average hearing threshold at 0.5, 1, 2 and 4 kHz. In 2004, Rejali et al conducted a meta-analysis of clinical trials and found that 21.6% of patients with tinnitus reported benefit from *G. biloba* versus 18.4% of patients who reported benefit from a placebo.

A 2004 Cochrane systematic review came to a similar conclusion, reporting that the limited evidence currently available does not support the use of ginkgo in tinnitus; however, the authors also pointed out that if a greater level of understanding and diagnostic accuracy could be reached about the different aetiologies of tinnitus, this may naturally highlight subgroups of patients in whom further controlled trials of *G. biloba* are worth considering (Hilton & Stuart 2004).

Salicylate-induced tinnitus

One in vivo study investigating the effects of ginkgo in salicylate-induced tinnitus found a statistically significant decrease in the behavioural manifestation of tinnitus for ginkgo in doses of 25, 50 and 100 mg/kg/day (Jastreboff et al 1997).

Sudden deafness

Ginkgo extract was as effective as pentoxifylline in the treatment of sudden deafness, according to one randomised, double-blind study (Reisser & Weidauer 2001). Both treatments equally reduced associated symptoms of tinnitus and produced the same effects on the return to normal of speech discrimination. Subjective assessment suggested that

G. biloba extract was more beneficial than pentoxifylline. EGb 761 (240 mg/day) has also been shown to accelerate and secure recovery of acute idiopathic sudden sensorineural hearing loss, observable within 1 week of treatment under randomised double-blind test conditions (Burschka et al 2001).

Commission E approves the use of standardised ginkgo extract in these conditions when of vascular origin (Blumenthal et al 2000).

Macular degeneration, glaucoma and retinopathy

With regard to these ophthalmological conditions, ginkgo has numerous properties that should theoretically make it a useful treatment, such as increasing ocular blood flow, antioxidant and platelet-activating factor inhibitor activity, NO inhibition and neuroprotective abilities.

Macular degeneration

Although some positive evidence exists, a 2000 Cochrane review has suggested that, overall, there is insufficient evidence currently available to conclude that *G. biloba* treatment is effective in macular degeneration, with further testing required (Evans 2000).

Glaucoma

With regard to glaucoma, the little research conducted so far appears promising.

Researchers using colour Doppler imaging have observed significantly increased end-diastolic velocity in the ophthalmic artery after treatment with EGb (120 mg/day) in a placebo-controlled, randomised, crossover study (Chung et al 1999). A randomised, double-blind, crossover study found that EGb 761 (120 mg/day) taken for 4 weeks produces positive effects in normal tension glaucoma (Quaranta et al 2003). Furthermore, ginkgo treatment did not significantly alter intraocular pressure, blood pressure or heart rate and was well tolerated.

Chloroquine retinopathy

In vivo tests using electroretinography have identified protective effects against the development of chloroquine-induced retinopathy using *G. biloba* (Droy-Lefaix et al 1992). This has been observed in both acute and chronic chloroquine toxicity of the retina (Droy-Lefaix et al 1995).

Prevention of altitude sickness

Eight clinical studies have investigated *G. biloba* as prophylactic treatment against altitude sickness (Chow et al 2005, Gertsch et al 2002, 2004, Leadbetter & Hackett 2003, Maakestad et al 2001, Moraga et al 2003, 2007, Roncin et al 1996).

The first study was conducted by Roncin et al (1996). It involved 44 subjects and found that a dose of 160 mg/day taken for 5 days as prophylactic treatment resulted in 0% of subjects developing the cerebral symptoms of acute mountain sickness versus 41% of subjects in the placebo group, whereas only three subjects (13.6%) in the EGb 761 group developed respiratory symptoms of acute mountain sickness (AMS), 18 (81.8%) in the placebo group developed these symptoms. Besides effectively preventing AMS for moderate altitude (5400 m), the treatment also decreased vasomotor disorders of the extremities. In 2001, Maakestad et al reported on a randomised, double-blind trial of *G. biloba* (120 mg twice daily starting 5 days before ascent) compared to placebo for the prevention of AMS in 40 college students who underwent rapid ascent from 1400 to 4300 m. Using the Lake Louise Symptoms (LLS) score and Environmental Symptoms Questionnaire as outcomes, *G. biloba* was shown to significantly reduce the incidence of AMS compared to placebo. A year later, a double-blind study also produced positive results for *G. biloba* 180 mg/day started 24 hours before rapid ascent from sea level to 4205 m (Gertsch et al 2002).

In subsequent years, some researchers compared ginkgo to acetazolamide. In 2003, two studies, which produced conflicting results, were published. Moraga et al (2003) compared prophylaxis with *G. biloba* (80 mg twice daily) versus acetazolamide (250 mg twice daily) versus placebo, which was started 24 hours before rapid ascent to 3700 m. Of 32 subjects enrolled, none of those in the *G. biloba* group developed AMS compared with 35% of those in the acetazolamide group and 54% of those receiving placebo. Alternately, ginkgo (120 mg twice daily) started 3 days before ascent produced no significant effects when compared to placebo or acetazolamide in a randomised, double-blind study by Leadbetter and Hackett (2003). The study involved 59 subjects who experienced a rapid ascent to 4300 m. Negative results were also obtained by Gertsch et al (2004) and Chow et al (2005). The largest negative study involved 487 healthy Western hikers (Gertsch et al 2004). It compared the effects of ginkgo (60 mg three times daily), acetazolamide (250 mg), combined acetazolamide and ginkgo, and placebo. Participants took at least 3–4 doses before ascent above 4000 m in the Nepal Himalayas. The incidence of acute mountain sickness was 34% for placebo, 12% for acetazolamide, 35% for ginkgo and 14% for combined ginkgo and acetazolamide. Chow et al conducted a smaller study of 57 healthy unacclimatised subjects using a randomised, placebo-controlled design. Subjects were taken to an elevation of 3800 m within 24 h, with acetazolamide producing significantly better effects than ginkgo or placebo using the Lake Louise Acute Mountain Sickness Scoring System. Subjects receiving ginkgo were as likely as placebo to experience acute mountain sickness, whereas acetazolamide was protective.

The most recent study was published in 2007 and tested a different type of treatment regimen that produced significant benefits. The placebo-controlled study of 36 people found that pretreatment followed by continued treatment with *G. biloba* prevented acute mountain sickness (AMS) and was significantly more effective than acetazolamide (Moraga et al 2007). Volunteers were given placebo, acetazolamide (250 mg per dose) or ginkgo (80 mg per dose) every 12 hours starting 24 hours before ascending and continued throughout the 3-day stay at high altitude. Not a single person

treated with ginkgo experienced AMS, compared with 36% taking acetazolamide and 54% taking placebo. Whilst ginkgo did not alter arterial oxygen saturation compared to acetazolamide, a marked increased saturation in arterial oxygen was seen in comparison with the placebo group.

Premenstrual syndrome (PMS)

A randomised, double-blind study evaluating the effects of EGb 761 in treating congestive symptoms of PMS in a group of 165 women found that treatment over two menstrual cycles (from day 16 until day 5 of the next cycle) was successful. Treatment was particularly effective in reducing breast symptoms, although neuropsychological symptoms were also alleviated (Tamborini & Taurelle 1993).

Vitiligo

A dose of 120 mg/day ginkgo extract significantly stopped active progression of depigmentation in slow-spreading vitiligo and induced repigmentation in some treated patients under double-blind, placebo-controlled study conditions (Parsad et al 2003). Although the mechanism of action responsible is unknown, antioxidant activity is thought to be important.

Asthma

Ginkgo shows promise as a treatment for asthma, according to studies using a mouse model of asthma and two clinical studies.

Ginkgo significantly reduced airway hyperreactivity, improved clinical symptoms and pulmonary function in asthmatic patients in one placebo-controlled study (Li et al 1997). Platelet-activating factor inhibitor, antioxidant and anti-inflammatory activities are likely to be involved.

Reduced airway inflammation was reported in another study of 75 asthma patients, which compared the effects of fluticasone propionate with fluticasone propionate plus ginkgo (Tang et al 2007b). The addition of ginkgo to treatment resulted in a significant decrease in the infiltration of inflammatory cells such as eosinophils and lymphocytes in the asthmatic airway and relieved airway inflammation.

Babayigit et al used a mouse model of asthma to evaluate the effects of ginkgo on lung histology (Babayigit et al 2008). Treatment with ginkgo was found to significantly improve the number of goblet cells, mast cells, thicknesses of epithelium, and basement membrane compared to placebo, indicating that active treatment improved all established chronic histological lung changes except smooth muscle thickness.

Sexual dysfunction

Due to its vasodilatory effects, ginkgo has been used in the management of sexual dysfunction in cases where compromised circulation is suspected. One open study has been conducted with subjects experiencing sexual dysfunction associated with antidepressant use (Cohen & Bartlik 1998).

Ginkgo extract (average dose 209 mg/day) was found to be 84% effective in treating antidepressant-induced sexual dysfunction, predominantly caused by selective serotonin reuptake inhibitor (SSRI), in a study of 63 subjects (Cohen & Bartlik 1998). A relative success rate of 91% was observed for women, compared with 76% for men, and a positive effect was reported on all four phases of the sexual response cycle: desire, excitement (erection and lubrication), orgasm and resolution. Although this was an open trial, the results are encouraging when one considers that the placebo effect is about 25% from past randomised trials of Federal Drug Administration (FDA)-approved medications for erectile dysfunction (Moyad 2002).

More recently, a small, triple-blind (investigator, patient, statistician), randomised, placebo-controlled, trial of *G. biloba* (240 mg/day for 12 weeks) was undertaken with 24 subjects experiencing sexual impairment caused by antidepressant drugs (Wheatley 2004). The authors report some spectacular individual responses in both groups, but no statistically significant differences, and no differences in side effects.

Meston et al (2008) conducted two studies of women with sexual dysfunction (Meston et al 2008). The first was a single-dose, placebo-controlled study using 300 mg ginkgo extract, which produced a small but significant facilitatory effect on physiological, but not subjective, sexual arousal in 99 sexually dysfunctional women. The second study investigated long-term use of ginkgo (300 mg/day) over 8 weeks, which found that herbal treatment combined with sex therapy significantly increased sexual desire and contentment compared to placebo or ginkgo as sole treatment.

Parkinson's disease

There is great interest in the application of safe substances, such as *G. biloba*, in neurodegenerative diseases such as Parkinson's disease because of their neuroprotective and mitochondrial protective effects. Currently, investigation with ginkgo is limited to animal studies of experimentally induced Parkinson's disease, which have shown it to afford some protection against neuronal loss (Ahmad et al 2005, Kim et al 2004).

OTHER USES

G. biloba is used for many other indications, including improving connective tissue conditions such as haemorrhoids, common allergies, reducing the effects of exposure to radiation and to prevent some of the complications associated with diabetes. In the UK and other European countries, the cardioprotective effects of EGb 761 in myocardial ischaemia and reperfusion are currently being investigated in preclinical studies.

Adjunct in cancer treatment

As a herb with significant antioxidant and neuroprotective activities, ginkgo has been used to reduce the toxic side effects of some chemotherapeutic drugs. Evidence from in vivo studies demonstrates protective effects against nephrotoxicity induced by cisplatin and cardiotoxicity induced by doxorubicin (Naidu et al 2002, Ozturk et al 2004).

More recently, *G. biloba* extract (EGb 761) given intraperitoneally as 200 mg/kg, was found to protect against cisplatin-induced ototoxicity in an animal model (Huang et al 2007). Another in vivo study showed that *G. biloba* extract prevented adriamycin-induced hyperlipidaemic nephrotoxicity and was associated with a decrease in oxidative stress and total NO levels of renal tissues (Abd-Ellah & Mariee 2007).

Clinical trials are not yet available to determine its effectiveness in practice.

Cancer prevention

A 2006 review puts forward the case that *G. biloba* should be more widely used as a safe preventative agent for reducing cancer incidence. This recommendation is based on results from numerous in vitro and experimental studies showing that ginkgo affects many factors associated with the incidence and mortality of cancer (Eli & Fasciano 2006).

Multiple sclerosis

Multiple sclerosis (MS) is a chronic demyelinating neurological disease afflicting young and middle-aged adults, resulting in problems with coordination, strength, cognition, affect and sensation. Two clinical studies have investigated whether ginkgo treatment may help reduce some of these impairments.

Johnson et al (2006) conducted a randomised, double-blind study which compared the effects of ginkgo (EGb 761; 240 mg/day) to placebo on depression, anxiety, fatigue, symptom severity and functional performance using validated measures for each outcome (Johnson et al 2006). Twenty-two people with MS were enrolled in the study. Significantly, more people administered ginkgo showed improvement on four or more measures with improvements associated with significantly larger effect sizes on measures of fatigue, symptom severity and functionality. The ginkgo group also exhibited less fatigue at follow-up compared with the placebo group and treatment was well tolerated with no side effects or adverse effects reported.

The cognitive function of people with multiple sclerosis significantly improved after 12 weeks of treatment with *G. biloba* extract (120 mg twice a day), according to a randomised, double-blind, placebo-controlled trial (Lovera et al 2007). A treatment effect trend, limited to the Stroop test, indicated that ginkgo treatment may have an effect on cognitive domains assessed by this test, such as susceptibility to interference and mental flexibility. People with greater cognitive impairment at the start of the study experienced more improvement with treatment than higher functioning people. No serious drug-related side effects occurred.

Schizophrenia — adjunctive treatment

G. biloba given as an adjunct to the atypical antipsychotic medicine, clozapine, in the treatment of refractory schizophrenia was shown to enhance drug effects on negative symptoms according to a placebo-controlled study involving 42 patients with chronic, treatment-resistant schizophrenia (Doruk et al 2008). Ginkgo was used at a dose of 120 mg/day for 12 weeks.

DOSAGE RANGE

The recommended dose varies, depending on indication and condition treated.

General guide

- Dried herb: 9–10 g/day.
- 120–240 mg of a 50:1 standardised extract daily in divided doses (40 mg extract is equivalent to 1.4–2.7 g leaves).
- Fluid extract (1:1): 0.5 mL three times daily.

According to clinical studies

- Asthma: 40 mg three times daily.
- Dementia and memory impairment: 120–240 mg standardised extract daily in divided doses.
- Intermittent claudication, vertigo: 120–320 mg standardised extract daily in divided doses.
- Normal tension glaucoma: 120 mg standardised extract daily.
- Multiple sclerosis — to improve cognitive function and mood: 120 mg twice daily.
- PMS: 80 mg twice daily, starting on the 16th day of the menstrual cycle until the 5th day of the next cycle.
- Prevention of altitude sickness: 160 mg standardised extract daily, starting 5 days prior to ascent or ginkgo (80 mg per dose) every 12 hours, starting 24 hours before ascending and continuing throughout stay at high altitude.
- Schizophrenia: as an adjunct to clozapine in refractory cases: 120 mg daily.
- Raynaud's syndrome: 360 mg/day divided into three doses.
- Sexual dysfunction associated with antidepressant drugs: 200 mg standardised extract daily.
- Sexual dysfunction (women): 300 mg daily in conjunction with sex therapy.
- Vitiligo: 120 mg standardised extract daily.

Although some studies report positive effects after 4–6 weeks' continual use, a trial of at least 12 weeks is recommended in chronic conditions.

ADVERSE REACTIONS

In most placebo-controlled studies, there is no difference between the side effect incidence with ginkgo and placebo. Standardised ginkgo leaf extracts have been used safely in trials lasting from several weeks to up to 6 years.

In a few cases (less than 0.001%), gastrointestinal upset, headaches and dizziness were reported. It does not appear to alter heart rate and blood pressure, change cholesterol and triglyceride levels or increase intraocular pressure in clinical studies (Chung et al 1999).

At least 10 clinical studies have found no significant effect on bleeding or platelets; however, rare case reports of subarachnoid haemorrhage, subdural haematoma, intracerebral haemorrhage, subphrenic haematoma, vitreous haemorrhage and postoperative bleeding have been reported.

Crude ginkgo plant parts that may contain concentrations of 5 ppm of the toxic ginkgolic acid

constituents should be avoided, as they can induce severe allergic reactions.

SIGNIFICANT INTERACTIONS

Adriamycin

Studies with an animal model indicate that ginkgo extract EGb 761 reduces the hyperlipidaemia and proteinuria associated with adriamaycin-induced nephropathy, which might be beneficial to enhance the therapeutic index of adriamycin (Abd-Ellah & Mariee 2007). Clinical trials have not been conducted to confirm the activity.

Antidepressant drugs

Ginkgo may reduce the sexual dysfunction side effects of these drugs and improve sleep continuity; however, results from clinical studies are mixed — possible beneficial interaction.

Bleomycin

Studies with an animal model indicate that ginkgo extract EGb 761 reduces oxidative stress induced by bleomycin. This may improve drug tolerance; however, clinical studies have not yet been conducted to test this further (Erdogan et al 2006).

Cholinergic drugs

Cholinergic activity has been identified for ginkgo; therefore, combined use may theoretically increase drug activity — observe patients using this combination, although the effects may be beneficial when used under supervision.

Cisplatin

As a herb with significant antioxidant activity, ginkgo has also been employed as a means of reducing the nephrotoxic effects of cisplatin, a use supported by two in vivo studies (Gulec et al 2006, Ozturk et al 2004). Other researchers using animal models have indicated that ginkgo may protect against cisplatin-induced ototoxicity (Huang et al 2007). Clinical trials are required to confirm significance — adjunctive use may be beneficial when used under professional supervision.

Clinical note — Does Ginkgo biloba cause significant bleeding and does it interact with warfarin?

The current body of evidence casts doubt on the clinical significance of the proposed interaction between warfarin and ginkgo, revealing that there is little evidence from controlled studies to demonstrate significant platelet inhibition, bleeding or changes to international normalised ratio (INR) with use of ginkgo (especially EGb 761 or phytochemically similar extracts).

To date five clinical trials have been published in peer-reviewed journals which demonstrate that *G. biloba* does not have a significant effect on platelet function, two studies showing no interaction with warfarin, one study showing no interaction with aspirin and a further study showing no interaction with clopidogrel (Aruna & Naidu 2007, Bal Dit et al 2003, Beckert et al 2007, Carlson et al 2007, Engelsen et al 2003, Gardner et al 2007, Jiang et al 2005, Kohler et al 2004). Studies have included young healthy volunteers and older adults, using doses up to 480 mg/day of ginkgo and time frames up to 4 months.

The first controlled study was published in 2003. Bal Dit et al conducted a double-blind, randomised, placebo-controlled study of 32 young healthy volunteers to evaluate the effect of three doses of *G. biloba* extract (120, 240 and 480 mg/day for 14 days) on haemostasis, coagulation and fibrinolysis (Bal Dit et al 2003). This escalating dose study found no effect on platelet function or coagulation for any dose tested. A year later, results from a larger randomised, placebo-controlled, crossover study that produced similar results was published (Kohler et al 2004). The study by Kohler, Funk and Keiser investigated the effects of ginkgo (2 × 120 mg/day EGb 761) on 29 different coagulation and bleeding parameters. Once again, no evidence of inhibition of blood coagulation and platelet aggregation was detected. In Australia, Jiang et al investigated the interaction between warfarin and *G. biloba* using a randomised, crossover study design (Jiang et al 2005). The study of 12 healthy males found no evidence that INR or platelet aggregation was affected by *G. biloba*. Engelsen, Nielson and Hansen also found no evidence of an interaction between *G. biloba* and warfarin under double-blind, placebo-controlled trial conditions (Engelsen et al 2003). The study involved patients stable on long-term warfarin and reported no changes to INR values.

In 2007, four more studies were published. Carlson et al conducted a study of 90 older adults (65–84 years) who were randomly assigned to placebo or a *G. biloba*-based supplement (160 mg/day) for 4 months (Carlson et al 2007). No evidence of alteration to platelet function was seen at this dose. Beckert et al conducted a smaller trial of 10 volunteers who were administered ginkgo for 2 weeks, after which in vivo platelet function was quantified using the PFA-100 assay (Beckert et al 2007). The study used aspirin as a control agent and found that platelet function was not affected by *G. biloba*, but was markedly inhibited by the administration of aspirin. No clinically or statistically significant differences were seen in a randomised, double-blind, placebo-controlled trial, which investigated the effects of *G. biloba* (EGb 761, 300 mg/day) on several measures of platelet aggregation among 55 older adults (age 69 ± 10 years) also consuming 325 mg/day aspirin (Gardner et al 2007). Reports of bleeding or bruising were infrequent and similar for both study groups. Finally, a study of 10 healthy volunteers investigated the effects of two different doses of *G. biloba* (120 mg and 240 mg) taken together with clopidogrel (75 mg) (Aruna & Naidu 2007). Platelet inhibition with the combination of *G. biloba* and clopidogrel was not statistically significant, compared with individual doses of drugs.

Clozapine
Ginkgo may enhance the effects of clozapine on negative affect in refractory schizophrenic patients, according to a placebo-controlled study (Doruk et al 2008) — beneficial interaction.

Doxorubicin
In vivo research suggests that ginkgo can prevent doxorubicin-induced cardiotoxicity suggesting a potentially beneficial interaction, although no human studies are available to confirm clinical significance (Naidu et al 2002).

Haloperidol
In three clinical trials, the effectiveness of haloperidol was enhanced when co-administered with 360 mg of ginkgo daily (Chavez et al 2006) — beneficial interaction under supervision.

Platelet inhibitor drugs
Due to its platelet-activating factor antagonist activity, *G. biloba* may theoretically enhance the effects of these drugs and increase risk of bruising or bleeding; however, evidence from recent clinical trials have cast doubt on the clinical significance of this activity.

Valproate, dilantin, depakote
There is a report of two patients using valproate who experienced seizures with ginkgo use (Chavez et al 2006). There is also a report of a patient taking Dilantin and Depakote and ginkgo, together with other herbal medicines, who suffered a fatal breakthrough seizure, with no evidence of non-compliance with anticonvulsant medications (Kupiec & Raj 2005). The autopsy report revealed subtherapeutic serum levels for both anticonvulsants, Depakote and Dilantin; however, it is uncertain whether effects can be attributed to ginkgo — observe patient taking ginkgo with these medicines.

Warfarin
Theoretically, ginkgo may increase bleeding risk when used together with warfarin; however, evidence from controlled clinical studies do not support this conclusion and have failed to identify any clinically significant pharmacodynamic or pharmacokinetic interaction. This conclusion is supported by a recent systematic review (Bone 2008) — observe.

CONTRAINDICATIONS AND PRECAUTIONS
If unusual bleeding or bruising occurs, stop use immediately. Although new clinical evidence suggests that *G. biloba* does not affect clotting times, it may be prudent to suspend use for 1 week prior to major surgery in at-risk populations.

Cerebral haemorrhage and epilepsy
Rare case reports have suggested that ginkgo should be used with caution in people with known risk factors for cerebral haemorrhage and epilepsy until further investigation can clarify its safety (Benjamin et al 2001, Granger 2001, Vale 1998).

PREGNANCY USE
Insufficient reliable evidence is available to determine safety.

PATIENTS' FAQs
What will this herb do for me?
Ginkgo is a very popular herbal treatment that increases peripheral circulation, beneficially influences brain chemicals, protects nerve cells from damage, and may stimulate immune function and reduce inflammation. Scientific evidence has shown that it may improve cognitive function in people with mild-to-moderate cognitive impairment when used long term in sufficient dosage, but it is less successful in people with normal function. It may also improve some aspects of memory in younger people when used short term. Ginkgo may improve symptoms of intermittent claudication and be useful in treating chilblains, PMS, vitiligo, preventing altitude sickness and seasonal affective disorder and possibly sexual dysfunction such as impotence. If taken long term, it does not protect against the development of dementia in the future and it does not effectively treat tinnitus.

PRACTICE POINTS/PATIENT COUNSELLING
- *G. biloba* is a complex herb that contains many different active constituents and works by means of multiple mechanisms. Therefore, it has applications in many varied conditions.
- Overall, the evidence suggests that oral ginkgo extract may improve cognitive function in people with mild-to-moderate cognitive impairment, but it is less successful in people with normal cognitive function.
- Long-term use does not appear to protect against the development of dementia and it is ineffective in treating tinnitus.
- It may be an effective treatment in peripheral vascular diseases such as intermittent claudication; however, study findings are not always consistent. Due to the herb's inherent safety, a therapeutic trial may be useful in practice to determine an individual's response.
- Some positive evidence exists for PMS, sudden deafness, Raynaud's syndrome, preventing altitude sickness, improving cognitive function in multiple sclerosis and depression when associated with cognitive decline.
- Preliminary evidence suggests a possible role as adjunctive therapy for patients receiving chemotherapy, to reduce drug toxicity side effects.
- Largely based on the herb's physiological actions, ginkgo is also used to treat chilblains, haemorrhoids, prevent macular degeneration, glaucoma, sexual dysfunction, impotence, allergies and asthma and improve wellbeing.
- The form of ginkgo most often tested and used is a preparation known as EGb 761, which is standardised to 24% ginkgo flavonol glycosides and 6% terpene lactones.
- Overall, *G. biloba* is a very safe herb and is extremely well tolerated.

When will it start to work?

This will depend on the condition treated and the dose used. Generally, *G. biloba* is a slow-acting herb that can take anywhere from 4 weeks to 3 months to exert maximal effects.

Are there any safety issues?

Ginkgo has been extensively studied and appears to be extremely safe with virtually no side effects in healthy people. Some contraindications and interactions are possible, so it is recommended that it should be taken under professional supervision.

Ginseng — Korean

HISTORICAL NOTE *Gin* refers to man and *seng* to essence in Chinese, whereas *Panax* is derived from the Greek word *pan* (all) and *akos* (cure), referring to its use as a cure-all. Ginseng is a perennial herb native to Korea and China and has been used as a herbal remedy in eastern Asia for thousands of years. It is considered to be the most potent Qi or energy tonic in Traditional Chinese Medicine (TCM). Modern indications include low vitality, poor immunity, cancer, cardiovascular disease and enhancement of physical performance and sexual function. However, a recent systematic review of randomised controlled trials (RCTs) found that the efficacy of ginseng root extract could not be established beyond doubt for any of these indications (Coon & Ernst 2002).

COMMON NAME
Korean ginseng

OTHER NAMES
Ren shen (Mandarin), red ginseng, white ginseng

BOTANICAL NAME/FAMILY
Panax ginseng C.A. Meyer (family Araliaceae)

It should be differentiated from *P. aquifolium* (American ginseng), *P. notoginseng* (Tien chi, pseudo-ginseng), *Eleutherococcus senticosis* (Siberian ginseng) and other ginsengs.

PLANT PART USED
Main and lateral roots. The smaller root hairs are considered an inferior source. There are two types of preparations produced from ginseng: white ginseng, which is prepared by drying the raw herb, and red ginseng, prepared by steaming before drying. Cultivated ginseng differs from wild ginseng, and plants from different countries or regions may also differ greatly. Processing of the crude herb to produce red ginseng appears to increase its potency. Steaming has been shown to alter the composition of the ginsenosides; for example, steaming produces the active 20(S)-ginsenoside-Rg(3) (Matsuda et al 2003) and makes certain ginsenosides more cytotoxic (Park et al 2002a).

The British Herbal Pharmacopoeia (1983) stipulates that ginseng should contain not less than 20% solids (70% ethanol). The German Pharmacopoeia requires not less than 1.5% total ginsenosides, calculated as ginsenoside Rg 1.

Chewing gums containing ginseng saponins have also been developed and demonstrate therapeutic effects in some trials (Ding et al 2004).

CHEMICAL COMPONENTS
The most characteristic compounds in the ginseng roots are the ginsenosides, and most biological effects have been ascribed to these compounds. The ginsenosides are dammarane saponins and can be divided into two classes: the protopanaxatriol class consisting primarily of Rg1, Rg2, Rf and Re and the protopanaxadiol class consisting primarily of Rc, Rd, Rb1 and Rb2. Ginseng also contains other saponins, polysaccharides, amino acids (in particular glutamine and arginine) (Kuo et al 2003), essential oils and other compounds. Three new sesquiterpene hydrocarbons have also recently been isolated from the essential oil: panaxene, panaginsene and ginsinsene (Richter et al 2005).

Ginsenosides Rh1, Rh2 and Rg3 are obtained from red ginseng as artifacts produced during steaming. It is likely that ginsenoside is actually a prodrug that is converted in the body by intestinal bacterial deglycosylation and fatty acid esterification into an active metabolite (Hasegawa 2004), and therefore, extrapolation from in-vitro studies or studies in which ginseng or isolated constituents were given by injection must be made very cautiously.

Commercial ginseng preparations are variable in quality. An analysis of 50 products sold in 11 countries shows that there is a large variation in the concentration of ginsenosides (from 1.9 to 9.0%). Some products were even found to be void of any specific ginsenosides. Some ginseng products have also been discovered to be contaminated with ephedrine. Therefore, it is essential that only quality ginseng products be used (Cui et al 1994). Although the root hairs have a higher level of total ginsenosides than the main root, the main and lateral roots are the preferred medicinal parts. In all probability, it is the ratio of ginsenosides that is

important and other important compounds are also active.

MAIN ACTIONS

Adaptogen

The pharmacological effects of ginseng are many and varied, contributing to its reputation as a potent adaptogen. The adrenal gland and the pituitary gland are both known to have an effect on the body's ability to respond to stress and alter work capacity (Filaretov et al 1988), and ginseng is thought to profoundly influence the hypothalamic–pituitary–adrenal axis (Kim et al 2003c). The active metabolites of protopanaxadiol and protopanaxatriol saponins reduce acetylcholine-induced catecholamine secretion in animal models (Tachikawa & Kudo 2004, Tachikawa et al 2003) and this may help to explain the purported antistress effects of ginseng.

Ginseng has been shown in numerous animal experiments to increase resistance to a wide variety of chemical, physical and biological stressors. Ginseng extract or its isolated constituents have been shown to prevent immunosuppression induced by cold water swim stress (Luo et al 1993) and to counter stress-induced changes from heat stress (Yuan 1989), food deprivation (Lee et al 1990), electroshock (Banerjee & Izquierdo 1982) and radiation exposure (Takeda et al 1981). As there are more than 1500 studies on ginseng and its constituents, it is outside the scope of this monograph to include all studies, so we have attempted to include those studies most relevant to the oral use of ginseng.

Animal models suggest that ginseng is most useful for chronic rather than acute stress, significantly reducing elevated scores on ulcer index, adrenal gland weight, plasma glucose, triglycerides, creatine kinase activity and serum corticosterone during chronic stress (Rai et al 2003).

(Refer to the Siberian ginseng monograph for more information about adaptogens and allostasis.)

Cardiovascular effects

According to in vitro and animal studies, ginseng may benefit the cardiovascular system 'through diverse mechanisms, including antioxidant, modifying vasomotor function, reducing platelet adhesion, influencing ion channels, altering autonomic neurotransmitter release, improving lipid profiles' and glycaemic control (Zhou et al 2004).

Antihypertensive

Red ginseng has been used as an antihypertensive agent in Korea, but its clinical effect is unclear despite several in-vivo and in-vitro experimental studies. Recent preliminary data suggest that the antihypertensive effects may be partly attributed to an angiotensin-converting enzyme (ACE) inhibitory effect demonstrated by *P. ginseng* extract in vitro (Persson et al 2006). These effects were additive to the traditional ACE inhibitor enalapril.

A study of isolated muscle preparations of animal heart and aorta with an alcohol-based extract of ginseng suggests that the hypotensive effect of ginseng is associated with a direct inhibition of myocardial contractility due to a reduction of calcium ion influx into cardiac cells, as well as the inhibition of catecholamine-induced contractility of vascular smooth muscles (Hah et al 1978).

In a prospective, randomised, double-blind, placebo-controlled study of 30 healthy adults, 200 mg ginseng extract given for 28 days was found to increase the QTc interval and decrease diastolic blood pressure 2 h after ingestion on the first day of therapy. These changes, however, were not thought to be clinically significant (Caron et al 2002).

Antiplatelet

Although reports from recent in-vitro and in vivo assays claim that *P. ginseng* is not one of the herbs that contributes to the antiplatelet effects of a Korean combination formula known as Dae-Jo-Hwan (Chang et al 2005), a number of studies have found that several ginsenosides inhibit platelet aggregation. Panaxynol has been shown to inhibit platelet aggregation induced by adenosine disphosphate, collagen and arachidonic acid. Panaxynol and ginsenosides Ro, Rg and Rg2 inhibit rabbit platelets while panaxynol prevented platelet aggregation and thromboxane formation (Kuo et al 1990).

Antihyperlipidaemic

Ginsenoside Rb1 has been shown to lower triglyceride and cholesterol levels via cyclic adenosine monophosphate (cAMP) production in the rat liver (Park et al 2002b). *P. ginseng* extract (6 g/day) for 8 weeks resulted in a reduction in serum total cholesterol, triglyceride, low density lipoprotein (LDL) and plasma malondialdehyde levels and an increase in high density lipoprotein (HDL) (Kim & Park 2003) in eight males. Ginseng has also been reported to decrease hepatic cholesterol and triglyceride levels in rats, indicating a potential use of ginseng in the treatment of fatty liver (Yamamoto et al 1983).

Other cardiovascular effects

Ginsenoside Rb2 has been shown to enhance the fibrinolytic activity of bovine aortic endothelial cells (Liu 2003). In animal studies, ginseng inhibits cardiomyocyte apoptosis induced by ischaemia and reperfusion (Zeng et al 2004) and the crude saponins have been shown to reduce body weight, food intake and fat content in rats fed a high-fat diet (Kim et al 2005a). In-vitro studies report that an extract of ginseng fruit can promote vascular endothelial cell proliferation, migration, DNA synthesis and vascular endothelial growth factor mRNA expression, suggesting an effect on the genesis and development of new vessels in the ischaemic myocardium (Lei et al 2008).

Gastrointestinal

Hepatorestorative

Oral administration of Korean red ginseng (250 and 500 mg/kg) on liver regeneration has been investigated in 15 dogs with partial hepatectomy. All haematological values except leucocyte counts

were within normal ranges for 3 days postoperatively. The levels of aspartate transaminase (AST and alanine aminotransferase (ALT) in the ginseng groups were significantly decreased compared with those in the control group ($P < 0.05$). The numbers of degenerative cells and areas of connective tissue were significantly decreased in the livers of the dogs treated with ginseng ($P < 0.01$) (Kwon et al 2003).

Anti-ulcerative

Ginseng has been shown in several studies to protect against ulceration. Among the hexane, chloroform, butanol and water fractions, the butanol fraction of a ginseng extract has been shown to be the most potent inhibitor of HCl-induced gastric lesions and ulcers induced by aspirin, acetic acid and Shay (ulcer induced by pylorus ligation). The butanol fraction showed significant increase in mucin secretion, and inhibited malondialdehyde and H^+/K^+ATPase activity in the stomach. These results indicate that the effectiveness of ginseng on gastric damage might be related to inhibition of acid secretion, increased mucin secretion and antioxidant properties (Jeong 2002). Furthermore, inhibition of *Helicobacter pylori*-stimulated 5-lipoxygenase activity may have a beneficial effect on *H. pylori*-associated gastric inflammation (Park et al 2007).

Effects on peristalsis

Ginseng root extract and its components, ginsenoside Rb1(4) and ginsenoside Rd(7), have been shown to significantly ameliorate chemically induced acceleration of small intestinal transit in vivo. The test results suggest that the protective mechanism involves both an inhibitory effect on the cholinergic nervous system and a direct suppressive effect on intestinal muscles (Hashimoto et al 2003).

Anti-inflammatory

Both a crude and a standardised extract (G115) of ginseng varying in saponin concentrations have been found to protect against muscle fibre injury and inflammation after eccentric muscle contractions in rats on a treadmill. The oral ginseng extracts significantly reduced plasma creatine kinase levels by about 25% and lipid peroxidation by 15%. Certain markers of inflammation were also significantly reduced (Cabral de Oliveira et al 2001). In a later study, pretreatment with ginseng extract (3, 10, 100 or 500 mg/kg) administered orally for 3 months to male Wistar rats resulted in a 74% decrease in lipid peroxidation caused by eccentric exercise (Voces et al 2004).

The many and varied effects of ginseng may be partly associated with the inhibition of transcription factor nuclear factor (NF)-kappaB, which is pivotal in the regulation of inflammatory genes. Inhibition of NF-kappaB may reduce inflammation and protect cells against damage.

Topical application of several ginsenosides (Rb1, Rc, Re, Rg1, Rg3) significantly attenuated chemically induced ear oedema in mice. The ginsenosides also suppressed expression of cyclooxygenase-2 (COX-2) and activation of NF-kappaB in the skin. Of the ginsenosides tested, Rg3 was found to be most effective (Surh et al 2002).

Immunomodulation

The immunomodulatory effect of ginseng is based on the production of cytokines, activation of macrophages, stimulation of bone marrow cells and stimulation of inductible nitric oxide synthase (iNOS), which produces high levels of NO in response to activating signals from Th1-associated cytokines and plays an important role in cytotoxicity and cytostasis (growth inhibition) against many pathogenic microorganisms. In addition to its direct effector function, NO serves as a potent immunoregulatory factor.

Ginseng enhances interleukin (IL)-12 production and may therefore induce a stronger Th1 response, resulting in improved protection against infection from a variety of pathogens (Larsen et al 2004), including *Pseudomonas aeruginosa* lung infection in animal models (Song et al 2005), although other studies suggest that it may also assist in the correction of Th1-dominant pathological disorders (Lee et al 2004a).

Ginseng polysaccharides have been shown to increase the cytotoxic activity of macrophages against melanoma cells, increase phagocytosis and induce the levels of cytokines, including tissue necrosis factor (TNF)-alpha, IL-1-beta, IL-6 and interferon-gamma in vitro (Shin et al 2002). Ginseng has been shown to be an immunomodulator and to enhance antitumour activity of macrophages in vitro (Song et al 2002). Ginseng has also been shown significantly to enhance natural killer (NK) function in an antibody-dependent cellular cytotoxicity of peripheral blood mononuclear cells in vitro (See et al 1997).

Incubation of macrophages with increasing amounts of an aqueous extract of ginseng showed a dose-dependent stimulation of iNOS. Polysaccharides isolated from ginseng showed strong stimulation of iNOS, whereas a triterpene-enriched fraction from an aqueous extract did not show any stimulation. As NO plays an important role in immune function, ginseng could modulate several aspects of host defence mechanisms due to stimulation of the iNOS (Friedl et al 2001).

Ginseng promotes the production of granulocytes in the bone marrow (granulocytopoiesis). The ginseng saponins have been shown to directly and/or indirectly promote the stromal cells and lymphocytes to produce human granulocyte–macrophage colony-stimulating factor (GM-CSF) and other cytokines and induce bone marrow haemopoietic cells to express GM-CSF receptors, leading to a proliferation of human colony-forming units for granulocytes and macrophages in vitro (Wang et al 2003).

Ginseng polysaccharides have been shown to have potent antisepticaemic activity by stimulating macrophages and helping modulate the reaction against sepsis induced by *Staphylococcus aureus*. Ginseng polysaccharides have been shown to reduce the intracellular concentration of *S. aureus* in macrophages in infected animals by 50% compared with

controls. Combination of the ginseng polysaccharides with vancomycin resulted in 100% survival of the animals, whereas only 67 or 50% of the animals survived, respectively, when treated with the ginseng polysaccharides or vancomycin alone (Lim et al 2002a).

According to animal studies, long-term oral administration of ginseng extract may potentiate humoral immune response but suppress spleen cell functions (Liou et al 2005).

Anticancer

Oral intake of standardised *P. ginseng* extract demonstrates a dose-dependent (1, 3 or 10 mg/kg) chemoprotective and antimutagenic effect in animal studies (Panwar et al 2005), and ginsenoside Rg3 has recently been produced as an antiangiogenic anticarcinogenic drug in China (Shibata 2001).

Chemoprotection

Oral administration of red ginseng extracts (1% in diet for 40 weeks) significantly ($P < 0.05$) suppressed spontaneous liver tumour formation in male mice. Oral white ginseng was also shown to suppress tumour promotion in vitro and in vivo (Nishino et al 2001).

Dietary administration of red ginseng in combination with 1,2-dimethylhydrazine suppresses colon carcinogenesis in rats (rats were fed 1% ginseng for 5 weeks). It is thought that the inhibition may be partly associated with inhibition of cell proliferation in the colonic mucosa (Fukushima et al 2001).

Oral administration of 50 mg/kg/day for 4 weeks of a ginseng intestinal metabolite has been shown to partially protect against doxorubicin-induced testicular toxicity in mice. The metabolite significantly ($P < 0.01$) prevented decreases in body weight, spermatogenic activities, serum levels of lactate dehydrogenase and creatine phosphokinase induced by doxorubicin. It also significantly attenuated germ cell injuries (Kang et al 2002).

The methanol extract of red ginseng has been shown to attenuate the lipid peroxidation in rat brain and scavenge superoxides in differentiated human promyelocytic leukaemia (HL-60) cells. Topical application of the same extract, as well as purified ginsenoside Rg3, has been demonstrated to suppress skin tumour promotion in mice. Rg3 also suppresses COX, NF-kappaB and extracellular-regulated protein kinase, which are all involved in tumour promotion (Surh et al 2001).

Pretreatment with oral red ginseng extract significantly reduced the development of cancer from diethylnitrosamine-induced liver cancer nodules in rats (the developmental rate of liver cancer in the experimental group was 14.3% compared with 100% in the control group). When ginseng was given concomitantly with diethylnitrosamine, the hepatoma nodules were smaller than those of the control group, the structure of hepatic tissue was well preserved and the structure of hepatocytes was normal. Ginseng also prolonged the average life span. These findings suggest benefits of ginseng in the prevention and treatment of liver cancer (Wu et al 2001).

Irradiation protection

Ginsenosides and specifically panaxadiol have been shown to have radioprotective effects in mice irradiated with high-dose and low-dose gamma radiation. Jejunal crypts were protected by pretreatment with extract of whole ginseng (50 mg/kg body weight intraperitoneally at 12 and 36 hours before irradiation, $P < 0.005$). Extract of whole ginseng ($P < 0.005$), total saponin ($P < 0.01$) or panaxadiol ($P < 0.05$) administration before irradiation (50 mg/kg body weight IP at 12 and 36 hours before irradiation) resulted in an increase in the formation of the endogenous spleen colony. The frequency of radiation-induced apoptosis in the intestinal crypt cells was also reduced by pretreatment with extract of whole ginseng, total saponin and panaxadiol (Kim et al 2003c).

These radioprotective effects are partly associated with the immunomodulatory effect of ginseng. Ginsan, a purified polysaccharide isolated from ginseng, has been shown to have a mitogenic activity, induce lymphokine-activated killer cells and increase levels of several cytokines. Ginsan reduced mutagenicity in a dose-dependent manner when applied to rats 30 min before or 15 min after 1.5 Gy of gamma irradiation. The radioprotective effect of ginsan has been partly attributed to a reduction in radiation-induced genotoxicity (Ivanova et al 2006). Ginsan has also been found to increase the number of bone marrow cells, spleen cells, granulocyte–macrophage colony-forming cells and circulating neutrophils, lymphocytes and platelets significantly in irradiated mice (Song et al 2003).

One of the causes of radiation damage is lipid peroxidation, which alters lysosomal membrane permeability, leading to the release of hydrolytic enzymes. Ginseng has been shown to markedly inhibit lipid peroxidation and protect against radiation damage in testes of mice (Kumar et al 2003).

Antitumour, antiproliferative, antimetastatic and apoptosis inducing

Stimulation of the phagocytic activity of macrophages may play a role in the anticarcinogenic and antimetastatic activities demonstrated for ginseng in vivo (Shin et al 2004b), and research has continually found tumour-inhibitory effects, especially in the promotion and progression phases (Helms 2004).

Ginsenosides Rg3, Rg5, Rk1, Rs5 and Rs4 have been shown to be cytotoxic to Hep-1 hepatoma cancer cells in vitro. Their 50% growth inhibition concentration (GI50) values were 41, 11, 13, 37 and 13 micromol/L, respectively. Cisplatin had a GI50 of 84 micromol/L in the same assay conditions (Park et al 2002a). Several triterpenoids found in the leaves have also demonstrated cytotoxic activity in vitro (Huang et al 2008).

Constituents in ginseng have also been shown to inhibit proliferation of cancer cells. Panaxytriol isolated from red ginseng was shown to have a significant dose-dependent cytotoxic activity and inhibit DNA synthesis in various tumour cells tested (Kim et al 2002a). Ginsenoside Rg3 has displayed inhibitory activity against human prostate cancer cells in vitro (Liu et al 2000).

Ginsenosides, especially 20(R)-ginsenoside Rg3, have been shown to specifically inhibit cancer cell invasion and metastasis (Shibata 2001), and ginsenoside Rh2 has been shown to inhibit human ovarian cancer growth in mice (Nakata et al 1998). It is likely that the antitumour-promoting activity of Rg3 is mediated through down-regulation of NF-kappaB and other transcription factors (Keum et al 2003).

Oral administration of 20(S)-protopanaxatriol (M4), the main bacterial metabolite of protopanaxatriol-type ginsenosides, has been shown to inhibit melanoma growth in mice, and pretreatment was shown to reduce metastases to the lungs. This effect is thought to be due to stimulation of NK-mediated tumour lysis (Hasegawa et al 2002).

The antimetastatic effects of ginseng are related to inhibition of the adhesion and invasion of tumour cells and also to antiangiogenesis activity. Ginsenosides Rg3 and Rb2 have been shown to significantly inhibit adhesion of melanoma cells to fibronectin and laminin, as well as preventing invasion into the basement membrane in vitro. Other experiments have demonstrated that the saponins exert significant antiapoptotic activity, decreasing the number of blood vessels oriented towards the tumour mass (Mochizuki et al 1995, Sato et al 1994).

Ginseng saponins have also been found to promote apoptosis (programmed cell death) in cancer cells in vitro (Hwang et al 2002).

Neurological

Analgesia

Intraperitoneal administration of ginsenoside Rf has been shown to potentiate opioid-induced analgesia in mice. Furthermore, ginsenosides prevented tolerance to the opiate that was not associated with opioid or GABA receptors (Nemmani & Ramarao 2003).

Neuroprotection

Ginseng saponins have demonstrated dose-dependent neuroprotective activity in vitro and in vivo (Kim et al 2005b). Ginsenosides Rb1 and Rg1 have a partial neurotrophic and neuroprotective role in dopaminergic cell cultures (Radad et al 2004), and Rg3 has been shown to inhibit chemically induced injuries in hippocampal neurons (Kim et al 2002b). Pretreatment with ginsenosides (50 or 100 mg/kg for 7 days) has been shown to be neuroprotective in vivo (Lee et al 2002a). An in-vitro survival assay demonstrated that ginsenosides Rb1 and Rg1 protect spinal cord neurons against damage. The ginsenosides protect spinal neurons from excitotoxicity induced by glutamate and kainic acid, as well as oxidative stress induced by H_2O_2. The optimal doses are 20–40 micromol/L for ginsenosides Rb1 and Rg1 (Liao et al 2002). The lipophilic fraction of ginseng has been shown to induce differentiation of neurons and promote neuronal survival in the rat cortex. The effect is thought to be mediated via protein kinase-C-dependent pathways (Mizumaki et al 2002). In-vitro studies have also suggested a benefit for ginseng in hypoxia-induced neuronal injury including ischaemia, trauma and degenerative diseases (Park et al 2007). Beneficial effects have yet to be demonstrated in clinical trials.

It has been suggested that the neuroprotective effects of ginseng against hypoperfusion/reperfusion-induced brain injury demonstrated in animal models suggest a potential for use in cardiovascular (CVD) (Shah et al 2005).

Cognitive function

Following oral consumption, the active metabolites of protopanaxadiol saponins may reactivate neuronal function in Alzheimer's disease according to in-vivo evidence (Komatsu et al 2005). Ginseng also enhances the survival of newly generated neurons in the hippocampus, which may contribute to the purported benefits of ginseng for improving learning tasks (Qiao et al 2005).

Anticonvulsant

Pretreatment (30 min) with 100 mg/kg ginseng significantly protected rats against pentylenetetrazole-induced seizures (Gupta et al 2001).

Antidiabetic

Hypoglycaemic/antihyperglycaemic effects

Human and animal studies have found American ginseng to lower blood glucose level (Vuksan et al 2000a, 2000b, 2000c, 2001a, 2001b). Results for Korean ginseng are less consistent (Sievenpiper et al 2003, 2004). Both ginseng root and berry (150 mg/kg) have been shown to significantly decrease fasting blood glucose levels in hyperglycaemic rats (Dey et al 2003). Intraperitoneal administration of glycans (polysaccharides known as panaxans) and other unidentified compounds has demonstrated hypoglycaemic activity in both normal and alloxan-induced hyperglycaemic mice (Waki et al 1982).

Oral administration of *P. ginseng* root (125.0 mg/kg) three times daily for 3 days reduced hyperglycaemia and improved insulin sensitivity in rats fed a high-fructose chow, suggesting a possible role in delaying or preventing insulin resistance (Liu et al 2005). However, these doses are very high, and human trials need to be conducted to confirm these results.

Diabetic complications

Aqueous extract of ginseng was shown to exert no significant effect on weight in normal rats, while it prevented weight loss in rats with streptozotocin-induced diabetes. Cell proliferation in the dentate gyrus of diabetic rats was increased by ginseng treatment, but it had no effect on cell proliferation in normal rats. These results suggest that ginseng may help reduce the long-term central nervous system complications of diabetes mellitus (Lim et al 2002b).

According to experimental studies, ginseng may also inhibit the formation of glycated haemoglobin due to its antioxidative activity (Bae & Lee 2004).

Steroid receptor activity

Ginseng has been shown to increase the mounting behaviour of male rats and increase sperm counts in rabbit testes. The effect is not by a direct sex

hormone-like function, but probably via a gonadotropin-like action. Ginsenoside Rb1 has been shown to increase luteinising hormone (LH) secretion by acting directly on the anterior pituitary gland in male rats (Tsai et al 2003). Ginsenoside Rh1 failed to activate the glucocorticoid and androgen receptors, but did demonstrate an interaction with oestrogen receptors in vitro. The effect was much weaker than 17-beta-oestradiol. Ginseng is therefore considered to contain phyto-oestrogens (Lee et al 2003). However, there are conflicting reports about oestrogen-binding activity, which may in part be explained by the presence or absence of zearalenone, an oestrogenic mycotoxin contaminant (Gray et al 2004).

OTHER ACTIONS

Prevention of damage from toxins

Ginseng extract has been shown to be beneficial in the prevention and treatment of testicular damage induced by environmental pollutants. Dioxin is one of the most potent toxic environmental pollutants. Exposure to dioxin either in adulthood or during late fetal and early postnatal development causes a variety of adverse effects on the male reproductive system. The chemical decreases spermatogenesis and the ability to conceive and carry a pregnancy to full term. Pretreatment with 100 or 200 mg/kg ginseng aqueous extract intraperitoneally for 28 days prevented toxic effects of dioxin in guinea pigs. There was no loss in body weight, testicular weight or damage to spermatogenesis (Kim 1999). In guinea pigs, *P. ginseng* also improves the survival and quality of sperm exposed dioxin (Hwang et al 2004).

Promoting haemopoiesis

Ginseng is traditionally used to treat anaemia. The total saponin fraction, and specifically Rg1 and Rb1, has been shown to promote haemopoiesis by stimulating proliferation of human granulocyte–macrophage progenitors (Niu et al 2001). The total saponins at a concentration of 50 microgram/mL most effectively promote $CD34^+$ cells to proliferate and differentiate by cooperating with hematopoietic growth factors (Wang et al 2006).

Antioxidant

In-vitro studies did not find various extracts of ginseng to be particularly potent antioxidants against several different free radicals (Kim et al 2002c). However, animal models have demonstrated effects in type 2 diabetes (Ryu et al 2005), particularly for the leaf, which may suppress lipid peroxidation in diabetic rats (Jung et al 2005). Ginseng extract has also been shown to protect muscle from exercise-induced oxidative stress in animal studies (Voces et al 2004).

Whether these effects are directly due to the antioxidant activity of ginseng components or secondary to other mechanisms, such as blood glucose regulation, is unclear. Additionally, ginseng compounds may require in-vivo conversion to active metabolites in order to exert their full effects.

Hair growth

Red ginseng extract (more so than white ginseng), and especially ginsenoside Rb1 and 20(S)-ginsenoside Rg3, has been shown to promote hair growth in mouse hair follicles in vitro (Matsuda et al 2003).

Anti-allergic activity

Ginsenosides have been demonstrated to have anti-allergic activity in vitro. One of the metabolites, 20-*O*-beta-D-glucopyranosyl-20(S)-protopanaxadiol, was found to inhibit beta-hexosaminidase release from rat basophil leukaemia cells and potently reduce passive cutaneous anaphylaxis reaction. The inhibitory activity of protopanaxadiol was more potent than that of disodium cromoglycate, an anti-allergic drug. The compound stabilised membranes but had no effect on hyaluronidase and did not scavenge free radicals. These results suggest that the anti-allergic action of protopanaxadiol originates from its cell membrane-stabilising activity and that the ginsenosides are prodrugs with anti-allergic properties (Choo et al 2003).

Anxiolytic effects

Ginsenosides, and especially ginsenoside Rc, regulate GABA-A receptors in vitro (Choi et al 2003a), and animal models have demonstrated an anxiolytic effect for ginseng saponins (Park et al 2005a).

Wound healing

Ginsenoside Rb2 has been reported to improve wound healing. It is believed that ginsenoside Rb2 enhances epidermal cell proliferation by enhancing the expressions of protein factors related to cell proliferation, such as epidermal growth factor and fibronectin (and their receptors), keratin and collagenase (Choi 2002). Ginsenoside Re may also enhance tissue regeneration by inducing angiogenesis (Huang et al 2005). Topical application of ginseng root extract may also promote collagen production via type I procollagen synthesis, suggesting potential anti-wrinkle effects (Lee 2007).

Improves acne

In an animal model of acne, ginseng extracts reduced the size of comedones by altering keratinisation of the skin and desquamating horny cells in comedones. In a study of experimentally induced hyperkeratosis, ginseng reduced the accumulation of lipids in the epidermis by regulating enzymes associated with epidermal metabolism (Kim et al 1990).

Male fertility

Ginseng-treated rats exhibit a significant increase in sperm count and motility due to activation of cAMP-responsive element modulator in the testes (Park et al 2007).

CLINICAL USE

In the scientific arena, ginseng and the various ginsenosides are used in many forms and administered via various routes. This review will focus primarily on those methods commonly used in clinical practice.

Cancer prevention

The various anticancer actions of *P.ginseng*, as demonstrated in animal and in-vitro trials, support its use as an agent to prevent the development and progression of cancer. A 5-year prospective study of 4634 patients over 40 years of age found that ginseng reduced the relative risk of cancer by nearly 50% (Yun 1996).

A retrospective study of 905 case-controlled pairs taking ginseng showed that ginseng intake reduced the risk of cancer by 44% (odds ratio equal to 0.56). The powdered and extract forms of ginseng were more effective than fresh sliced ginseng, juice or tea. The preventative effect was highly significant ($P < 0.001$). There was a significant decline in cancer occurrence with increasing ginseng intake ($P < 0.05$) (Yun & Choi 1990).

Epidemiological studies in Korea strongly suggest that cultivated Korean ginseng is a non-organ-specific human cancer preventative agent. In case–control studies, odds ratios of cancer of the lip, oral cavity and pharynx, larynx, lung, oesophagus, stomach, liver, pancreas, ovary and colorectum were significantly reduced by ginseng use. The most active compounds are thought to be ginsenosides Rg3, Rg5 and Rh2 (Yun 2003).

Ginseng polysaccharide (18 mg/day) has also been shown to be effective in improving immunological function and quality of life (QOL) in elderly patients with non-small cell lung cancer (Zhang et al 2004).

Chemotherapy

Overexpression of P-glycoprotein or multidrug resistance-associated protein may lead to multidrug resistance of cancer cells. Protopanaxatriol ginsenosides have been shown to sensitise cancer cells to chemotherapeutic agents in vitro by increasing the intracellular accumulation of the drugs through direct interaction with P-glycoprotein (Choi et al 2003b, Kim et al 2003a). The ginsenoside Rh2 possesses strong tumour-inhibiting properties and sensitises multidrug-resistant breast cancer cells to paclitaxel (Jia et al 2004), and animal models demonstrate a synergistic antitumour effect for ginseng acidic polysaccharides and paclitaxel (Shin et al 2004a).

Panax ginseng polysaccharide (12 mg IV daily) has also been trialled during treatment for ovarian cancer, and the authors suggest that it is 'effective, safe and reliable for reducing the toxic effects of chemotherapy' (Fu et al 2005).

In a cohort of 1455 patients with breast cancer recruited to the Shanghai Breast Cancer Study, ginseng use prior to diagnosis was associated with a significantly reduced risk of death (adjusted hazard ratios 0.71; 95% confidence interval: 0.52–0.98). Use of the following diagnosis resulted in a dose-dependent improvement in QOL scores (especially for psychological and social wellbeing) (Cui et al 2006).

Diabetes

The putative effects of Korean ginseng on blood glucose and lipid regulation, oxidative stress and protein glycation suggest a possible role as an adjunctive therapy in the management of diabetes and diabetic complications.

A double-blind, placebo-controlled study with 36 subjects found that 200 mg ginseng elevated mood, improved psychophysical performance, and reduced fasting blood glucose and body weight in patients with newly diagnosed type 2 diabetes (Sotaniemi et al 1995). A double-blind, randomised, dose-finding study reported that 2 g of Korean ginseng rootlets is sufficient to achieve reproducible reductions in postprandial glycaemia (Sievenpiper 2006), although studies using 200–400 mg have also demonstrated benefits for lowering fasting blood glucose levels (Reay et al 2006a).

In a recent clinical trial, 19 participants with well-controlled type 2 diabetes (sex: 11 M:8 F, age: 64 ± 2 years, body mass index (BMI): 28.9 ± 1.4 kg/m^2, HbA_{1c}: 6.5%) received 2 g Korean ginseng 40 minutes prior to meals (total 6 g/day) for 12 weeks in addition to their usual antidiabetic therapy. While HbA_{1c} levels remained unchanged, improvements were noted for plasma glucose (75 g-oral glucose tolerance test-plasma glucose (OGTT-PG) reduced by 8–11%), plasma insulin (PI) (fasting PI and 75 g-OGTT-PI reduced by 33–38%), and insulin sensitivity index (ISI) (75 g-OGTT-ISI increased by 33%) compared with placebo ($P < 0.05$) (Vuksan et al 2008).

Cardiovascular disease

A 2006 systematic review concluded that there is currently a lack of well-designed, randomised, controlled trials to support the use of ginseng to treat cardiovascular risk factors despite some studies suggesting improvements in blood pressure, blood glucose and lipid profiles (Buettner et al 2006).

Although there are reports of ginseng causing hypertension, red ginseng is actually used as an antihypertensive agent in Korea.

Acute administration of an aqueous preparation of Korean ginseng (100 mg/kg body weight) to 12 healthy, nonsmoking male volunteers resulted in an increase in NO levels and a concomitant reduction in mean blood pressure and heart rate (Han et al 2005).

Ginseng is often used in practice as an adjuvant to both conventional and Complementary and Alternative Medicine (CAM) treatments. Trials have reported that 1.5 g three times daily of Korean red ginseng (4.5 g/day) is useful as an adjuvant to antihypertensive medication (Han et al 1995, 1998). It should be noted however that results in these trials while statistically significant (e.g. systolic pressure −5.7 mmHg) may not be clinically significant. A combination of red ginseng and digoxin was found to be more beneficial than either drug alone in an open study of advanced congestive heart failure. There were no adverse reactions (Ding et al 1995). A combination of ginseng and ginkgo extracts has been found to improve circulation and lower blood pressure in a controlled single-dose study of 10 healthy young volunteers (Kiesewetter et al 1992).

Korean red ginseng has also been shown to improve vascular endothelial function in patients with hypertension. The effect is thought to be mediated through increasing the synthesis of nitric oxide (Sung et al 2000).

Hyperlipidaemia

In a small trial of eight males receiving 2 g Panax ginseng extract three times daily (total Panax ginseng extract (PGE) 6 g/day) for 8 weeks, serum total cholesterol, LDL and triglyceride concentrations were decreased by 12, 45 and 24%, respectively, and a 44% increase in HDL was reported (Kim & Park 2003).

Red ginseng, 1.5 g three times daily before meals for 7 days, reduced liver cholesterol, decreased the atherogenic index, and elevated HDL cholesterol in 11 patients (5 normal subjects and 6 with hyperlipidaemia). Serum cholesterol was not significantly altered, but serum triglycerides were significantly decreased (Yamamoto & Kumagai 1982).

Immunomodulation

Ginseng has been shown to significantly enhance NK function in healthy subjects and in those suffering from chronic fatigue syndrome or AIDS ($P < 0.01$) (See et al 1997).

Ginseng polysaccharide injection has been shown, in a randomised study, to improve immunity in 130 patients with nasopharyngeal carcinoma and to reduce adverse reactions to radiotherapy compared with controls (Xie et al 2001).

Red ginseng powder has been shown to restore immunity after chemotherapy and reduce the recurrence of stage III gastric cancer. The 5-year disease-free survival and overall survival rates were significantly higher in patients taking the red ginseng powder during postoperative chemotherapy versus control (68.2 vs 33.3%, 76.4 vs 38.5%, respectively, $P < 0.05$). Despite the limitation of a small number of patients ($n = 42$), these findings suggest that red ginseng powder may help to improve postoperative survival in these patients. Additionally, red ginseng powder may have some immunomodulatory properties associated with CD3 and CD4 activity in patients with advanced gastric cancer during postoperative chemotherapy (Suh et al 2002).

Vaccine adjuvant activity

Ginseng extract (100 mg ginsan G115/day) improved the response to an influenza vaccine in a multicentre, randomised, double-blind, placebo-controlled, two-arm study of 227 subjects. Compared with vaccine without the ginseng, the addition of ginseng resulted in fewer cases of influenza and common cold. Ginseng increased NK activity and increased antibody production (Scaglione et al 1996).

The addition of 2 mg ginseng dry extract per vaccine dose has been shown to potentiate the antibody response of commercial vaccines without altering their safety. The enhancing effect of ginseng was demonstrated during the vaccination of pigs against porcine parvovirus and *Erysipelothrix rhusiopathiae* infections using commercially available vaccines (Rivera et al 2003).

Cognitive function

There is some contention about the benefits of ginseng for improving memory, concentration and learning (Persson et al 2004). Well-controlled clinical trials are lacking, and variations in dosage and standardisation may affect study results.

Some studies have demonstrated that ginseng improves the quality of memory and associated secondary memory (Kennedy et al 2001a). In a randomised, placebo-controlled, double-blind, balanced, crossover study of healthy, young adult volunteers, 400 mg ginseng was shown to improve secondary memory performance on a Cognitive Drug Research computerised assessment battery and two serial subtraction mental arithmetic tasks. Ginseng also improved attention and the speed of performing the memory tasks (Kennedy et al 2002). In a later double-blind, placebo-controlled, balanced, crossover study of 30 healthy young adults, acute administration of ginseng (400 mg) was again shown to improve speed of attention (Sunram-Lea et al 2005).

In a double-blind, placebo-controlled study of healthy young subjects, ginseng extract (G115) improved accuracy and slowed responses during one of two computerised serial subtraction tests (Serial Sevens) and it was also shown to improve mood during these tasks (Kennedy et al 2001b). In acute dosing trials, a single dose of ginseng (200 mg G115 extract, with or without 25 g glucose) and glucose has been shown to enhance cognitive performance in healthy young adults. Participants experienced enhanced performance on a mental arithmetic task and a reduction in subjective feelings of mental fatigue during the later stages of the sustained, cognitively demanding task (Reay et al 2006b).

In a double-blind, randomised, placebo-controlled 8–9-week trial, standardised ginseng extract 400 mg was found to significantly improve abstract thinking ($P < 0.005$) and reaction time (not significant) in 112 healthy subjects over 40 years of age. Ginseng was found not to affect concentration or memory (Sorensen & Sonne 1996).

In a controlled open-label study, 97 consecutive patients with Alzheimer's disease were randomly assigned to a treatment ($n = 58$) or control group ($n = 39$). The treatment group received Korean ginseng powder (4.5 g/day) for 12 weeks, which resulted in improvements in the cognitive subscale of Alzheimer's disease assessment scale (ADAS) and the mini-mental state examination (MMSE) ($P = 0.029$ and $P = 0.009$ vs baseline, respectively). After discontinuing ginseng, the improved ADAS and MMSE scores declined to the levels of the control group (Lee 2008). In addition, similar trials using 0, 4.5 or 9 g ginseng daily found that patients in the high-dose group showed significant improvement on the ADAS and Clinical Dementia Rating after 12 weeks of ginseng therapy ($P = 0.032$ and 0.006, respectively). Improvements in MMSE did not reach statistical significance (Heo et al 2008).

In clinical practice, Korean ginseng and *Ginkgo biloba* are frequently used in combination for cognitive benefits. Combining ginseng with ginkgo dramatically improves memory, concentration and speed of completing mental tasks (Kennedy et al 2001a, Scholey & Kennedy 2002). In clinical trials, ginseng directly modulates cerebroelectrical activity

on EEG recordings to a greater extent than *Ginkgo biloba* (Kennedy et al 2003).

In a double-blind, placebo-controlled study, postmenopausal women aged 51–66 years were randomly assigned to 12 weeks' treatment with a combination formula containing 120 mg *Ginkgo biloba* and 200 mg *Panax ginseng* ($n = 30$) or matched placebo ($n = 27$). The combination appeared to have no effect on mood or cognition after 6 and 12 weeks; however, these doses may be too low (Hartley et al 2004). According to other trials, it would appear that doses of 400–900 mg of ginseng are required for best results and 200 mg doses have been associated with 'cognitive costs', slowing performance on attention tasks (Kennedy & Scholey 2003).

Menopausal symptoms

Korean red ginseng is used to alleviate symptoms associated with menopause; 6 g ginseng for 30 days was shown in a small study of 20 women significantly ($P < 0.001$) to improve menopausal symptoms, in particular fatigue, insomnia and depression. The women treated had a significant decrease in cortisol and cortisol-to-dehydroepiandrosterone ratio ($P < 0.05$). No adverse effects were recorded (Tode et al 1999).

Erectile dysfunction

Korean red ginseng has been shown to alleviate erectile dysfunction and improve the ability to achieve and maintain erections even in patients with severe erectile dysfunction (Price & Gazewood 2003). Ginsenosides can facilitate penile erection by directly inducing the vasodilatation and relaxation of the penile corpus cavernosum. Moreover, the effects of ginseng on the corpus cavernosum appear to be mediated by the release and/or modification of release of NO from endothelial cells and perivascular nerves (Murphy & Lee 2002). In men with type 2 diabetes, oxidative stress has been suggested as a contributing factor to erectile dysfunction and animal studies suggest that ginseng can preserve 'potency' via its antioxidant effect (Ryu et al 2005).

In a double-blind, placebo-controlled study, 60 patients presenting with mild or mild to moderate erectile dysfunction received 1 g (three times daily) of Korean ginseng or placebo. In the five-item International Index of Erectile Function (IIEF)-5, 66.6% (20 patients) reported improved erection, rigidity, penetration and maintenance ($P < 0.01$) after 12 weeks. Serum testosterone, prolactin and cholesterol were not significantly different (de Andrade et al 2007).

In a double-blind crossover study, 900 mg Korean red ginseng was found to significantly improve the Mean IIEF scores compared with placebo. Significant subjective improvements in penetration and maintenance were reported by participants, and penile tip rigidity on the RigiScan showed significant improvement for ginseng versus placebo (Hong et al 2002).

A significant improvement in erectile function, sexual desire and intercourse satisfaction was demonstrated in 45 subjects following 8 weeks' oral administration of Korean red ginseng (900 mg three times daily) in a double-blind, placebo-controlled, crossover trial. Subjects demonstrated significant improvement in mean IIEF scores compared with placebo (baseline, 28 ± 16.7; Korean red ginseng, 38.1 ± 16.6; placebo, 30.9 ± 15.7) (Hong et al 2003).

Quality of life

An 8-week, randomised, double-blind study found that 200 mg/day ginseng ($n = 15$, placebo: $n = 15$) improved aspects of mental health and social functioning after 4 weeks' therapy but that these differences disappeared with continued use (Ellis & Reddy 2002). A review of eight clinical studies with ginseng found some improvement in QOL scores. However, the findings were equivocal. Despite some positive results, improvement in overall health-related QOL cannot, given the current research, be attributed to *P. ginseng*. However, the possibility that various facets of QOL may have improved and the potential of early transient effects cannot be discounted (Coleman et al 2003). A double-blind, placebo-controlled, randomised clinical trial of 83 subjects also did not find ginseng to enhance psychological wellbeing in healthy young adults (Cardinal & Engels 2001).

A double-blind, placebo-controlled, crossover study found that 1200 mg ginseng was only slightly more effective than placebo and not as effective as a good night's sleep in improving bodily feelings, mood and fatigue in 12 fatigued night nurses. Volunteers slept less and experienced less fatigue but rated sleep quality worse after ginseng administration (Hallstrom et al 1982).

A recent double-blind, placebo-controlled, balanced, crossover design of 30 healthy young adults taking *P. ginseng* extract (200 or 400 mg) or placebo demonstrated improvements in performance and subjective feelings of mental fatigue during sustained mental activity. It has been hypothesised that this effect may be due in part to the ability of ginseng to regulate blood glucose levels (Reay et al 2005).

Adaptogenic and tonic effects

A randomised double-blind study involving 232 subjects between the ages of 25 and 60 years found that extract equivalent to about 400 mg ginseng root for 4 weeks significantly improved fatigue. Side effects were uncommon, with only two subjects withdrawing from the study (Le Gal & Cathebras 1996).

A randomised double-blind study of 83 subjects found that extract equivalent to 1 g ginseng root for 4 months decreased the risk of contracting a common cold or bronchitis and improved appetite, sleep, wellbeing and physical performance (Gianoli & Riebenfeld 1984).

Improved athletic performance

Ginseng is used by many athletes to improve stamina and to facilitate rapid recovery from injuries; however, supporting evidence from well-designed clinical trials is lacking. To examine the

effects of ginseng supplements on hormonal status following acute resistance exercise, eight male college students were randomly given water (control group) or 20 g ginseng root extract treatment immediately after a standardised training exercise. Human growth hormone, testosterone, cortisol and insulin-like growth factor 1 levels were determined by radioimmunoassay. The responses of plasma hormones following ginseng consumption were not significant between the control and the ginseng groups during the 2-hour recovery period (Youl et al 2002).

Although ginseng is commonly used to improve endurance, a double-blind study of 19 healthy active women found that 400 mg of a ginseng extract (G115) did not improve supramaximal exercise performance or short-term recovery. Analysis of variance using pretest to posttest change scores revealed no significant difference between the ginseng and placebo study groups for the following variables measured: peak anaerobic power output, mean anaerobic power output, rate of fatigue and immediate postexercise recovery heart rates (Engels et al 2001). A recent study by the same authors also failed to find any benefit from ginseng (400 mg/day G115; equivalent to 2 g *P. ginseng* C.A. Meyer root material for 8 weeks) on improving physical performance and heart rate recovery of individuals undergoing repeated bouts of exhausting exercise (Engels et al 2003). When 60 men from the Naval Medical Corps, Royal Thai Navy (aged 17–22 years), given 3 g/day of ginseng or placebo for an 8-week period, were measured for blood lactic acid levels for determination of lactate threshold (LT), no improvements were noted, nor was there any beneficial effect on physical performance (Kulaputana et al 2007).

A small study of seven healthy male subjects given 2 g ginseng (three times daily) for 8 weeks reported a significant increase in exercise duration until exhaustion (+1.5 min; $P < 0.05$), which was related to improvements in lipid peroxidation and scavenger enzymes (Kim et al 2005); however, this study is too small to make generalisations.

OTHER USES

Gastroprotection during heart surgery

In a trial of 24 children undergoing heart surgery for congenital heart defects, 12 children received 1.35 mg/kg ginsenoside compound or placebo intravenously before and throughout the course of cardiopulmonary bypass surgery. Ginseng administration resulted in attenuation of gastrointestinal injury and inflammation (Xia et al 2005).

Respiratory disease

Ginseng extract (G115) has been shown significantly ($P < 0.05$) to improve pulmonary function test, maximum voluntary ventilation, maximum inspiratory pressure and maximal oxygen consumption (VO_{2max}) in a study of 92 patients suffering moderately severe chronic obstructive pulmonary disease ($n = 49$, G115 100 mg twice daily for 3 months) (Gross et al 2002).

Helicobacter pylori

Helicobacter pylori can provoke gastric inflammation, ulceration and DNA damage, resulting in an increased risk of carcinogenesis (Park et al 2005b). As preliminary evidence suggests that *P. ginseng* inhibits the growth of *H. pylori* (Kim et al 2003b) and can inhibit adhesion (Lee et al 2004b), it may be useful as a gastroprotective agent against *H. pylori*-associated gastric mucosal cell damage (Park 2005b).

HIV infection

Long-term intake of Korean ginseng slows the depletion of $CD4^+$ T cells and may delay disease progression in people with HIV type 1 (Sung et al 2005). Ginseng intake in HIV-1-infected patients may also be associated with the occurrence of grossly deleted nef genes (gDeltanef) (Cho et al 2006) and gross deletions (gDelta) in HIV-1 5' LTR and gag regions (Cho & Jung 2008). Long-term intake (60 ± 15 months) has also been shown to delay the development of resistance mutation to zidovudine (Cho et al 2001).

DOSAGE RANGE

- Extract equivalent to 0.9–3 g crude ginseng root (Bensky & Gamble 1986).
- Standardised extract: 1.5–4.0% total ginsenosides calculated as ginsenoside Rg1.
- Liquid extract (1:2): 1–6 mL/day.
- Cognitive function: Clinical trials using 1.5–3 g three times daily have reported benefits. Lower doses may be associated with 'cognitive costs' and slowing performance on attention tasks (Kennedy & Scholey 2003).
- Cardiovascular use: 1.5–2 g three times daily.

Many of the clinical studies published in the scientific literature have used a proprietary extract of ginseng standardised to 4% total ginsenosides (G115 or Ginsana produced by Pharmaton, Lugano, Switzerland).

Ginseng is usually given in the earlier part of the day. It should not be given in the evening, unless it is used to promote wakefulness. Ginseng is usually not given to children.

ADVERSE REACTIONS

Ginseng abuse syndrome (hypertension, nervousness, insomnia, morning diarrhoea, inability to concentrate and skin reactions) has been reported, and there has been a report of a 28-year-old woman who had a severe headache after ingesting a large quantity of ethanol-extracted ginseng. Cerebral angiograms showed 'beading' appearance in the anterior and posterior cerebral and superior cerebellar arteries, consistent with cerebral arteritis (Ryu & Chien 1995). High doses (15 g/day) have been associated with confusion, depression and depersonalisation in four patients (Coon & Ernst 2002).

However, the majority of the scientific data suggest that ginseng is rarely associated with adverse events or drug interactions. A systematic review found that the most commonly experienced adverse events are headache, sleep and gastrointestinal disorders. Data from clinical trials suggest that the

incidence of adverse events with ginseng monopreparations is similar to that of placebo. Any documented effects are usually mild and transient. Combined preparations are more often associated with adverse events, but causal attribution is usually not possible (Coon & Ernst 2002).

Allergic reactions to Korean ginseng, including occupation asthma, may occur via an IgE-mediated mechanism (Kim 2008). A case of suspected ginseng allergy has recently been reported in the scientific literature. The case involved a 20-year-old male who developed urticaria, dyspnoea and hypotension after ingesting ginseng syrup. The subject recovered fully and was discharged after 24 h (Wiwanitkit & Taungjararuwinai 2004).

While ginseng use has been associated with the development of hypertension, it has actually been shown to reduce blood pressure in several studies (Coon & Ernst 2002).

Ginseng has very low toxicity. Subacute doses of 1.5–15 mg/kg of a 5:1 ginseng extract did not produce negative effect on body weight, food consumption, haematological or biochemical parameters or histological findings in dogs (Hess et al 1983), and no effects have been observed from the administration of similar doses in two generations of rat offspring (Hess et al 1982).

Traditionally, ginseng is not recommended with other stimulants such as caffeine and nicotine, and a case report exists of a 39-year-old female experiencing menometrorrhagia, arrhythmia and tachycardia after using oral and topical ginseng along with coffee and cigarettes (Kabalak et al 2004).

SIGNIFICANT INTERACTIONS

Albendazole

Panax ginseng significantly accelerated the intestinal clearance of the anthelmintic albendazole sulfoxide, when coadministered to rats (Merino et al 2003).

Alcohol

Ginseng may increase the clearance of alcohol from the blood according to an open trial of 14 healthy volunteers (Coon & Ernst 2002) — beneficial interaction possible, but needs confirmation.

Chemotherapy, radiotherapy and general anaesthetics

Preliminary evidence suggests that *P.ginseng* saponins may reduce nausea and vomiting associated with chemotherapy, radiotherapy and general anaesthetics by antagonising serotonin (5-hydroxytryptamine) type 3A receptors (Min et al 2003). Ginseng may also help to sensitise cancer cells to chemotherapeutic agents according to preliminary evidence.

Digoxin

Ginseng contains glycosides with structural similarities to digoxin, which may modestly interfere with digoxin results (Dasgupta et al 2003). These naturally occurring glycosides may cause false elevation of fluorescence polarisation and falsely low microparticle enzyme results, although Tina-quant results appear unaffected (Dasgupta & Reyes 2005). It should be noted that measuring free digoxin does not eliminate these modest interferences in serum digoxin measurement by the Digoxin III assay (Dasgupta et al 2008). There are no confirmed case reports of actual interaction (Chow et al 2003, Dasgupta et al 2003).

Drugs metabolised chiefly by CYP1A, CYP2D6 and CYP3A4

Mixed reports exist as to whether ginseng may act as an inhibitor of cytochrome CYP1A (Gurley et al 2005, Lee et al 2002b, Yu et al 2005) or CYP2D6 (Gurley et al 2005). Ginsenosides F1 and Rh1 (but not ginseng extract) may inhibit CYP3A4 at 10 micromolar (Etheridge et al 2007). Whether these effects are likely to be clinically significant has not been established. Observe for increased drug bioavailability and clinical effects.

Nifedipine

Ginseng increased the mean plasma concentration of the calcium channel blocker nifedipine by 53% at 30 minutes in an open trial of 22 healthy subjects. Effects at other time points were not reported (Smith et al 2001).

Vancomycin

In animal studies, the combination of ginseng polysaccharides with vancomycin resulted in a 100% survival rate for animals treated for *Staphylococcus aureus* compared to only 67 or 50% survival in animals treated with ginseng polysaccharides or vancomycin alone (Lim et al 2002b). A beneficial additive effect is possible, but clinical use in humans has not yet been established.

Warfarin

No effects on the pharmacokinetics or pharmacodynamics of either S-warfarin or R-warfarin were revealed in an open-label, crossover randomised trial of 12 healthy male subjects who received a single 25-mg dose of warfarin alone or after 7 days' pretreatment with ginseng (Jiang et al 2004). Whether these effects are consistent in less 'healthy' people likely to be taking warfarin or for prolonged concurrent use is unclear.

There have been two case reports of ginseng reducing the antithrombotic effects of warfarin (Janetzky & Morreale 1997, Rosado 2003). Additionally, it inhibits platelet aggregation according to both in vitro and animal studies. Avoid using this combination unless under medical supervision to monitor antithrombotic effects.

Zidovudine

Long-term intake (60 ± 15 months) of Korean red ginseng in HIV-1-infected patients has been shown to delay the development of resistance mutation to zidovudine (Cho et al 2001).

CONTRAINDICATIONS AND PRECAUTIONS

Korean ginseng is generally contraindicated in acute infections with fever and in persons who are very hot, tense and overly stimulated. Overuse may result in headache, insomnia and palpitation (Bensky & Gamble 1986). Ginseng should not be

PRACTICE POINTS/PATIENT COUNSELLING

Traditional use

Ginseng is traditionally used for deficiency of Qi (energy/life force) manifested by shallow respiration, shortness of breath, cold limbs, profuse sweating and a weak pulse (such as may occur from severe blood loss). Ginseng is also used for wheezing, lethargy, lack of appetite, abdominal distension and chronic diarrhoea. Ginseng may also be used for palpitations, anxiety, insomnia, forgetfulness and restlessness associated with low energy and anaemia (Bensky & Gamble 1986)

Scientific evidence

There is some scientific evidence for the beneficial effects of ginseng for the following conditions. In practice, it is mostly used as a supportive treatment and combined with other herbs to treat a specific condition.

- Prevention and supportive treatment of cancer
- Chronic immune deficiency
- Menopausal symptoms
- Erectile dysfunction
- Chronic respiratory disease
- Enhancement of psychomotor activity, memory and concentration
- Adaptogenic effects in any chronic condition and for the elderly and infirm
- Type 1 diabetes
- Cardiovascular disease (the effects on hypertension remain to be fully investigated)
- QOL (equivocal scientific support)

Commission E recommends ginseng as a tonic for invigoration and fortification in times of fatigue, debility and convalescence or declining capacity for work and concentration. The World Health Organization suggests that ginseng can be used as a prophylactic and restorative agent for enhancement of mental and physical capacities, in cases of weakness, exhaustion, tiredness and loss of concentration and during convalescence (Blumenthal 2001).

taken concurrently with other stimulants including caffeine and should be discontinued 1 week before major surgery. Use in hypertension should be supervised; however, it may prove beneficial for this indication.

PREGNANCY USE

Ginseng is traditionally used in Korea as a tonic during pregnancy. Commission E does not list any restrictions (Blumenthal 2001). There is in-vitro evidence of teratogenicity based on exposure to isolated ginsenosides (especially Rb1) (Chan et al 2003) at much higher levels than achievable through normal consumption in humans and conflicting evidence as to its oestrogenic properties. In light of the lack of good clinical evidence, Korean ginseng should be used cautiously during pregnancy (especially the first trimester) and lactation until more data are available (Seely et al 2008).

In a two-generation rat study, a ginseng extract fed at doses as high as 15 mg/kg/day did not produce adverse effects on reproductive performance, including embryo development and lactation (Hess et al 1982).

PATIENTS' FAQs

What will this herb do for me?

Ginseng is a safe herb used to support the body during times of prolonged stress or chronic disease and to restore mental and physical functioning during the rehabilitative process. Numerous studies have identified a range of pharmacological activities that suggest that it may be useful in the treatment of many conditions.

When will it start to work?

In practice, it generally appears that ginseng has a quick onset of action with the condition continuing to improve with long-term use; however, this will vary depending on the individual and the indication.

Are there any safety issues?

Ginseng may interact with warfarin and other blood-thinning drugs and should not be used with these medications, unless under medical supervision. Avoid use in children or in hypertension, unless under supervision. Use with caution in pregnancy.

Ginseng — Siberian

HISTORICAL NOTE Siberian ginseng has been used for over 2000 years, according to Chinese medical records, where it is referred to as Ci Wu Jia. It was used to prevent colds and flu and to increase vitality and energy. In modern times, it has been used by Russian cosmonauts for improving alertness and energy and to aid in adaptation to the stresses of life in space. It also has been used as an ergogenic aid by Russian athletes before international competitions (Mills & Bone 2000) and used after the Chernobyl accident to counteract the effects of radiation (Chevallier 1996).

OTHER NAMES
Ci Wu Jia, devil's bush, devil's shrub, eleuthero, eleutherococcus, eleuthero root, gokahi, ogap'I, russisk rod, taigawurzel, touch-me-not, Wu Jia Pi

BOTANICAL NAME/FAMILY
Eleutherococcus senticosus (synonym: *Acanthopanax senticosus*) (family Araliaceae)

PLANT PART USED
Root, rhizome

CHEMICAL COMPONENTS
Glycosides (eleutherosides A–M, including saponins, coumarins, lignans, phenylpropanoids, oleanolic acids, triterpenes, betulinic acid and vitamins), steroid glycoside (eleutheroside A), lignans (syringin, sesamin, chlorigenic acid), glycans (eleutherans A–G), triterpenoid saponins (friedelin), saponin (protoprimulagenin A), hydroxycoumarin (isofraxidin), phenolics, polysaccharides, lignans, coumarins and resin.

Nutrients include magnesium 723 microgram/g, aluminium 188 microgram/g and manganese 37 microgram/g and vitamins A and E (Eleutherococcus senticosus 2006, Meacham et al 2002, Nissen 2003, Skidmore-Roth 2001, Panossian et al 1999).

MAIN ACTIONS

Adaptogenic (modulates stress response)
Siberian ginseng appears to alter the levels of different neurotransmitters and hormones involved in the stress response, chiefly at the hypothalamic-pituitary-adrenal axis (HPA) axis. Various mechanisms have been proposed including inhibition of catechol-O-methyltransferase, which inactivates catecholamines (Gaffney et al 2001a). As a result, catecholamine levels are not depleted and release of new catecholamines from nerve synapses is decreased (Panossian et al 1999). In theory, this may reduce the risk of the organisms' adaptive responses becoming depleted and moving into the exhaustion phase of the stress response. In addition, eleutherosides have been shown to improve carbohydrate metabolism and energy provision and increase the synthesis of protein and nucleic acids, although the direct molecular targets responsible for this adaptive response remain unknown (Panossian et al 1999). Eleutherosides have also been reported to bind to receptor sites for progestin, oestrogen, mineralocorticoids and glucocorticoids in vitro and therefore may theoretically exert numerous pharmacological actions important for the body's stress response (Pearce et al 1982).

Owing to such actions, herbalists and naturopaths describe the herb's overall action as 'adaptogenic'. The term 'adaptogen' describes substances that increase the ability of an organism to adapt to environmental factors and to avoid damage from such factors (Panossian et al 1999). The term 'allostasis' (see Clinical note) has been adopted in the medical arena to describe 'the ability to achieve stability through change'.

Clinical note — Allostasis
Allostasis is the body's adaptation to stress. Allostatic (adaptive) systems are critical to survival and enable us to respond to changes in our physical (such as asleep, awake, standing, sitting, eating, exercising and infection) and psychological states (such as anticipation, fear, isolation, worry and lack of control). The consumption of tobacco, alcohol and our dietary choices also induces allostatic responses (McEwan 1998). These systems are complex and have broad boundaries, in contrast to the body's homeostatic systems (e.g. blood pH and body temperature), which are maintained within a narrow range.

Most commonly, allostatic responses involve the sympathetic nervous system and the HPA axis. Upon activation (e.g. when a challenge is perceived), catecholamines are released from nerves and the adrenal medulla, corticotrophin is secreted from the pituitary and cortisol is released from the adrenal cortex. Once the threat has passed (e.g. the environment is more comfortable or infection is controlled), the system is inactivated and levels of cortisol and catecholamine secretion return to baseline.

Chronic exposure to stress can lead to allostatic load, a situation resulting from chronic overactivity or underactivity of allostatic systems. The situation is characterised by maladaptive responses whereby systems become inefficient or do not turn off appropriately. Currently, there is much interest in understanding the association between numerous diseases such as cardiovascular disease and overwhelming allostatic load.

One measure that is used to gauge an individual's allostatic response is the cortisol response to a variety of stressors. As such, cortisol is seen as the classical 'stress' hormone.

Although the mechanism of action responsible is still unclear, several theories have been proposed to explain the effect of Siberian ginseng on allostatic systems, largely based on the pharmacological actions observed in test tube and animal studies. Depending on the stage of the stress response, Siberian ginseng can act in different ways to support the 'stress system'. Research suggests that there is a threshold of stress below which the herb increases the stress response and above which it decreases the stress response (Gaffney et al 2001b). Therefore, for example, if allostatic load is such that responses have become inadequate, then the resulting increase in hormone levels would theoretically induce a more efficient response. Alternatively, situations of chronic overactivity, also due to allostatic load, would respond to Siberian ginseng in a different way, with negative feedback systems being triggered to inactivate the stress response (Gaffney et al 2001a). As a result, Siberian ginseng could theoretically induce quite different effects, largely dependent on whether allostatic responses were underactive or overwhelmed.

The dosing regimen may also be significant. While multi-dose administration in chronic stress engages the HPA axis balancing the switch-on and switch-off responses, single doses (~ 4 mL) in acute stress trigger a rapid response from the sympathoadrenal system, resulting in secretion of catecholamines, neuropeptides, adenosine triphosphate (ATP) and nitric oxide (Panossian & Wagner 2005). Studies have demonstrated that maximal effects are achieved around 4 weeks but do not persist at the 8-week time point, which may help to explain the practice of giving Siberian ginseng for 6 weeks with a 2-week break before repeating.

Immunomodulation

Siberian ginseng appears to exert an immunomodulatory rather than just an immunosuppressive or stimulating action; however, evidence for the immune enhancing effects of Siberian ginseng is contradictory. Clinical studies in vitro and in vivo have revealed stimulation of general non-specific resistance and an influence on T-lymphocytes, natural killer (NK) cells and cytokines (Bohn et al 1987, Schmolz et al 2001), although other studies suggest that Siberian ginseng does not significantly stimulate the innate macrophage immune functions that influence cellular immune responses (Wang et al 2003). Alternatively, another in-vitro study has demonstrated that activation of macrophages and NK cells does occur and may be responsible for inhibiting tumour metastasis both prophylactically and therapeutically (Yoon et al 2004).

The main constituents responsible appear to be lignans (sesamin, syringin) and polysaccharides, such as glycans, which demonstrate immunostimulant effects in vitro (Davydov & Krikorian 2000, Wagner et al 1984). Additionally, effects on the HPA axis will influence immune responses.

It has been suggested that eleutheroside E may be responsible for the improved recovery from reduced NK activity and the inhibition of corticosterone elevation induced by forced swimming in mice (Kimura & Sumiyoshi 2004) and may contribute to the antifatigue action.

Antiviral

In vitro studies show a strong antiviral action, inhibiting the replication of ribonucleic acid (RNA) type viruses such as human rhinovirus, respiratory syncytial virus and influenza A virus (Glatthaar-Saalmuller et al 2001).

Anabolic activity

Syringin and other eleutherosides appear to improve carbohydrate metabolism and energy provision by increasing the formation of glucose-6-phosphate and activating glucogen transport (Panossian et al 1999), and Siberian ginseng extracts have been reported to improve the metabolism of lactic and pyruvic acids (Farnsworth et al 1985). Additionally, preliminary evidence of possible anabolic effects makes this herb a popular treatment among athletes in the belief that endurance, performance and power may improve with its use.

While initial animal studies showed promise for improving weight gain and increasing organ and muscle weight (Farnsworth et al 1985, Kaemmerer & Fink 1980), clinical studies confirming whether anabolic effects occur also in humans could not be located.

OTHER ACTIONS

Anticoagulant and antiplatelet effects

Animal studies have demonstrated prevention against thrombosis induced by immobilisation (Shakhmatov et al 2007), and the 3,4-dihydroxybenzoic acid constituent of Siberian ginseng has demonstrated antiplatelet activity in vivo (Yun-Choi et al 1987). A controlled trial using Siberian ginseng tincture for 20 days in 20 athletes detected a decrease in the blood coagulation potential and activity of the blood coagulation factors that are normally induced by intensive training of the athletes (Azizov 1997). Whether the effects also occur in non-athletes is unknown.

Vascular relaxant

In vitro studies have demonstrated vasorelaxant effects for Siberian ginseng. The effect is thought to be endothelium dependent and mediated by NO and/or endothelium-derived hyperpolarising factor, depending on the size of the blood vessel. Other vasorelaxation pathways may also be involved (Kwan et al 2004).

Anti-allergic

In-vitro studies demonstrate that Siberian ginseng has anti-allergic properties in mast cell-mediated allergic reactions (Jeong et al 2001). The mechanism appears to involve inhibition of histamine, tumour necrosis factor-alpha (TNF-alpha) and interleukin-6.

Anti-inflammatory

Excess production of nitric oxide (NO) is a characteristic of inflammation, and Siberian ginseng has been shown to significantly suppress NO production and inducible nitric oxide synthase (iNOS) gene expression in a dose-dependent manner (Lin et al 2008). The downregulation of iNOS expression may be the result of inhibition of intracellular peroxide production (Lin et al 2008) or through blocking c-Jun NH2-terminal kinase (JNK) and Akt activation (Jung et al 2007). Contradictory results have been shown for inhibition of cyclooxygenase (COX)-2 expression (Jung et al 2007, Raman et al 2008).

Radioprotective

Animal studies have found that administration of Siberian ginseng prior to a lethal dose of radiation produced an 80% survival rate in mice (Miyanomae & Frindel 1988). This result suggests that Siberian ginseng may protect against radiation toxicity.

Cardioprotective

Oral administration of Siberian ginseng (1 mL/kg) to rats for 8 days prevented stress-induced heart damage and chronic administration increased beta-endorphin levels and improved cardiac tolerance to D, L-isoproterenol and arrhythmia caused by

adrenaline. The cardioprotective and antiarrhythmic effect may be related to an increase in endogenous opioid peptide levels (Maslov & Guzarova 2007). Benefits following a 45-min coronary artery occlusion were not demonstrated in this study (Maslov & Guzarova 2007) but have been in studies using Siberian ginseng in a polypharmacy combination known as 'Tonizid'® (Lishmanov et al 2008).

Neuroprotective

Preliminary animal studies have suggested possible neuroprotective effects in transient middle cerebral artery occlusion in Sprague-Dawley rats. Infarct volume was reduced by 36.6% by inhibiting inflammation and microglial activation in brain ischaemia after intraperitoneal injection of a water extract of Siberian ginseng (Bu et al 2005). Similarly, intraperitoneal injection of Siberian ginseng was found to relieve damage to neurons following hippocampal ischaemia hypoxia and improve the learning and memory of rats with experimentally induced vascular dementia (Ge et al 2004). Siberian ginseng extract appears to protect against neuritic atrophy and cell death under amyloid beta treatment; the effect is thought to be due at least in part to eleutheroside B (Tohda et al 2008). The saponins present in Siberian ginseng have also been shown to protect against cortical neuron injury induced by anoxia/reoxygenation by inhibiting the release of NO and neuron apoptosis in vitro (Chen et al 2004).

Hepatoprotective

Animal studies have demonstrated that an intravenous extract of Siberian ginseng decreased thioacetamide-induced liver toxicity when given before and after thioacetamide administration (Shen et al 1991). More recently, oral administration of aqueous extract and polysaccharide was found to attenuate fulminant hepatic failure induced by D-galactosamine/lipopolysaccharide in mice, reducing serum aspartate aminotransferase (AST), alanineaminotransferase (ALT) and tissue necrosis factor (TNF)-alpha levels (Park et al 2004). The protective effect is thought to be due to the water-soluble polysaccharides. Coadministration of Siberian ginseng may also act to enhance the antihypoxant action of amtizole, improving the protective effect on hepatic antitoxic function and lipid metabolism (Kushnerova & Rakhmanin Iu 2008).

Reduces obesity

Animal studies have demonstrated that the inclusion of Siberian ginseng attenuated the 'weight gain, serum low density lipoprotein (LDL) cholesterol concentration and liver triglyceride accumulation in mice with obesity induced by high-fat diets' (Cha et al 2004).

Glycaemic control and insulin-sensitising effect

Animal studies have indicated a potential for hypoglycaemic effects when used intravenously. Syringin appears to enhance glucose utilisation (Niu et al 2008) and lower plasma glucose levels in animal experiments. The effect may be due to an increase in the release of acetylcholine from nerve terminals, stimulating muscarinic M (3) receptors in pancreatic cells to increase insulin release (Liu et al 2008). Syringin may also enhance the secretion of beta-endorphin from the adrenal medulla to stimulate peripheral micro-opioid receptors, resulting in a decrease of plasma glucose in insulin-depleted diabetic rats (Niu et al 2007).

Eleutherans A–G exert marked hypoglycaemic effects in normal and alloxan-induced hyperglycaemic mice (Hikino et al 1986), and eleutherosides show an insulin-like action in diabetic rats (Dardymov et al 1978). However, these effects have not been borne out in human studies (Farnsworth et al 1985) and may not relate to oral dosages of Siberian ginseng.

A small, double-blind, randomised, multiple, crossover study using 12 healthy participants actually showed an increase in postprandial plasma glucose at 90 and 120 min when 3 g Siberian ginseng was given orally 40 min before a 75-g oral glucose tolerance test (Sievenpiper et al 2004). More recently, oral administration of an aqueous extract of Siberian ginseng was shown to improve insulin sensitivity and delay the development of insulin resistance in rats (Liu et al 2005). As a result, further trials in people with impaired glucose tolerance and/or insulin resistance are warranted.

CLINICAL USE

Stress

Siberian ginseng is widely used to treat individuals with nervous exhaustion or anxiety due to chronic exposure to stress or what is now termed 'allostatic load situations'. The biochemical effects on stress responses observed in experimental and human studies provide a theoretical basis for this indication (Abramova et al 1972, Gaffney et al 2001a).

One placebo-controlled study conducted over 6 weeks investigated the effects of an ethanolic extract of Siberian ginseng (8 mL/day, equivalent to 4 g/day dried root). In the study, active treatment resulted in increased cortisol levels, which may be consistent with animal research, suggesting a threshold of stress below which Siberian ginseng increases the stress response and above which it decreases the stress response (Gaffney et al 2001b).

Fatigue

Siberian ginseng is used to improve physical and mental responses during convalescence or fatigue states. While traditional stimulants can produce a temporary increase in work capacity followed by a period of marked decrease, the initial increase in performance from adaptogens is followed by only a slight dip and performance remains above basal levels (Panossian et al 1999). The ability of Siberian ginseng to increase levels of noradrenaline, serotonin, adrenaline and cortisol provides a theoretical basis for its use in situations of fatigue. However, controlled studies are limited.

A randomised, double-blind, placebo-controlled trial of 300 mg/day (*E. senticosus* dry extract) for 8 weeks assessed health-related quality of life scores in 20 elderly people. Improvements were observed

in social functioning after 4 weeks of therapy but did not persist to the 8-week time point. It would appear that improvements diminish with continued use (Cicero et al 2004), which may help to explain the practice of giving Siberian ginseng for 6 weeks with a 2-week break before repeating.

A recent randomised placebo-controlled trial evaluated the effectiveness of Siberian ginseng in chronic fatigue syndrome (CFS). No significant improvements were demonstrated overall; however, subgroup analysis showed improvements in fatigue severity and duration ($P < 0.05$), in CFS sufferers with less severe fatigue at 2-month follow-up (Hartz et al 2004). Further studies are required to determine whether Siberian ginseng may be a useful therapeutic option in cases of mild to moderate fatigue.

Commission E approves the use of Siberian ginseng as a tonic in times of fatigue and debility, for declining capacity for work or concentration and during convalescence (Blumenthal et al 2000). In practice, it is often used in low doses in cases of fatigue due to chronic stress (Gaffney et al 2001a).

Ergogenic aid

Siberian ginseng extracts have been reported to provide better usage of glycogen and high-energy phosphorus compounds and improve the metabolism of lactic and pyruvic acids (Farnsworth et al 1985). Experimental data suggest that syringin and other eleutherosides may improve carbohydrate metabolism and energy provision by increasing the formation of glucose-6-phosphate and activating glucogen transport (Panossian et al 1999). While initial animal studies showed promise for improving weight gain and increasing organ and muscle weight (Wagner et al 1985), recent randomised, controlled clinical trials have produced inconsistent results in healthy individuals and athletes (Dowling et al 1996, Eschbach et al 2000, Mahady et al 2000), and a recent review concluded that only poorer quality trials have demonstrated benefit while well-designed trials have not shown significant improvement in endurance performance, cardiorespiratory fitness or fat metabolism during exercise ranging in duration from 6 to 120 minutes (Goulet & Dionne 2005).

In the mid 1980s, a Japanese controlled study conducted on six male athletes over 8 days showed that Siberian ginseng extract (2 mL twice daily) improved work capacity compared with a placebo (23.3 versus 7.5%) in male athletes, owing to increased oxygen uptake ($P < 0.01$). Time to exhaustion (stamina) also increased (16.3 versus 5.4%, $P < 0.005$) (Asano et al 1986). Other research however has failed to confirm these effects (Dowling et al 1996, Eschbach et al 2000).

A randomised, double-blind, crossover trial using a lower dose of 1200 mg/day Siberian ginseng for 7 days reported that treatment did not alter steady-state substrate use or 10 km cycling performance time (Eschbach et al 2000). Additionally, an 8-week, double-blind, placebo-controlled study involving 20 experienced distance runners failed to detect significant changes to heart rate, oxygen consumption, expired minute volume, respiratory exchange ratio, perceived exertion or serum lactate levels compared with placebo. Overall, both submaximal and maximal exercise performance were unchanged (Dowling et al 1996).

Siberian ginseng may however reduce blood coagulation factors induced by intensive training in athletes (Azizov 1997) and has been shown in combination with micronutrients to improve iron metabolism and immunological responsiveness in 39 high-grade unarmed self-defence sportsmen (Nasolodin et al 2006). Whether these effects also occur in other scenarios is yet to be established.

Clinical studies investigating whether ergogenic or anabolic effects observed in experimental studies occur in humans are lacking, and therefore Siberian ginseng cannot currently be recommended to improve athletic performance (Palisin & Stacy 2006). Siberian ginseng does not appear on 'The 2008 Prohibited List' of the World Anti-doping Agency (WADA 2008).

Prevention of infection

Due to the herb's ability to directly and indirectly modulate immune responses, it is also used to increase resistance to infection. One double-blind study of 1000 Siberian factory workers supports this, reporting a 50% reduction in general illness and a 40% reduction in absenteeism over a 12-month period, following 30 days' administration of Siberian ginseng (Farnsworth et al 1985).

More recently, a 6-month controlled trial in males and females with recurrent herpes infection found that Siberian ginseng (2 g/day) successfully reduced the frequency of infection by 50% (Williams 1995).

In practice, Siberian ginseng is generally used as a preventative medicine, as administration during acute infections is widely thought to increase the severity of the illness, although this has not been borne out in controlled studies using Siberian ginseng in combination with other herbs. A small randomised controlled trial (RCT) demonstrated a significant reduction in the severity of familial Mediterranean fever in children using a combination of Siberian ginseng with licorice, andrographis and schisandra (Amaryan et al 2003), and a combination of Siberian ginseng with schisandra and rhodiola was found to expedite the recovery of patients with acute non-specific pneumonia (Narimanian et al 2005).

Cancer therapy

A polypharmacy preparation known as AdMax®, which contains *Eleutherococcus senticosus* in combination with *Leuzea carthamoides*, *Rhodiola rosea* and *Schizandra chinensis*, has been shown to boost the suppressed immunity in patients with ovarian cancer who are subject to chemotherapy (Kormosh et al 2006). Which herb or combination of herbs is responsible for the effect is unclear.

OTHER USES

Given the herb's ability to increase levels of serotonin and noradrenaline in animal studies (Abramova et al 1972), a theoretical basis exists for the use of Siberian ginseng in depression.

In traditional Chinese medicine (TCM), Siberian ginseng is used to encourage the smooth flow of Qi and blood when obstructed, particularly in the elderly, and is viewed as a general tonic. It is therefore used for a myriad of indications, usually in combination with other herbal medicines. Numerous studies use Siberian ginseng in combination with other adaptogens, such as *Rhodiola rosea* and *Schisandra chinensis*, which may potentially act synergistically for improved effects.

DOSAGE RANGE

- 1–4 g/day dried root or equivalent preparations.
- Fluid extract (1:2): 2–8 mL/day (15–55 mL/week).
- Tincture (1:5): 10–15 mL/day.
- Acute dosing: 4 mL in a single dose before activity.
- Extracts with standardised levels of eleutheroside E (syringin) (> 0.5 mg/mL) are recommended. Russian and Korean sources appear to have higher levels of this constituent. So, variations in therapeutic activity may be predicted (Wagner et al 1982). As there can be a significant product variability in the level of eleutherosides between capsules and liquids, standardisation may be necessary for quality assurance (Harkey et al 2001).

In practice, Siberian ginseng is often given for 6 weeks with a break of at least 2 weeks before resuming treatment.

Clinical note — Case reports of Siberian ginseng need careful consideration

Some adverse reactions attributed to Siberian ginseng have subsequently been found to be due to poor product quality, herbal substitution and/or interference with test results. For example, initial reports linking maternal ginseng use to neonatal androgenisation are now suspected to be due to substitution with another herb, *Periploca sepium* (called Wu jia or silk vine), as American herb companies importing Siberian ginseng from China have been known to be supplied with two or three species of *Periploca* (Awang 1991). Additionally, rat studies have failed to detect significant androgenic action (Awang 1991, Waller et al 1992) for Siberian ginseng.

Another example is the purported interaction between digoxin and Siberian ginseng, which was based on a single case report of a 74-year-old man found to have elevated digoxin levels for many years (McRae 1996). It was subsequently purported that the herbal product may have been adulterated with digitalis. Additionally, Siberian ginseng contains glycosides with structural similarities to digoxin that may modestly interfere with digoxin fluorescence polarisation (FPIA), microparticle enzyme (MEIA) results, falsely elevating digoxin values with FPIA and falsely lowering digoxin values with MEIA (Dasgupta & Reyes 2005). It should be noted that measuring free digoxin does not eliminate these modest interferences in serum digoxin measurement by the Digoxin III assay (Dasgupta et al 2008).

ADVERSE REACTIONS

Clinical trials of a 6 months' duration have shown no side effects from treatment (Bohn et al 1987). High doses may cause slight drowsiness, irritability, anxiety, mastalgia, palpitations or tachycardia, although these side effects may be more relevant to *Panax ginseng*.

It is suggested that a spontaneous subarachnoid haemorrhage in a 53-year-old woman who was using an herbal supplement containing red clover, dong quai and Siberian ginseng was likely to be due to the dong quai (Friedman et al 2007).

SIGNIFICANT INTERACTIONS

As controlled studies are not available, interactions are currently speculative and based on evidence of pharmacological activity and case reports. Studies have reported that normal doses of Siberian ginseng are unlikely to affect drugs metabolised by CYP2D6 or CYP3A4 (Donovan et al 2003).

Anticoagulants

An in-vivo study demonstrated that an isolated constituent in Siberian ginseng has anticoagulant activity (Yun-Choi et al 1987), and a clinical trial found a reduction in blood coagulation induced by intensive training in athletes (Azizov 1997). Whether these effects also occur in nonathletes is unknown. Given that a study looking at the concomitant application of Kan Jang (Siberian ginseng in combination with andrographis) and warfarin did not produce significant effects on the pharmacokinetics or pharmacodynamics of the drug (Hovhannisyan et al 2006), a negative clinical effect is unlikely.

Chemotherapy

An increased tolerance for chemotherapy and improved immune function has been demonstrated in women with breast (Kupin 1984, Kupin & Polevaia 1986) and ovarian (Kormosh et al 2006) cancer undergoing chemotherapy treatment. Caution — as coadministration may theoretically reduce drug effects. However, beneficial interaction may be possible under medical supervision.

Diabetic medications

Claims that Siberian ginseng has hypoglycaemic effects are based on intravenous use in animal studies and not observed in humans for whom oral intake may actually increase postprandial glycaemia (Sievenpiper et al 2004). Observe diabetic patients taking ginseng.

Influenza virus vaccine

Ginseng may reduce the risk of post-vaccine reactions (Zykov & Protasova 1984), a possible beneficial interaction.

CONTRAINDICATIONS AND PRECAUTIONS

Some authors suggest that high-dose Siberian ginseng should be avoided by those with cardiovascular disease or hypertension (blood pressure (BP) > 80/90 mmHg) (Mahady et al 2000). Others merely suggest a caution, as reports are largely unsubstantiated (Holford & Cass 2001). As such, it is recommended that people with hypertension should be monitored

PRACTICE POINTS/PATIENT COUNSELLING

- Siberian ginseng appears to alter the levels of different neurotransmitters and hormones involved in the stress response, chiefly at the HPA axis.
- It is widely used to treat individuals with nervous exhaustion or anxiety due to chronic exposure to stress or what are now termed 'allostatic load situations'. It is also recommended during convalescence or fatigue to improve mental and physical responses.
- Siberian ginseng may increase resistance to infection and has been shown to reduce frequency of genital herpes outbreaks with long-term use.
- The herb is popular among athletes in the belief that endurance, performance and power may improve with its use, but clinical studies have produced inconsistent results.
- It is not recommended for use in pregnancy, and people with hypertension should be monitored if using high doses.

if using high doses. In a study of elderly people with hypertension, 8 weeks of Siberian ginseng use did not affect BP control (Cicero et al 2004).

Due to possible effects on glycaemic control (Sievenpiper et al 2004), care should be taken in people with diabetes until safety is established. Suspend use 1 week before major surgery.

Traditional contraindications include hormonal changes, excess energy states, fever, acute infection, concurrent use of other stimulants and prolonged use.

PREGNANCY USE

Insufficient reliable information is available, but the herb is not traditionally used in pregnancy.

PATIENTS' FAQs

What will this herb do for me?

Siberian ginseng affects many chemicals involved in switching on and off the body's stress responses. As such, it is used to improve wellbeing during times of chronic stress; however, scientific research has yet to fully investigate its use in this regard. It may also boost immune function and reduce the frequency of genital herpes outbreaks. Evidence for improved performance in athletes is unconvincing.

When will it start to work?

Effects on stress levels should develop within 6 weeks, whereas immune responses develop within 30 days.

Are there any safety issues?

It should not be used in pregnancy, and high doses should be used with care by those with hypertension.

Globe artichoke

HISTORICAL NOTE Artichoke has a long history of use as a vegetable delicacy and medicinal agent, and its cultivation in Europe dates back to ancient Greece and Rome. It was domesticated in Roman times, possibly in Sicily, and spread by the Arabs during early Middle Ages. Traditional use of artichoke has always pertained to the liver where it is considered to increase bile flow and act as a protective agent against various toxins. As such, it has been used for jaundice, dyspepsia, nausea, gout, pruritis and urinary stones. It is still a popular medicine in Europe today.

COMMON NAME
Artichoke

OTHER NAMES
Alcachofa, artichaut, alcaucil, carciofo, cynara

BOTANICAL NAME/FAMILY
Cynara scolymus L. (family [Compositae] Asteraceae)

PLANT PART USED
Leaf

CHEMICAL COMPONENTS
Key constituents of the leaf include phenolic acids, mainly caffeic acid derivatives (e.g. chlorogenic acid), sesquiterpenes, lactones (e.g. cynaropicrin) and flavonoids (e.g. cynaroside, luteolin derivatives, anthocyanin), phytosterols, inulin and free luteolin.

MAIN ACTIONS
The main pharmacologically active constituents are thought to be the phenolic acids and flavonoids.

Antioxidant
Artichoke leaf extract exerts antioxidant effects, according to in vitro and clinical studies (Skarpanska-Stejnborn et al 2008, Speroni et al 2003). According to a double-blind trial, oral globe artichoke (400 mg three times daily) significantly elevates plasma total antioxidant capacity compared to placebo (Skarpanska-Stejnborn et al 2008). Studies further confirm the bioavailability of the metabolites of hydroxycinnamic acids after ingestion of cooked edible globe artichoke (Azzini et al 2007).

Hepatoprotective
Improved hepatic regeneration, improved hepatic blood flow, increased hepatocyte counts, increased hepatic RNA concentrations and a stimulation of hepatic cytogenesis have been associated with artichoke extract in animal studies (Ursapharm Arzneimittel 1998).

Tests with primary hepatocyte cultures and animal models indicate that artichoke extracts have marked antioxidative and hepatoprotective potential (Gebhardt 1997, Mehmetcik et al 2008, Miccadei et al 2008).

Choleretic and cholagogue
A significant increase in bile flow has been demonstrated in studies using isolated perfused rat liver in vivo after acute treatment, as well as after repeated administration (Saenz et al 2002). Choleretic activity has also been reported in a double-blind, placebo-controlled study, with maximal effects on mean bile secretion observed 60 min after a single dose (Kirchhoff et al 1994).

A study that evaluated the effects of four extracts and phenolic content on bile flow and liver protection demonstrated that the extract with the highest concentration of phenolic derivatives exerted the strongest effect (Speroni et al 2003).

One study determined that treatment does not produce changes to the liver enzymes gamma glutamyl transpeptidase (GGTP), aspartate transaminase (AST), alanine transaminase (ALT) or glutamic dehydrogenase (Pittler et al 2002).

Diuretic
Artichoke administration stimulated urine excretion in animal studies (Ursapharm Arzneimittel 1998).

Lipid-lowering
Artichoke leaf extract inhibited cholesterol biosynthesis in primary cultured rat hepatocytes (Gebhardt 1998) and indirect modulation of hydroxymethylglutaryl-CoA-reductase activity is the most likely inhibitory mechanism. When several known constituents were screened for activity, cynaroside, and particularly its aglycone luteolin, were mainly responsible for the effect. These results have been confirmed recently (Gebhardt 2002). Clinical studies have found that artichoke leaf extract causes a modest but statistically significant reduction in total cholesterol (Bundy et al 2008, Skarpanska-Stejnborn et al 2008).

OTHER ACTIONS
Artichoke administration had beneficial effects on lowering blood glucose levels in alloxan-treated rabbits (Ursapharm Arzneimittel 1998). Studies using artichoke leaf juice showed that it improved endothelial reactivity, most likely by its antioxidant constituents (Juzyszyn et al 2008, Lupattelli et al 2004).

Artichoke leaves exhibit some antifungal activities in vitro (Zhu et al 2005).

According to German commission E, human studies have confirmed carminative, spasmolytic and antiemetic actions (Blumenthal et al 2000). The antispasmodic activity of some fractions and cynaropicrin, a sesquiterpene lactone from *Cynara scolymus*, has recently been confirmed in vivo (Emendorfer et al 2005).

In-vitro studies using the edible part of artichoke exerted apoptotic activity on a human liver cancer cell line (Miccadei et al 2008).

Clinical note — Inulin: a natural prebiotic
Inulin is a plant-derived carbohydrate that is not digested or absorbed in the small intestine, but is fermented in the colon by beneficial bacteria. It functions as a prebiotic, stimulating growth of bifidobacteria in the intestine and has been associated with the enhanced function of the gastrointestinal system and immune system (Lopez-Molina et al 2005). Increasing levels of beneficial bacteria, such as bifidobacteria, allow them to 'out compete' potentially detrimental organisms and improve the health of the host. Inulin also increases calcium and magnesium absorption, influences blood glucose levels and reduces the levels of cholesterol and serum lipids. Globe artichoke contains 3% of fresh-weight inulin and smaller amounts are found in the leaves. According to animal studies, this concentration is sufficient to favourably affect the intestinal health (Goñi et al 2005).

CLINICAL USE

Hyperlipidaemia

Data are available from both controlled and uncontrolled studies that have investigated the effects of artichoke leaf extract in hyperlipidaemia. Most studies use Hepar SL forte® or Valverde Artischoke bei Verdauungsbeschwerden (artichoke dry extract) containing 450 g of herbal extract as a coated tablet.

Overall, evidence from five uncontrolled studies, case series and placebo-controlled trials suggests that artichoke leaf extract and cynarin have lipid-lowering effects and a possible role as adjunctive therapy in hyperlipidaemia (Ulbricht & Basch 2005).

A Cochrane systematic review that analysed the results of two controlled studies concluded that artichoke leaf extract appears to have a modest positive effect on the levels of total cholesterol and LDL; however, there is insufficient evidence to recommend it as a treatment option for hypercholesterolaemia and trials with larger sample sizes are still required (Pittler et al 2002).

One of the studies was a randomised, placebo-controlled, double-blind, multicentre trial involving 143 subjects with total cholesterol levels > 7.3 mmol/L (> 280 g/dL) (Englisch et al 2000). A dose of 1800 mg artichoke leaf extract was administered daily for 6 weeks. Active treatment resulted in 18.5% decrease in serum cholesterol compared with 8.6% for placebo, a result that was significant. No differences were observed between the groups for blood levels of either HDL or triglycerides. Although dietary habits were recorded, the food intake was not strictly controlled in the entire patient sample. The second randomised, placebo-controlled, double-blind study involved 44 healthy volunteers and compared 1920 mg artichoke extract daily to placebo over a 12-week treatment period. No significant effects on serum cholesterol levels were observed in this study; however, subgroup analyses suggested that patients with higher initial total cholesterol levels experienced a significant reduction in total cholesterol levels compared to placebo.

Two placebo-controlled clinical studies were published, which further demonstrated modest but significant reductions in total cholesterol for artichoke leaf extract. Bundy et al (2008) conducted a 12-week, randomised study of 75 adults which found that treatment with artichoke leaf (1280 mg of a standardised extract) significantly reduced plasma total cholesterol by an average of 4.2% (from 7.16 mmol/L (SD 0.62) to 6.86 mmol/L (SD 0.68)) compared with controls, although no significant differences were observed for LDL cholesterol, HDL cholesterol or triglyceride levels.

A smaller randomised, double-blind study of 22 volunteers found that oral artichoke leaf extract (400 mg three times daily) significantly reduced serum total cholesterol levels by the end of the 5-week study compared to placebo (Skarpanska-Stejnborn et al 2008).

European Scientific Co-operative of Phytotherapy (ESCOP) approves the use of artichoke leaf as an adjunct to a low-fat diet in the treatment of mild-to-moderate hyperlipidaemia (ESCOP 2003).

Dyspepsia

Artichoke leaf extract has been studied as a bile secretion stimulant and primarily recommended in this way for non-ulcer dyspepsia.

A double-blind, randomised, placebo-controlled trial of 247 patients with functional dyspepsia (persistent or recurrent pain or discomfort in the upper abdomen with one or more of the following symptoms: early satiety, postprandial fullness, bloating and nausea) found that treatment with two capsules of 320 mg artichoke leaf extract LI 220 (HeparSL® forte) taken three times daily significantly improved overall symptoms over the 6 weeks compared with the placebo (Holtmann et al 2003). Additionally, active treatment significantly improved global quality of life (QOL) scores compared with the placebo.

A randomised, open study of 454 subjects investigated the efficacy of a low-dose artichoke leaf extract (320 mg or 640 mg daily) on amelioration of dyspeptic symptoms and improvement of QOL (Marakis et al 2002). Both doses achieved a significant reduction of all dyspeptic symptoms, with an average reduction of 40% in global dyspepsia score. Although no differences in primary outcome measures were reported between the two treatment groups, the higher dosage resulted in greater improvements in anxiety.

An uncontrolled study of 553 patients with non-specific digestive disorders (dyspeptic discomforts, functional biliary colic and severe constipation) experienced a significant reduction of symptoms after 6 weeks of treatment with artichoke extract. Symptoms improved by an average of 70.5%, with strongest effects on vomiting (88.3%), nausea (82.4%), abdominal pain (76.2%), loss of appetite (72.3%), constipation (71.0%), flatulence (68.2%) and fat intolerance (58.8%). In 85% of patients, the global therapeutic efficacy of artichoke extract was judged by the physicians as excellent or good (Fintelmann 1996).

The German Commission E approves artichoke leaf and preparations made from artichoke leaf as a choleretic agent for dyspeptic problems (Blumenthal et al 2000).

Irritable bowel syndrome (IBS)

Artichoke leaf extract appears to have substantial benefits in IBS, according to the available evidence; however, large controlled studies are required to confirm these observations. The antispasmodic and probiotic activities of artichoke leaf are likely to contribute to the beneficial effects produced by this preparation.

A subgroup of patients with IBS symptoms was identified from a sample of subjects with dyspeptic syndrome who were being monitored for 6 weeks (Walker et al 2001). Analysis of the data revealed 96% of patients rated artichoke leaf extract as better than or at least equal to previous therapies administered for their symptoms. Physicians also provided favourable reports on its effects in these patients.

A study of 208 adults with IBS observed before and after a 2-month intervention period of changes in symptoms (Bundy et al 2004). A significant reduction in the incidence of IBS by 26.4% and a significant shift in self-reported usual bowel pattern towards 'normal' were also reported after treatment. The Nepean Dyspepsia Index (NDI) total symptom score significantly decreased by 41% after treatment and there was a significant 20% improvement in the NDI total QOL score.

Reducing alcohol-induced hangover

Artichoke extract does not prevent the signs and symptoms of alcohol-induced hangover in healthy adults, according to a small randomised, double-blind, crossover trial (Pittler et al 2003). The dose used in the study was 960 mg taken immediately before and after consuming alcohol for 2 days. The same researchers later conducted a systematic review to assess the clinical evidence on the effectiveness of any medical intervention for preventing or treating alcohol hangover and found that no compelling evidence exists (Pittler et al 2005).

OTHER USES

Traditional uses include treatment for jaundice, dyspepsia, nausea, gout, pruritis and urinary stones. Due to its choleretic effect, it has also been used to improve digestion of fats.

Wild artichoke (*C. cardunculus*) significantly restores proper vasomotion after simulation of oxidative stress in rat models. This may have clinical significance for treatment in the elderly, where a progressive loss of vascular endothelial function and concurrent loss of vasomotor control is frequent (Rossoni et al 2005). The antioxidant activity of artichoke has been shown to offer a protective effect on gonads of cadmium-treated rats (Gurel et al 2007).

DOSAGE RANGE

- 1:2 liquid extract: 3–8 mL/day in divided doses.
- 6 g daily of dried cut leaves, pressed juice of the fresh plant or equivalent.

According to clinical studies

- Hyperlipidaemia: 4–9 g/day of dried leaves or 1800 mg/day artichoke leaf extract.
- Dyspepsia: artichoke leaf extract 640 mg/day.
- IBS: artichoke leaf extract 640 mg/day.

ADVERSE REACTIONS

Studies with hyperlipidaemic subjects indicate that globe artichoke leaf extract is generally well tolerated. Mild symptoms of flatulence, hunger and weakness were reported in approximately 1% of subjects when the fresh plant was used (Fintelmann 1996). Contact dermatitis is possible with the fresh plant and urticaria–angio-oedema has been reported in one case of ingestion of raw and boiled herb (Mills & Bone 2005).

SIGNIFICANT INTERACTIONS

None known.

CONTRAINDICATIONS AND PRECAUTIONS

Not to be used by people with known allergy to globe artichoke or other members of the Asteraceae/Compositae family of plants.

Herbs with choleretic and cholagogue activities should be used with caution by people with bile duct obstruction (Blumenthal et al 2000), acute or severe hepatocellular disease (e.g. cirrhosis), septic cholecystitis, intestinal spasm or ileus, liver cancer or with unconjugated hyperbilirubinaemia (Mills & Bone 2005).

PREGNANCY USE

Safety has not been scientifically established for the leaf extract. Dietary intake is likely to be safe.

PRACTICE POINTS/PATIENT COUNSELLING

- Artichoke leaf extract has antioxidant, choleretic, diuretic, antispasmodic and lipid-lowering activity and possibly hepatoprotective and antiemetic effects.
- According to controlled clinical trials, artichoke extract has a modest but significant effect in lowering total cholesterol levels although effects on other blood lipids are less consistent. ESCOP recommends that a low-fat diet should also be undertaken when artichoke leaf extract is used for mild-to-moderate hyperlipidaemia.
- Artichoke leaf extract is an effective symptomatic treatment for non-ulcer dyspepsia and shows promise for IBS.
- The extract is well tolerated with few side effects, but should not be used by people with known allergy to globe artichoke or other members of the Asteraceae/Compositae family of plants and used with caution in bile duct obstruction, acute or severe hepatocellular disease (e.g. cirrhosis), septic cholecystitis, intestinal spasm or ileus, liver cancer or people with unconjugated hyperbilirubinaemia.

PATIENTS' FAQs

What will this herb do for me?

Artichoke leaf extract effectively reduces symptoms in non-ulcer dyspepsia and possibly IBS.

It also modestly reduces total cholesterol levels and improves digestion, flatulence and nausea.

When will it start to work?

Symptomatic relief in dyspepsia and IBS appear after 2–3 weeks of treatment; however, further improvements are possible with long-term use. A reduction in cholesterol may take 4–6 weeks and is best achieved when combined with a low-fat diet.

Are there any safety issues?

The extract is well tolerated with few side effects, but should not be used by people with known allergy to globe artichoke or other members of the Asteraceae/Compositae family of plants and used with caution in bile duct obstruction, acute or severe hepatocellular disease (e.g. cirrhosis), septic cholecystitis, intestinal spasm or ileus, liver cancer or people with unconjugated hyperbilirubinaemia.

Glucosamine

OTHER NAMES

D-Glucosamine, amino monosaccharide, glucosamine sulfate, glucosamine hydrochloride, glucosamine hydroiodide, *N*-acetyl D-glucosamine, 2-amino-2-deoxy-beta-D-glucopyranose

BACKGROUND AND RELEVANT PHARMACOKINETICS

Glucosamine is a naturally occurring substance that is required for the production of proteoglycans, mucopolysaccharides and hyaluronic acid, which

are substances that make up joint tissue, such as articular cartilage, tendons and synovial fluid. It is also a component of blood vessels, heart valves and mucus secretions (Kelly 1998).

Glucosamine sulfate is 90% absorbed after oral administration. The bioavailability is approximately 20% after first-pass metabolism (Aghazadeh-Habashi et al 2002). Unbound glucosamine is concentrated in the articular cartilage and the elimination half-life is 70 h, with excretion as CO_2 in expired air, as well as by the kidneys and in faeces (Setnikar & Canali 1993). A study of the pharmacokinetics of glucosamine sulfate in humans found that it is rapidly absorbed after oral administration and its elimination half-life was tentatively estimated to average 15 h, therefore supporting once-daily dosing (Persiani et al 2005). Twice-daily dosing with 500 mg of a time-release formula has also been shown to provide comparable serum levels after 24 h as three divided doses of 500 mg (Basak et al 2004).

A further study suggests that glucosamine is bioavailable both systemically and at the joint, and that steady state concentrations in human plasma and synovial fluid were correlated and in line with levels deemed effective in in vitro studies (Persiani et al 2007). This is contrasted by the suggestion from a study of 18 people with osteoarthritis (OA) that found serum glucosamine levels were significantly less than those previously shown to have in vitro effects (Biggee et al 2006). Similar results were reported in an equine study that found levels attained in serum and synovial fluid were 500-fold lower than those reported to modify chondrocyte anabolic and catabolic activities in tissue and cell culture experiments (Laverty et al 2005).

CHEMICAL COMPONENTS

2-amino-2-deoxy-D-glucose

FOOD SOURCES

Glucosamine is present in chitin from the shells of prawns and other crustaceans. As a supplement, glucosamine is derived from marine exoskeletons or produced synthetically and is available in salt forms, including glucosamine sulfate, glucosamine hydrochloride, glucosamine hydroiodide and *N*-acetyl glucosamine. Glucosamine salts are likely to be completely ionised in the stomach, although clinical equivalence of the different salts has not been established. The purity and content of products has been questioned in the USA, where glucosamine is regarded as a food supplement and its quality is unregulated (Consumer Lab 2006).

MAIN ACTIONS

Chondroprotective effect

Glucosamine is a primary substrate and stimulant of proteoglycan biosynthesis and inhibits the degradation of proteoglycans. Glucosamine may also stimulate synovial production of hyaluronic acid, a compound responsible for the lubricating and shock-absorbing properties of synovial fluid (McCarty 1998a, McCarty et al 2000). Glucosamine promoted cell differentiation and increased alkaline phosphatase (ALP) activity, collagen synthesis, osteocalcin secretion and mineralisation in osteoblastic cells (Kim et al 2007) as well as caused a statistically significant stimulation of proteoglycan production by chondrocytes from human osteoarthritic cartilage culture (Bassleer et al 1998). Glucosamine sulfate has also been found to modify cultured OA chondrocyte metabolism by acting on protein kinase C, cellular phospholipase A_2, protein synthesis and possibly collagenase activation (Piperno et al 2000). *N*-acetyl glucosamine also has been found to produce proliferation of matured cartilaginous tissues and matured cartilage substrate in experimentally produced cartilaginous injuries in rabbits (Tamai et al 2003), and oral administration of glucosamine has been shown to have limited site-specific, partial disease-modifying effect in animal models of OA (Tiraloche et al 2005). In another animal model, co-administration with chondroitin was seen to prevent both biochemical and histological alterations and provide pain reduction (Silva et al 2009). Glucosamine may be a useful adjunct to intraarticular corticosteroid injections, as it was seen to protect equine chondrocytes from methylprednisolone-induced inhibition of proteoglycan synthesis in vitro (Byron et al 2008).

The results of one in vitro study suggest that the experimental effects of glucosamine are sensitive to the experimental model, the doses and length of treatment and that in the model using bovine chondrocytes, pharmacological doses of glucosamine induced a broad impairment in the metabolic activity of the chondrocytes, leading to cell death (de Mattei et al 2002).

Glucosamine was found to have no effect on type 2 collagen fragment levels in serum or urine in a 6-month RCT of 137 subjects with OA of the knee (Cibere et al 2005) and exogenous glucosamine was found not to stimulate chondroitin sulfate synthesis by human chondrocytes in vitro. Furthermore, these cells were found to have the capacity to form amounts of glucosamine from glucose far in excess of that provided by levels achievable through oral administration (Mroz & Silbert 2004).

It has been suggested that at least some of the chondroprotective action of glucosamine sulfate is due to the provision of a source of additional inorganic sulfur which is essential for glycosaminoglycan (GAG) synthesis as well as being a structural component of glutathione and other key enzymes, coenzymes and metabolites that play fundamental roles in cellular homeostasis and control of inflammation (Nimni & Cordoba 2006).

Anti-inflammatory

A number of in vitro and in vivo tests have identified anti-inflammatory activity for glucosamine. Anti-inflammatory and chondroprotective activities have been observed in human OA cartilage (Sumantran et al 2008). In vitro studies have found that glucosamine sulphate exerts anti-inflammatory effects by altering production of TNF-alpha, interleukins and prostaglandin E2 in macrophage cells (Kim et al 2007). Glucosamine and *N*-acetyl

glucosamine inhibit IL-1-beta- and TNF-alpha-induced NO production in normal human articular chondrocytes (Shikhman et al 2001). However glucosamine, but not *N*-acetyl glucosamine, inhibits human neutrophil functions such as superoxide generation, phagocytosis, granule enzyme release and chemotaxis (Hua et al 2002). Glucosamine restores proteoglycan synthesis and prevents the production of inflammatory mediators induced by the cytokine IL-1-beta in rat articular chondrocytes in vitro (Gouze et al 2001). Furthermore, glucosamine has been found to suppress PGE_2 production and partly suppress NO production in chondrocytes in vitro (Mello et al 2004, Nakamura et al 2004), as well as suppressing the production of matrix metalloproteases in normal chondrocytes and synoviocytes (Nakamura et al 2004).

Glucose metabolism

Exogenous glucosamine is actively taken up by cells. Its entry into cells is stimulated by insulin and involves the glucose transporter system (Pouwels et al 2001); however, the affinity of glucosamine for these transporters is substantially lower than that of glucose (Nelson et al 2000).

Early preliminary evidence suggested that glucosamine may cause changes in glucose metabolism and insulin secretion similar to those seen in type 2 diabetes in both rats (Balkan & Dunning 1994, Giaccari et al 1995, Lippiello et al 2000, Shankar et al 1998) and humans (Monauni et al 2000); however, these findings have been disputed (Echard et al 2001). In the 10 years following the original research, clinical trial evidence has accumulated which has failed to find any significant effect on glucose metabolism in humans (Anderson et al 2005, Tannis et al 2004).

Gastrointestinal protection

Glycoproteins are important in protecting the bowel mucosa from damage, and the breakdown of glycosaminoglycans is an important consequence of inflammation of mucosal surfaces (Salvatore et al 2000). Abnormalities in colonic glycoprotein synthesis have been implicated in the pathogenesis of ulcerative colitis and Crohn's disease (Burton & Anderson 1983, Winslet et al 1994).

OTHER ACTIONS

Glucosamine might have some activity against HIV. Preliminary evidence shows that it inhibits intracellular viral movement and blocks viral replication (Bagasra et al 1991). Other studies have found that glucosamine has immunosuppressive properties and can prolong graft survival in mice (Ma et al 2002). Oral, intraperitoneal and intravenously administered glucosamine significantly reduces CNS inflammation and demyelination in an animal model of multiple sclerosis (Zhang et al 2005).

CLINICAL USE

Osteoarthritis

There is strong evidence to suggest that glucosamine is effective in treating the symptoms of OA, as well as being effective in slowing disease progression. Reviews of clinical trials generally confirm the efficacy of glucosamine in providing pain relief from OA, although there are some inconsistent results (Bruyere & Reginster 2007, Reginster et al 2007, Vangsness et al 2009). A Cochrane review of 16 RCTs concluded that 'there is good evidence that glucosamine is both effective and safe in treating OA' and that 'glucosamine therapy may indeed represent a significant breakthrough in the pharmacological management of OA' (Towheed et al 2003). Although most studies have been of OA of the knee, there is some clinical evidence that it is also active against OA of the spine (Giacovelli & Rovati 1993), temporomandibular joint (Shankland 1998) and hands (Scarpellini et al 2008).

The first placebo-controlled clinical trials investigating glucosamine in OA were published in the early 1980s. Drovanti et al showed that a dose of 1500 mg glucosamine sulfate significantly reduced symptoms of OA, almost twice as effectively and twice as fast as placebo (Drovanti et al 1980). Perhaps the most exciting results were found when electron microscopy analysis of cartilage showed that those people taking glucosamine sulfate had cartilage more similar to healthy joints than the placebo group. Based on this finding, researchers suggested that glucosamine sulfate had not only provided symptom relief but also had the potential to induce rebuilding of the damaged cartilage.

Since that time, multiple human clinical trials lasting from a few weeks (Crolle & D'Este 1980, Drovanti et al 1980, Lopes Vaz 1982, McAlindon 2001, Pujalte et al 1980, Qiu et al 1998) to 3 years (Pavelka et al 2002, Reginster et al 2001), as well as systematic reviews (Poolsup et al 2005, Towheed et al 2003, 2006) and meta-analyses (McAlindon et al 2000, Richy et al 2003) have shown that glucosamine sulfate (1500 mg/day) can significantly improve symptoms of pain and functionality measures in patients with OA of the knee, with side effects comparable to those of placebo.

The National Institutes of Health (NIH) recently spent US$14 million on a Glucosamine Chondroitin Arthritis Intervention Trial (GAIT), a 24-week, placebo-controlled, parallel, double-blind, five-arm trial involving 1583 patients that aimed to answer the question as to the efficacy of glucosamine hydrochloride and chondroitin by comparing glucosamine alone, glucosamine plus chondroitin, chondroitin alone, placebo and the COX-2 inhibitor celecoxib (Clegg et al 2006, NIH 2002). The results of this study provide good evidence that glucosamine and chondroitin are more effective when given in combination than when either substance is given alone and that combined treatment with glucosamine and chondroitin is more effective than celecoxib for treating moderate-to-severe, but not mild, arthritis. The design of the GAIT trial can be criticised for the fact that it included a large number of people with very mild disease who were more likely to be susceptible to placebo (as evidenced by the very high (60%) placebo response). Furthermore, the criteria for effectiveness was set very high (20% reduction in Western Ontario and McMaster Osteoarthritis Index (WOMAC) pain score)

and that when the internationally accepted Outcome Measures in Rheumatology-Osteoarthritis Research Society International (OMERACT-OARSI) response criteria for judging clinical trials of OA was used, the combined treatment was significantly better than placebo for patients with either mild or moderate-to-severe disease (Clegg et al 2006).

In addition to providing symptomatic relief from OA, there is evidence from two long-term (3-year) studies (Pavelka et al 2002, Reginster et al 2000) and two year-long studies of glucosamine and chondroitin (Rai et al 2004, Scarpellini et al 2008) that glucosamine also slows disease progression. Reginster et al (2000) compared the effects of 1500 mg glucosamine sulfate with placebo daily over 3 years in 212 patients aged over 50 years with primary knee OA. This was heralded as a landmark study at the time because it not only detected modest symptom-relieving effects, but also was the first to identify significant joint-preserving activity with long-term use. Two years later, Pavelka et al confirmed these results in another randomised, double-blind study that involved 202 patients with knee OA (Pavelka et al 2002) and once again observed that long-term treatment with glucosamine sulfate retarded disease progression. A post hoc analysis of these studies found that the disease-modifying effect was evident in 319 postmenopausal women (Bruyere et al 2004) and another subanalysis found that patients with less severe radiographic knee OA, who are likely to experience the most dramatic disease progression, may be particularly responsive to treatment with glucosamine (Bruyere et al 2003). A 1-year trial involving 104 subjects with OA of the hands, hip and knee found that treatment with both glucosamine and chondroitin reduced pain and significantly slowed disease progression as measured by radiographs and measures of urinary C-terminal cross-linking telopeptides of type I collagen (Scarpellini et al 2008). In contrast to the above findings, a 24-month, double-blind, placebo-controlled study of 572 patients conducted as part of the GAIT study did not demonstrate reductions in joint space narrowing, although there was a trend for improvement in knees with Kellgren and Lawrence (K/L) grade 2 radiographic OA. The authors state, however, that power of this study was diminished by the limited sample size, variance of joint space width (JSW) measurement and a smaller than expected loss in joint space (Sawitzke et al 2008).

A study suggests that treatment with glucosamine sulfate for at least 12 months results in significant reduction in health resource utilisation even after treatment is discontinued. This study which involved 275 subjects previously involved in 12-month glucosamine intervention trials followed subjects for up to 5 years after treatment was discontinued (making up a total of 2178 patient-years of observation). The study showed that total knee replacement had occurred in over twice as many patients from the placebo group (19/131 or 14.5%), than in those formerly receiving glucosamine sulphate (9/144 or 6.3%) (Bruyere et al 2008).

Not all clinical trials of glucosamine for OA have produced positive results. A 2-year randomised controlled trial of 222 patients with hip OA who received either 1500 mg of oral glucosamine sulfate or placebo daily found no difference in WOMAC scores or joint space narrowing after 24 months (Rozendaal et al 2008). Similarly a 12-week, double-blind, randomised, placebo-controlled trial of glucosamine performed over the internet involving 205 subjects with symptomatic knee OA found no difference in pain, stiffness, analgesic use or physical function between the glucosamine and placebo groups (McAlindon et al 2004). In another 6-month randomised, double-blind, placebo-controlled study of glucosamine sulfate in knee OA there was no significant difference in the time to disease flare, symptoms or analgesic medication use between the glucosamine and placebo groups (Cibere et al 2004). A further controlled trial of 80 OA patients using glucosamine sulfate over 6 months found no difference between the glucosamine group and placebo for symptoms, except for a small but significant difference in knee flexion, which was suggested to be caused by measurement error (Hughes & Carr 2002). Further studies suggest that glucosamine either alone or in combination with chondroitin offered no additional benefit to exercise in people with OA of the knee (Messier et al 2007, Kawasaki et al 2008).

Theories to explain inconsistencies

It has been suggested that the type of glucosamine preparation, inadequate allocation concealment and industry bias may account for the inconsistent results seen in glucosamine trials. A study of 15 separate trials suggests that glucosamine hydrochloride is not effective (effect size 0.06) while glucosamine sulfate is effective (effect size 0.44) and that other than allocation concealment there were no study design features that could explain differences between studies. It is further suggested that differences may be a result of industry bias (Vlad et al 2007). Most clinical trials have used a specific patented oral formulation of glucosamine sulfate from Rottapharm, Italy, which is available as a prescription medicine in Europe. Although other forms of glucosamine are used in practice, there is significantly more evidence supporting the use of glucosamine sulfate than others (Reginster et al 2005, Vlad et al 2007, Felson 2008). An updated Cochrane review that looked at 20 studies involving a total of 2570 patients found that studies using a non-Rottapharm preparation failed to show benefit in pain and function, whereas studies of the Rottapharm preparation found glucosamine to be superior to placebo in the treatment of pain and functional impairment (Towheed et al 2006).

Combination therapy

Chondroitin sulfate and glucosamine are frequently marketed together in combination products and some studies suggest that this combination is effective in treating symptoms (Clegg et al 2006, Das & Hammad 2000, Leffler et al 1999, McAlindon et al 2000, Nguyen et al 2001, NIH 2002) and reducing

joint space narrowing (Rai et al 2004). This is supported by an in vitro study of horse cartilage, which found that a combination of glucosamine and chondroitin was more effective than either product alone in preventing articular cartilage glycosaminoglycan degradation (Dechant et al 2005). Further support for combination therapy comes from an in vivo study of rats, which found that combined treatment with chondroitin and glucosamine prevented the development of cartilage damage and was associated with a reduction in IL-1-beta and matrix metalloprotease-9 synthesis (Chou et al 2005).

Although glucosamine has not been shown to have direct analgesic activity, certain combinations with non-opioid analgesics have demonstrated synergistic (e.g. ibuprofen and ketoprofen), additive (e.g. diclofenac, indomethacin, naproxen and piroxicam) or subadditive (e.g. aspirin and paracetamol) antinociceptive interactions in the mouse abdominal irritant test, suggesting that combinations of certain ratios of glucosamine and specific non-steroidal anti-inflammatory drugs (NSAIDs) might enhance pain relief or provide adequate pain relief with lower doses of NSAIDs (Tallarida et al 2003).

In a 12-week, randomised, placebo-controlled trial of glucosamine and methylsulfonylmethane involving 118 patients, combined therapy was found to produce a greater and more rapid reduction in pain, swelling and loss of function than either agent alone (Usha & Naidu 2004).

In an in vivo study of arthritic rats, the combination of glucosamine and essence of chicken was more effective in reducing the histopathological severity of arthritis than glucosamine alone (Tsi et al 2003).

A topical preparation containing glucosamine with chondroitin and camphor has been shown to reduce pain from OA of the knee in one randomised controlled trial (Cohen et al 2003).

Comparisons with NSAIDs

There are many studies suggesting that glucosamine is at least as effective as NSAIDs in treating the symptoms of OA (Herrero-Beaumont et al 2007, Muller-Fassbender et al 1994, Reichelt et al 1994, Rovati 1992, Ruane & Griffiths 2002), although glucosamine has a slower onset of action, taking 2–3 weeks to establish an effect. The GAIT trial (see earlier) found that the combination of glucosamine and chondroitin was more effective than celecoxib in treating moderate to severe OA, whereas glucosamine alone was not (Clegg et al 2006).

Inflammatory bowel disease

In vitro and in vivo studies suggest that glucosamine may be useful in treating inflammatory bowel disease with in vitro studies demonstrating suppression of cytokine-induced activation of intestinal epithelial cells and in vivo studies finding that glucosamine improved clinical symptoms and suppressed colonic inflammation and tissue injury in a rat model of inflammatory bowel diseases (Yomogida et al 2008). The anti-inflammatory activity of glucosamine is partly mediated by an increased production of heparan sulfate proteoglycans by the vascular endothelium, thereby improving the endothelium's barrier function (McCarty 1998b). It is possible that the step in glycoprotein synthesis involving the amino sugar is relatively deficient in patients with inflammatory bowel disease and this could reduce the synthesis of the glycoprotein cover that protects the mucosa from damage by bowel contents (Burton & Anderson 1983, Winslet et al 1994). In a pilot study, *N*-acetyl glucosamine proved beneficial in children with chronic inflammatory bowel disease (Salvatore et al 2000).

OTHER USES

Glucosamine demonstrates benefits in alleviating symptoms of degenerative joint disease in both horses (Forsyth et al 2006) and dogs (McCarthy et al 2007). There is the suggestion that glucosamine may provide symptomatic relief for people with rheumatoid arthritis; however, controlled studies are not available to confirm clinical effectiveness (Nakamura et al 2007).

It has been suggested that glucosamine may be a suitable cosmetic ingredient for use in skin care products. Because of its stimulation of hyaluronic acid synthesis, glucosamine has been shown to accelerate wound healing, improve skin hydration and decrease wrinkles. In addition, as an inhibitor of tyrosinase activation, it inhibits melanin production and is useful in treatment of disorders of hyperpigmentation (Bissett 2006). This is supported by an 8-week, double-blind, placebo-controlled trial, which found that hyperpigmentation was reduced with topical use of *N*-acetyl glucosamine with the effect being enhanced by niacinamide (Bissett et al 2007).

DOSAGE RANGE

- 1500 mg glucosamine/day (500 mg three times daily).
- A 2–3-month trial is generally used to determine whether it is effective for an individual patient.
- Intramuscular glucosamine sulfate: 400 or 800 mg three times/week (Reichelt et al 1994) for 4–6 weeks or longer if required.
- Glucosamine sulfate, hydrochloride, hydroiodide and *N*-acetyl forms are available. Most research has been done on the sulfate forms. Topical, intravenous, intramuscular and intraarticular forms are also available in some countries.

ADVERSE REACTIONS

Glucosamine has been used safely in multiple clinical trials lasting from 4 weeks to 3 years with minimal or no adverse effects (Lopes Vaz 1982, Pavelka et al 2002, Pujalte et al 1980, Reginster et al 2001). A 2006 Cochrane systematic review concluded that glucosamine is as safe as placebo (Towheed et al 2006). Glucosamine has an observed safe level (OSL) of 2000 mg/day.

Glucosamine sulphate has no significant effect on serum lipids (Albert et al 2007, Østergaard et al 2007). There is one case report of asthma

Clinical note — Should people with diabetes avoid glucosamine?

Clinicians' concern about the safety of glucosamine in diabetes were probably first fuelled by an article published in Lancet in 1999 (Adams 1999). The article entitled 'Hype about glucosamine' by Adams stated that glucosamine increases glucose resistance in normal and in experimentally diabetic animals (McClain & Crook 1996) and intravenous glucosamine in doses as low as 0.1 mg/kg/min result in a 50% reduction in the rate of glucose uptake in skeletal muscle (Baron et al 1995). Adams concluded by suggesting that perhaps all people, but especially those who are overweight or have diabetes, should be urged to have caution when using glucosamine. Nearly 10 years after the Adams article was published, a much larger body of evidence has accumulated which indicates that such concerns are not necessary.

In 2005, a critical review of clinical trial data for 3063 human subjects concluded that glucosamine does not affect glucose metabolism, there are no adverse effects of oral glucosamine administration on blood, urine or faecal parameters and side effects are significantly less common with glucosamine than with placebo or NSAIDs (Anderson et al 2005). Thirty-three studies were evaluated which included both diabetic and non-diabetic subjects. Twenty-eight studies were randomised, controlled trials; one study was controlled and five were observational trials. Sixteen chronic studies evaluated fasting plasma glucose levels and included 854 subjects followed for a weighted average of 37 weeks. Additionally, 26 studies used glucosamine sulphate and doses ranged from 1500 mg to 3200 mg daily.

being exacerbated by glucosamine–chondroitin supplementation (Tallia & Cardone 2002).

SIGNIFICANT INTERACTIONS

Controlled studies are not available so interactions remain speculative and are based on evidence of pharmacological activity.

Non-steroidal anti-inflammatory drugs

Glucosamine may theoretically enhance the anti-inflammatory activity of NSAIDs — drug dosage may require modification after several weeks' glucosamine use — a potentially beneficial combination.

CONTRAINDICATIONS AND PRECAUTIONS

Although there is a theoretical link between glucosamine and insulin resistance, this has not been demonstrated in human trials. Nevertheless, diabetics using glucosamine should have their blood sugar levels checked regularly.

Glucosamine is made from shellfish and, although it is not extracted from the protein component and appears to pose no threat to shrimp-allergic individuals (Villacis et al 2006), it should be used with caution in patients with shellfish allergy.

PRACTICE POINTS/PATIENT COUNSELLING

- Glucosamine is a naturally occurring building block of joint tissue and cartilage.
- Glucosamine is considered effective in treating the pain and disability of OA and it may act to slow the progression of the disease, although several weeks are required before a clinical effect is evident. The effects appear to be most consistent for glucosamine sulfate.
- It is considered extremely safe and may reduce the need for NSAIDs (which can have serious side effects).
- Glucosamine may have better clinical effects when used in conjunction with chondroitin.
- People with severe shellfish allergy should be advised to use a form that is not derived from shellfish.
- Patients with diabetes should monitor their blood glucose levels while taking glucosamine, although no significant changes are anticipated.

PREGNANCY USE

Insufficient reliable information is available to advise on safety in pregnancy. Some limited data suggest no increased risk for major malformations or other adverse fetal effects with glucosamine use during pregnancy (Sivojelezova et al 2007).

PATIENTS' FAQs

What will this supplement do for me?

Multiple scientific studies have shown that glucosamine sulfate reduces symptoms of OA and may also reduce further progression of the condition. Some people find that they do not require NSAIDs as often when taking it.

When will it start to work?

Symptom relief generally takes 2–3 weeks to establish, but joint protection effects occur only with long-term use of several years.

Are there any safety issues?

Although considered very safe for the general population, it should be used with caution in people with severe shellfish allergies.

L-Glutamine

HISTORICAL NOTE Glutamine and glutamate were originally described in the mid-19th century and their functions began to be examined in the early 20th century. The role of glutamine in the immune system and gastrointestinal tract has been investigated since the 1980s.

BACKGROUND AND RELEVANT PHARMACOKINETICS

L-Glutamine (L-Gln) is a conditionally essential amino acid found in all life forms and the most abundant amino acid in the human body. During conditions of metabolic stress characterised by catabolism and negative nitrogen balance, such as trauma (including surgical trauma), prolonged stress, glucocorticoid use, excessive exercise, starvation, infection, sepsis, cancer and severe burns, the body is unable to synthesise L-Gln in sufficient quantities to meet biological needs and it becomes essential to have an exogenous intake (Miller 1999, PDRHealth 2006a).

L-Glutamine is absorbed from the lumen of the small intestine by active transport (Meng et al 2003) and is then transported to the liver via the portal circulation and enters systemic circulation, where it is distributed to various tissues and transported into cells via an active process. Elimination occurs via glomerular filtration and it is almost completely reabsorbed by the renal tubules. Some metabolism of L-Gln takes place in the enterocytes and hepatocytes and it is involved in various metabolic activities, including the synthesis of L-glutamate (catalysed by glutaminase), proteins, glutathione, pyrimidine and purine nucleotides and amino sugars. L-glutamate is converted to L-glutamine by glutamine synthase in the presence of ammonia, ATP and magnesium or manganese.

L-Glutamine is predominantly synthesised and stored in skeletal muscles where it comprises around 60% of the free amino acids and makes up 4–5% of muscle protein. In times of metabolic stress, glutamine is released into circulation and transported to tissues in need (Kohlmeier 2003, Miller 1999, PDRHealth 2006a).

Unfortunately L-Gln is not very soluble or stable in solution, especially upon heating for sterilisation, and as a result, until recently, was not included in total parenteral nutrition (TPN). The more soluble and stable glutamine dipeptides are now commonly used as the delivery forms in TPN solutions and some nutritional supplements (Kohlmeier 2003, PDRHealth 2000b).

Common forms available

The terms L-glutamine and glutamine are often used interchangeably. L-glutamine is the amide form of L-glutamic acid and contains 15.7% nitrogen (Kohlmeier 2003). It is also known as 2-aminoglutaramic acid, levoglutamide, (S)-2,5-diamino-5-oxopentaenoic acid and glutamic acid 5-amide.

Two synthetic glutamine dipeptides that may be used in TPN are L-alanyl-L-glutamine (Ala-Gln) and glycyl-L-glutamine (Gly-Gln). D-Glutamine, the stereoisomer of L-glutamine, has no known biological activity (Kohlmeier 2003, PDRHealth 2006b).

Since the late 1960s, L-Gln has been manufactured for pharmaceutical use using a fermentation broth. The manufacture of high-quality, low-cost L-Gln requires a strain of microorganism with good production efficiency and minimum by-products. Impurities can then be removed from the broth using a nanofiltration membrane to obtain a fine crystalline powder (Kusumoto 2001, Li et al 2003).

FOOD SOURCES

Typical dietary intake of L-Gln is 5–10 g/day (Miller 1999). Sources include animal and plant proteins, vegetable juices (especially cabbage), eggs, wheat, soybeans and fermented foods, such as miso and yoghurt (Kohlmeier 2003, PDRHealth 2006a).

DEFICIENCY SIGNS AND SYMPTOMS

Although traditionally considered a nonessential amino acid, L-Gln is now considered 'conditionally essential' during periods of metabolic stress characterised by catabolism and negative nitrogen balance.

Critical illness, stress and injury can lead to a significant decrease in plasma levels of L-Gln, which if severe, can increase the risk of mortality (Boelens et al 2001, Wischmeyer 2003).

Prolonged protein malnutrition may cause growth inhibition, muscle wasting and organ damage (Kohlmeier 2003). In the absence of sufficient plasma glutamine, the body will break down skeletal muscle stores, and gut integrity (gut mucosal barrier function) and immunity will be compromised. Because L-Gln is utilised during exercise, a more recent phenomenon of deficiency has been explored and glutamine depletion has been linked with 'over-training syndrome'.

MAIN ACTIONS

L-Glutamine has many important biological functions within the human body. It is an important fuel for the intestinal mucosal cells, hepatocytes and rapidly proliferating cells of the immune system, assists in the regulation of acid balance, thus preventing acidosis, acts as a nitrogen shuttle protecting the body from high levels of ammonia, and is involved in the synthesis of amino acids (including L-glutamate), gamma aminobutyric acid (GABA), glutathione (an important antioxidant), purine and pyramidine nucleotides, amino acid sugars in glycoproteins and glycans, and nicotinamide adenosine dinucleotide (NAD). It is also involved in protein synthesis and energy production (Boelens et al 2001, Kohlmeier 2003, Miller 1999, Niihara et al 2005, Patel et al 2001, PDRHealth 2006a).

Gastrointestinal protection/repair

According to in vitro and in vivo research, L-Gln aids in the proliferation and repair of intestinal cells (Chun et al 1997, Rhoads et al 1997, Scheppach et al 1996) and is the preferred respiratory fuel for enterocytes (and also utilised by colonocytes) (Miller 1999). It is thus vital for maintaining the integrity of the intestinal lining and preventing the translocation of microbes and endotoxins into the body. In addition, L-Gln helps to maintain secretory IgA, which functions primarily by preventing the attachment of bacteria to mucosal cells (PDRHealth 2006a, Yu et al 1996).

According to evidence from animal studies, it may also assist in preventing atrophy following colostomy (Paulo 2002) and irradiation (Diestel et al 2005), and intestinal injury by inhibiting intestinal cytokine release (Akisu et al 2003). L-glutamine depletion induces apoptosis by triggering intercellular events that lead to cell death (Paquette et al 2005), resulting in altered epithelial barrier competence (increased intestinal permeability), bacterial translocation and increased mortality. Under experimental conditions, L-Gln may assist in maintaining intestinal barrier function by increasing epithelial resistance to apoptotic injury, reducing oxidative damage, attenuating programmed cell death and promoting re-epithelialisation (Masuko 2002, Ropeleski et al 2005, Scheppach et al 1996) and may thus reduce bacterial and endotoxin translocation (Chun et al 1997).

Immunomodulation

L-Glutamine has demonstrated immunomodulatory activity in animal models of infection and trauma, as well as trauma in humans. L-Glutamine acts as the preferred respiratory fuel for lymphocytes, is essential for cell proliferation, and can enhance the function of stimulated immune cells.

Extracellular glutamine concentration affects lymphocyte, IL-2 and interferon-gamma (IFN-gamma) proliferation, cytokine production, phagocytic and secretory macrophage activities and neutrophil bacterial killing (Miller 1999, Newsholme 2001, PDRHealth 2006a). In humans, L-Gln may enhance both phagocytosis and reactive oxygen intermediate production by neutrophils (Furukawa et al 2000) and support the restoration of type-1T-lymphocyte responsiveness following trauma (Boelens et al 2004). In a randomised trial, there was a reduced frequency of pneumonia, sepsis and bacteraemia in patients with multiple traumas who received glutamine-supplemented enteral nutrition (Houdijk et al 1998).

In addition, effects on the gastrointestinal tract may contribute significantly to immune defence by maintaining gut-associated lymphoid tissue and secretory IgA (preventing the attachment of bacteria to the gut mucosa) and maintaining gut integrity (thus preventing the translocation of microbes and their toxins, especially gram-negative bacteria from the large intestine) (Miller 1999, Yu et al 1996).

Antioxidant

As a precursor to glutathione (together with cysteine and glycine), L-Gln can assist in ameliorating the oxidation that occurs during metabolic stress. Glutathione protects epithelial cell membranes from damage, and its depletion can negatively affect gut barrier function and result in severe degeneration of colonic and jejunal epithelial cells (Iantomasi 1994, Ziegler et al 1999). In animal studies, it has also been shown to inhibit fatty acid oxidation, resulting in a reduction in body weight and alleviation of hyperglycaemia and hyperinsulinaemia in mice fed a high-fat diet (Opara et al 1996).

Anabolic/anticatabolic

As L-Gln is stored primarily in skeletal muscles and becomes conditionally essential under conditions of metabolic stress, the anticatabolic/anabolic properties of supplemented L-Gln are likely due to a sparing effect on skeletal muscle stores.

Following strenuous exercise, glutamine levels are depleted by approximately 20%, resulting in immunodepression (Castell 2003, Castell & Newsholme 1997, Rogero et al 2002). As a result supplemental L-Gln may be of benefit in athletes to prevent the deleterious effects of glutamine depletion associated with 'over-training syndrome'. Evidence supporting a direct ergogenic effect is currently lacking.

Cardioprotective

In vitro, L-Gln has been shown to assist in the maintenance of myocardial glutamate, ATP and phosphocreatine, and in the prevention of lactate accumulation (Khogali et al 1998). In addition to its antioxidant properties and effects on hyperglycaemia

and hyperinsulinaemia (Opara et al 1996), this may suggest a possible role as a cardioprotective agent.

CLINICAL USE

Deficiency: prevention and treatment

During periods of increased need, L-glutamine is considered conditionally essential. Glutamine depletion can result in increased intestinal permeability, microbial translocation across the gut barrier, impaired wound healing, sepsis and multiple organ failure (Miller 1999). Experimental studies have proposed a number of benefits for patients with conditions that increase glutamine requirements. The suggested mechanisms include effects on pro-inflammatory cytokine expression, gut integrity, enhanced ability to mount a stress response and improved immune cell function, and studies have shown potential benefit with regard to mortality, length of hospital stay and infection.

To date, the results of studies using glutamine dipeptides in TPN have proven to be very promising in treating patients for whom enteral feeding is impossible. Benefits from studies of enteral glutamine supplementation have tended to be less pronounced, but preliminary trials have demonstrated benefits in some conditions, especially at high doses (e.g. 30 g/day enterally) (Wischmeyer 2003).

Critical care settings

A systematic review found trends to suggest that parenteral and enteral glutamine supplementation may reduce mortality, the development of infection and organ failure in critical illness; however, poor study design and possible publication bias limits what conclusions can be drawn from the current data (Avenell 2006).

Abdominal surgery and trauma

A meta-analysis of nine RCTs involving 373 patients was performed to assess the clinical and economical validity of glutamine dipeptide supplementation to parenteral nutrition (PN) in patients undergoing abdominal surgery. The review concluded that glutamine dipeptide has a positive effect in decreasing postoperative infectious morbidity (odds ratio (OR) = 0.24, P = 0.04), shortening the length of hospital stay (WMD = −3.55, 95% $P < 0.00001$) and improving postoperative cumulative nitrogen balance (WMD = 8.35, P = 0.002). No serious adverse effects were identified (Zheng 2006).

Enteral supplementation has not been shown to be as effective in abdominal trauma. In a recent trial, 120 patients with peritonitis or abdominal trauma were randomised to receive either enteral glutamine (45 g/day for 5 days) in addition to standard care (n = 63) or standard care alone (n = 57). No statistically significant benefits were noted in the treatment group for serum malondialdehyde or glutathione levels, infectious complications, survival rate or duration of hospital stay (Kumar et al 2007).

Trauma

Enteral glutamine has been shown to be protective to the gut in experimental models of shock and thus improve clinical outcomes. In a pilot study, enteral glutamine was administered during active shock resuscitation (0.5 g/kg/day during the first 24 hours) and continued for 10 days through the early post-injury period. The treatment was found to be safe and improved gastrointestinal tolerance (vomiting, nasogastric output, diarrhoea and distension). Intensive care unit (ICU) and hospital length of stay were comparable (McQuiggan et al 2008). In a randomised trial using glutamine-enriched enteral nutrition in patients with multiple traumas, there was a reduction in the incidence of pneumonia, sepsis and bacteraemia (Houdijk et al 1998). Parenteral supplementation of alanyl-glutamine dipeptide may also result in better insulin sensitivity in multiple-trauma patients (Bakalar et al 2006).

Clinical note — Total parenteral nutrition (TPN)

L-Glutamine is not very soluble or stable in solution, especially upon heating for sterilisation. As a result, until recently it was not included in TPN, resulting in compromised glutamine status in patients for whom reduced immune status and increased intestinal permeability could potentially increase the risk of morbid infection and mortality. The more soluble and stable synthetic glutamine dipeptides (L-alanyl-L-glutamine (Ala-Gln) and glycyl-L-glutamine (Gly-Gln)) have now been developed as delivery forms of L-Gln for use in TPN. The dipeptide forms can also be used orally and have demonstrated a potential for greater bioavailability than glutamine alone (Macedo Rogero et al 2004).

Numerous studies have now been conducted using glutamine dipeptides in TPN and have shown benefit in preventing deterioration of gut permeability and preserving mucosal structure (Hall et al 1996, Jiang et al 1999, PDRHealth 2006a, van der Hulst et al 1993). In addition, animal studies suggest that glutamine-enriched TPN may attenuate the suppression of CYP3A and CYP2C usually associated with TPN (Shaw et al 2002).

In a meta-analysis of European and Asian randomised controlled trials (RCTs) in elective surgery patients, 13 studies (pooled n = 355) met inclusion criteria and demonstrated a significant reduction in infectious complication and length of hospital stay (weighted mean difference (WMD) of 3.86 days) (Jiang et al 2004). Conversely, a small study using glutamine (10 g) as part of home parenteral nutrition (HPN) for 6 months did not reveal any significant effects compared to placebo for infective complications (36% versus 55%; P = 0.67), nutritional status, intestinal permeability or quality of life. It should be noted that plasma glutamine concentrations were also not affected in this study (Culkin et al 2008).

Burns

Acute burn injury results in depletion of plasma and muscle glutamine, which contributes to muscle wasting, weight loss and infection. In critical illness, supplementation has been shown to minimise these effects and reduce the rate of mortality and length of stay (Windle 2006). In a double-blind controlled trial, 48 severely burned patients (total burn surface area 30–75%, full thickness burn area 20–58%) were randomised into treatment (n = 25; 0.5 g/kg/day glutamine granules for 14 days with oral or tube feeding) or control group (n = 23; glycine placebo). The results indicated that significantly reduced plasma glutamine and damaged immunological function occurred and supplementation with glutamine granules increased plasma glutamine concentration and reduced the degree of immunosuppression. Glutamine improved immunological function (especially cellular immunity), wound healing and length of hospital stay (46.59 ± 12.98 days versus 55.68 ± 17.36 days, $P < 0.05$) (Peng et al 2006).

According to animal studies, oral glutamine supplementation may reduce bacterial and endotoxin translocation after burns by maintaining secretory IgA in the intestinal mucosa (Yu et al 1996). Systematic reviews and practice guidelines generally support glutamine supplementation in critical illness; however, in large or severe burns or inhalation injury there may be a prolonged critical illness phase (>4 weeks). Further research focussing on enteral and parenteral glutamine supplementation and long-term use is required (Windle 2006).

Infants

Enteral and parenteral glutamine supplementation in preterm infants has been shown to have some beneficial effects on neonatal morbidity and mortality; however, these results are controversial (Korkmaz et al 2007). A Cochrane review, which captured studies published prior to mid-2007, assessed seven randomised controlled trials involving 2365 preterm infants and reported that available data from good quality randomised controlled trials indicates that glutamine supplementation does not confer benefits for preterm infants (Tubman et al 2008).

In a recent trial, which was not included in the review, preterm infants (birth weight ≤ 1500 g) received either enteral glutamine supplementation (n = 36; 300 mg/kg/day adjusted over time according to the current weight) or placebo (n = 33) between 8 and 120 days of life. At the end of the fourth month, the glutamine-supplemented group had significantly higher mean weight, length, head circumference, left upper mid-arm circumference (MAC) and left mid-thigh circumference (MTC) than the control group. The effects appeared to occur in a time-dependent pattern (Korkmaz et al 2007). Another study not captured in the Cochrane review reported that oral supplementation (0.25 mg/kg BW) with glutamine did not improve growth or intestinal permeability [lactulose:mannitol ratio: 0.29 (95% confidence interval (CI): 0.23, 0.35) and 0.26 (95% CI: 0.21, 0.32)] in malnourished Gambian infants (Williams et al 2007). It should be noted, however, that this dose is exceptionally low compared to other trials. The dose, route of administration and length of supplementation require further elucidation in larger scale trials before full assessment can be made.

Experimental data has suggested that by stimulating the rate of recovery of the villi and lipid synthesising enzymes, L-Gln treatments could improve the efficacy of enteral feeding in infants recovering from bowel damage (Ahdieh et al 1998). However, a Cochrane review concluded that there was insufficient data available from randomised controlled trials to determine whether glutamine supplementation confers clinically significant benefits for infants with severe gastrointestinal disease (Grover et al 2007).

Some authors have suggested that early glutamine supplementation may also provide longer term benefits. Enteral glutamine supplementation (300 mg/kg/day) between 3 and 30 days of life has been shown to lower the incidence of atopic dermatitis (OR, 0.13; 95% CI, 0.02–0.97) but not the incidence of bronchial hyperreactivity and infectious diseases (upper respiratory, lower respiratory and gastrointestinal) during the first year of life (van den Berg et al 2007). Longer term benefits for neurodevelopment in such infants have also not been confirmed (van Zwol et al 2008).

Strenuous exercise

Following strenuous exercise, glutamine levels are depleted approximately 20% resulting in immunodepression (Castell 2003, Castell & Newsholme 1997, Rogero et al 2002). The type of training is important to note, however, as although previous reports suggest decreased glutamine concentrations in overtrained athletes, progressive endurance training may lead to steady increases in plasma glutamine levels (Kargotich et al 2007).

The provision of glutamine after exercise has been shown to improve immune status (Castell & Newsholme 1997). In a study of 200 elite runners and rowers given a glutamine or placebo drink immediately after and again 2 hours after strenuous exercise, 151 participants returned questionnaires reporting the incidence of infection over the subsequent 7 days. The percentage of athletes reporting no infections was considerably higher in the glutamine group (81%, n = 72) compared to the placebo group (49%, n = 79, $P < 0.001$) (Castell et al 1996).

During recovery from strenuous exercise, rates of lymphocyte apoptosis, hyperammonaemia and whole-body proteolysis may be affected by glutamine supplementation. In a small study of nine triathletes, glutamine supplementation (4 tablets of 700 mg of hydrolysed whey protein enriched with 175 mg of glutamine dipeptide dissolved in 250 mL water) partially prevented lymphocyte apoptosis induced by exhaustive exercise, possibly by a protective effect on mitochondrial function (Cury-Boaventura et al 2008). Both intermittent and continuous intensity exercises increase ammonia, urate, urea and creatinine in the bloodstream. Chronic glutamine supplementation (100 mg/kg BW) given

immediately before exercise may partially protect against elevated ammonia but not urate, urea or creatinine (Bassini-Cameron et al 2008). The addition of glutamine (300 mg/kg BW) to an oral carbohydrate (1 g/kg/h) and essential amino acid (9.25 g) solution had no effect on post-exercise muscle glycogen resynthesis or muscle protein synthesis, but may suppress a rise in whole-body proteolysis during the later stages of recovery (Wilkinson et al 2006).

Conversely, a trial assessing the possible ergogenic effects of glutamine supplementation (300 mg/kg BW) to improve high-intensity exercise performance in trained males was unable to determine a beneficial effect (Haub et al 1998). Currently, the use of glutamine to enhance exercise performance is speculative at best and the cost of the high doses indicated must be considered. Further large-scale research is required to elucidate any potentially beneficial effects.

Gut repair

Preliminary research on enteral (as well as parenteral) glutamine supplementation suggested promise for the use of glutamine in gut repair by: (i) protecting the intestinal mucosa from damage and promoting repair, thus improving intestinal permeability and reducing subsequent microbial and endotoxin translocation, promoting glutathione and S-IgA, and (ii) improving gut immunity. However, while there is some evidence for the use of glutamine in TPN (Hall et al 1996), clinical evidence using oral supplementation is less convincing. As in vitro data suggests that the colonic mucosa receives its nutrients preferentially from the luminal (not vascular) side (Roediger 1986), it has been suggested that glutamine should be more effective when delivered by the enteral route (Kouznetsova et al 1999). This has yet to be determined in clinical trials.

L-Glutamine enemas, twice daily for 7 days, have been shown to reduce mucosal damage and inflammation in experimental models of colitis in rats (Kaya et al 1999); however, preliminary trials in humans using parenteral glutamine (da Gama Torres et al 2008) and oral supplementation in malnourished preterm infants (Williams et al 2007) have not confirmed benefits for intestinal permeability.

Postoperative administration of TPN supplemented with a combination of glutamine and recombinant human growth hormone (rhGH) in patients following portal hypertension surgery prevented intestinal mucous membrane atrophy and preserved intestinal integrity, although the role of glutamine is unclear (Tang et al 2007). In a 1998 randomised, double-blind, placebo-controlled, 4-week trial of 24 HIV patients with abnormal intestinal permeability using 0, 4 or 8 g/day of glutamine, the authors reported a dose-dependent trend towards improved intestinal permeability and enhanced intestinal absorption with glutamine supplementation and recommended further studies to be carried out with higher doses (e.g. 20 g/day) over a longer study period (Noyer et al 1998). It is difficult to extrapolate the findings of this study to the wider community for the purpose of gut repair as there are factors involved in HIV/AIDS that may increase the biological demand for glutamine. Longer term studies may provide more convincing results; however, it is possible that glutamine only stabilises gut barrier function under certain conditions and more research is required to elucidate these.

Crohn's disease

A 4-week study on 18 children with active Crohn's disease fed a glutamine-enriched polymeric diet (Akobeng et al 2000) was unable to demonstrate benefits. A Cochrane review is currently underway to evaluate the effectiveness of glutamine supplementation for induction of remission in Crohn's disease (Srinivasan & Akobeng 2008).

HIV

L-Glutamine has been shown to improve glutathione levels and significantly increase lean body mass in HIV patients (Patrick 2000); however, not all studies confirm this latter effect (Huffman & Walgren 2003). Combined therapy with arginine and the leucine metabolite beta-hydroxy-beta-methylbutyrate has been shown to reverse lean tissue loss in HIV and cancer patients (Rathmacher et al 2004).

During initial HIV infection, the rapid turnover and proliferation of immune cells increase glutamine requirements and later the repeated episodes of infection, fever and diarrhoea may lead to further depletion. As a result, the doses used in the trial mentioned above (4 g and 8 g) may have been insufficient to meet the increased requirement in such patients (Noyer et al 1998).

Highly active antiretroviral therapy may be associated with diarrhoea and other gastrointestinal side effects. In a prospective, randomised, double-blind crossover study, HIV-infected patients with nelfinavir-associated diarrhoea (for >1 month) received L-Gln (30 g/day) or placebo for 10 days. Glutamine supplementation resulted in a significant reduction in the severity of nelfinavir-associated diarrhoea (Huffman & Walgren 2003). A prospective 12-week trial of 35 HIV-positive men experiencing diarrhoea as a result of nelfinavir or lopinavir/ritonavir therapy was also conducted using probiotics and soluble fibre. When glutamine (30 g/day) was added to the regimen of non-responders at week 4, the response rate improved (Heiser et al 2004).

Cancer prevention

In addition to being the major fuel source for rapidly proliferating intestinal and immune cells, L-Gln is also the main fuel source for many rapidly growing tumours and as a result, tumour growth is associated with a depletion in glutamine and glutathione stores and a depression of NK cell activity (Fahr et al 1994, Miller 1999). The increased intestinal permeability, immune suppression and oxidative damage that may result may further compromise the body's ability to deal with the tumour. While concerns exist, and are supported by in vitro evidence, that glutamine supplementation may feed the tumour, animal studies suggest that glutamine supplementation may assist in decreasing tumour growth by enhancing NK cell activity (Fahr et al

Clinical note — Cancer therapy
Side effects of chemotherapy and radiation therapy can significantly affect the quality of life (QOL) of patients undergoing treatment for cancer. A number of trials have demonstrated the benefits of glutamine supplementation for improving side effects such as oral pain and inflammation, increased gut permeability and reduced lymphocyte count.

1994, Miller 1999). Animal studies have demonstrated that glutamine supplementation prevents the promotion of tumour cells in an implantable breast cancer model (Kaufmann et al 2003). The exact effects in different human tumour cell lines require further elucidation.

Gastrointestinal effects

Adding glutamine to chemotherapy appears to reduce the incidence and severity of oral mucositis, a frequent complication of mucotoxic cancer therapy, which causes significant oral pain, increased infection risk and impaired functioning (Peterson et al 2007). For instance, oral glutamine (30 g/day) appears to reduce the incidence of fluorouracil/leucovorin (FU/LV)-induced mucositis/stomatitis (9% versus 38% in the control group; $P < 0.001$) (Choi et al 2007). Reduced oral pain and inflammation have also been observed in patients receiving radiation and chemotherapy during bone marrow transplantation taking oral glutamine (1 g four times daily) (Miller 1999). In a retrospective study involving 41 patients with stage III lung carcinoma treated with thoracic irradiation, prophylactic supplementation with powdered glutamine (10 g/8 hours) was found to be associated with a 27% lower incidence of grade 2 or 3 acute radiation-induced oesophagitis (ARIE), a 6-day delay in ARIE (22 days versus 16 days), and weight gain during radiotherapy (Topkan et al 2008). In another study, L-Gln (4 g twice daily, swish and swallow) was given to 12 patients receiving doxorubicin, one receiving etoposide, and one receiving ifosfamide, etoposide and carboplatinum from day 1 of chemotherapy for 28 days or for 4 days past the resolution of any post-chemotherapy mucositis. Oral supplementation with glutamine significantly decreased the severity of chemotherapy-induced stomatitis (Skubitz & Anderson 1996). In a small study, parenteral glutamine supplementation was shown to protect the gastrointestinal mucosa against fluorouracil/calcium-folinate (CF) chemotherapy-induced damage (Decker-Baumann et al 1999). Yoshida et al (1998, 2001) have also shown that 30 g/day L-Gln for 28 days attenuates the increased gut permeability and reduced lymphocyte count observed in patients undergoing cisplatin and fluorouracil therapy for oesophageal cancer.

In a small Phase I trial ($n = 15$), glutamine was co-administered in an attempt to escalate the dose of a chemoradiotherapy regimen (weekly paclitaxel and carboplatin with concurrent radiation therapy). The addition was deemed unsuccessful due to multiple severe toxicities including haematological toxicities and oesophagitis (Jazieh et al 2007). The role of glutamine in reducing taxane-associated dysgeusia (taste alteration) appears limited (Strasser et al 2008).

In a double-blind, placebo-controlled, randomised trial, oral glutamine (18 g/day) or placebo was given to 70 chemotherapy naive patients with colorectal cancer 5 days prior to their first cycle of fluorouracil (450 mg/m^2) in association with folinic acid (FA) (100 mg/m^2), which was administered intravenously for 5 days. Glutamine treatment was continued for 15 days and was shown to reduce the negative effects on intestinal absorption and permeability induced by the chemotherapy and to potentially reduce diarrhoea (Daniele et al 2001). L-Glutamine may also reverse the decrease in goblet cells induced by fluorouracil (Tanaka & Takeuchi 2002). A Cochrane review is currently underway to assess whether glutamine supplementation decreases complications in patients with colorectal cancer, and whether glutamine supplementation decreases the length of hospital stay and thereby the costs of treatment (Lemos et al 2008).

Chemotherapy-induced peripheral neuropathy (CIPN)

CIPN is a significant adverse effect associated with neurotoxic chemotherapy (especially taxanes, platinum compounds and vinca alkaloids). In a recent review, two studies were identified that suggested beneficial effects. In one study, oral glutamine was found to be effective in reducing peripheral neuropathy associated with high-dose paclitaxel resulting in a reduction in numbness, dysaesthesias and motor weakness, as well as a smaller loss of vibratory sensation (Amara 2008). Another study found that the addition of oral glutamine (15 g twice daily for seven consecutive days every 2 weeks starting on the day of oxaliplatin infusion) resulted in a significant reduction in the incidence and severity of peripheral neuropathy, less interference with activities of daily living (16.7% versus 40.9%), and less need for oxaliplatin dose reduction due to adverse effects (7.1% versus 27.3%). The addition of Gln did not affect response to chemotherapy or survival (Wang et al 2007).

Other benefits

In one report, L-Gln (10 g three times daily), given 24 h after receiving paclitaxel, appeared to prevent the development of myalgia and arthralgia associated with treatment (PDRHealth 2006a). In children with solid tumours receiving chemotherapy, oral glutamine supplementation (4 g/m^2/day) may improve nutritional and immunological parameters and reduce requirements for antibiotics (Okur et al 2006). Glutamine may also increase tumour methotrexate concentration and tumoricidal activity and reduce side effects and mortality rates (Miller 1999, PDRHealth 2006a).

OTHER USES

Alcoholism

Preliminary studies suggested a potential for glutamine to reduce alcohol cravings; however, these effects have not yet been studied in controlled trials

on humans (PDRHealth 2006a). More recently, in vitro research has suggested that glutamine supplementation may inhibit the deleterious effects of alcohol on the tight junctions of the gut mucosa and in turn reduce the increased risk for gastrointestinal cancers in alcoholics (Basuroy et al 2005, Seth et al 2004).

Acute pancreatitis

The enteral administration of L-Gln (15 mg/kg/day) to rats with acute pancreatitis resulted in a reduction in necrosis and infectious complications by decreasing the bacterial translocation rate (Avsar et al 2001).

Sickle cell disease

Orally administered L-Gln improves the nicotinamide adenosine dinucleotide (NAD) redox potential of sickle red blood cells (RBC). Investigations of blood samples taken from five adult patients with sickle cell anaemia who had been on L-Gln (30 g/day) therapy for at least 4 weeks consistently resulted in improvement of sickle RBC adhesion to human umbilical vein endothelial cells compared to the control group. The authors conclude that these results suggest positive physiological effects for L-Gln in sickle cell disease (Niihara et al 2005).

Other conditions

Glutamine is a popular supplement in naturopathic practice and sometimes used for conditions that may be associated with compromised intestinal permeability such as food allergies, leaky gut syndrome and malabsorption syndromes, including diarrhoea. It may also be used for conditions such as dermatitis and general fatigue, based on the theory that compromised intestinal permeability provides the opportunity for undigested food particles (especially proteins) to enter the systemic circulation and gives rise to an unwanted immune response that manifests as a skin reaction or as lethargy.

DOSAGE RANGE

Naturally occurring food proteins contain 4–8% of their amino acid residues as glutamine and so the daily consumption is usually less than 10 g/day (Hall et al 1996).

Supplemental L-Gln is available for oral and enteral use (in capsules, tablets and powder form) and in a dipeptide form for parenteral use.

While solubility and stability are primarily factors for TPN solutions, several factors should also be considered when using oral supplements, as powder forms are often mixed into a solution to enable easy administration of higher doses: 1 g of L-Gln dissolves in 20.8 mL of water at 30°C (PDRHealth 2006a) and is stable for up to 22 days if stored at 4°C (Hornsby-Lewis et al 1994). Ideally, powdered formulas should be consumed immediately after mixing.

- Gut repair: 7–21 g taken orally as a single dose or in divided doses.
- Cancer therapy: 2–4 g twice daily swished in the mouth and swallowed (up to 30 g have been used in trials and given orally in divided doses).
- Critical illness: 5 g/500 mL of enteral feeding solution.
- HIV: 30 g/day taken orally as a single dose or in divided doses.
- Infection: 12–30.5 g in an enteral feeding solution.
- Infants: 300 mg/kg/day added to breast milk or to preterm formula.

ADVERSE REACTIONS

Toxicity studies in rats fed up to 5% of their diet in L-Gln showed no toxic events (Tsubuku et al 2004) and glutamine dose–response studies have demonstrated 'good tolerance without untoward clinical or biochemical effects' (Ziegler et al 1999). Based on the available published human clinical trial data, glutamine intakes up to 14 g/day appear to be safe in normal healthy adults. Higher levels have been tested without adverse effects and may be safe; however, the data for intakes above 14 g is not sufficient for a confident conclusion of long-term safety (Shao & Hathcock 2008).

Most adverse reactions are mild and uncommon; they include gastrointestinal complaints such as constipation and bloating (PDRHealth 2006a). No evidence of harm has been observed in the studies conducted to date (Wischmeyer 2003).

A report exists of mania in two hypomanic patients after self-medication with up to 4 g/day glutamine (Membane 1984). As glutamine is a precursor of GABA, this may provide a possible explanation.

Two cases of a transient increase in liver enzyme levels have also been reported (Hornsby-Lewis et al 1994).

SIGNIFICANT INTERACTIONS

Radiation and chemotherapy

Benefits have been observed for the use of L-Gln during radiation and chemotherapy (see 'Clinical note — Cancer therapy').

Indomethacin/NSAIDs

Concomitant use of L-Gln (7 g three times daily) and indomethacin may ameliorate the increased intestinal permeability caused by indomethacin. The inclusion of misoprostol may also have a synergistic effect with this combination (Hond et al 1999, PDRHealth 2006a, Tanaka & Takeuchi 2002) — beneficial interaction possible.

Human growth hormone

In patients with severe short bowel syndrome, concomitant use of L-Gln and human growth hormone may enhance nutrient absorption (PDRHealth 2006a).

CONTRAINDICATIONS AND PRECAUTIONS

It is contraindicated in patients with hypersensitivity to glutamine or hepatic disease or any condition where there is a risk of accumulation of nitrogenous wastes in the blood, thus increasing the risk of ammonia-induced encephalopathy and coma.

It should only be used in people with chronic renal failure under professional supervision.

PREGNANCY USE

Safety in pregnancy has not been established; however, doses in line with normal dietary intake (approximately 10 g/day) are unlikely to be cause for concern.

PATIENTS' FAQs

What will this supplement do for me?

L-Glutamine is an amino acid that is used by the immune systems and intestinal cells as a fuel source. People with critical illnesses, stress, burns, injury or having undergone surgery or undertaking strenuous physical exercise require an increased intake to restore glutamine levels to normal and avoid loss of muscle mass and compromised immune function. It also promotes gastrointestinal repair and may improve tolerance to some anticancer treatments.

When will it start to work?

This will depend on the indication for which it is being used.

Are there any safety issues?

Glutamine appears to be a safe supplement; however, it should not be used by people who are hypersensitive to this compound, those with liver disease or any condition where there is a risk of accumulation of nitrogenous wastes in the blood (e.g. Reyes syndrome).

It should be used only by people with chronic renal failure under professional supervision.

Goji

HISTORICAL NOTE For thousands of years in traditional Chinese medicine, the fruit of the lycium shrub has been used as both a food and an important medicinal substance. In fact, the earliest known Chinese medicinal monograph documented medicinal use of *L. barbarum* around 2300 years ago. According to this tradition, it is believed that the fruit has anti-ageing properties, nourishes the kidneys and liver by tonifying yin deficiency and brightens the eyes. It also has a long history of use as a traditional remedy for male infertility and is included in most fertility-promoting Chinese herbal remedies (Luo et al 2006). In China it is known by several names such as Gou Qi Zi or Gouqizi which probably led to the name it is known as here, goji.

COMMON NAME
Goji

OTHER NAMES
Gou Qi Zi, Gouqizi, Fructus Lycii, Kei Tze, Wolfberry

SCIENTIFIC NAME
Lycium barbarum (Solanaceae family)

PLANT PART USED
Fruit

Goji berry is a deep-red, dried fruit about the same size as a raisin, but with a different taste. The berries have a slight chewy consistency and taste like a mixture of cherries and cranberries without the sweetness of raisins.

CHEMICAL COMPONENTS
The reddish orange colour of the fruit is derived from a group of carotenoids, which make up only 0.03–0.5% of the dried fruit. The predominant carotenoid is zeaxanthin, which comprises about one-third to one-half of the total carotenoids present (Inbaraj et al 2008). The fruit also contains various small molecules, such as betaine, cerebroside, beta-sitosterol, p-coumaric acid, various vitamins (e.g. B1, B2, vitamin C), and minerals (e.g. iron, selenium, zinc). Among these chemical constituents, the most valuable and pharmacologically active components are a group of unique, water-soluble glycoconjugates — collectively termed *Lycium barbarum* polysaccharides (LBPs) — that are estimated to comprise 5–8% of the dried fruit (Amagase et al 2009).

MAIN ACTIONS

Antioxidant
LBPs have a high in vitro antioxidant score (Amagase et al 2009). Goji stimulates endogenous antioxidant mechanisms and has been shown to significantly increase superoxide dismutase (SOD) and glutathione peroxidase (GSH-Px), and reduce lipid peroxidation (indicated by decreased levels of malondialdehyde, MDA) in humans (Amagase et al 2009). A study of streptozocin-induced diabetic animals found that LBP can restore abnormal oxidative indices to near normal levels (Li 2007).

The zeaxanthin component found in whole goji berries is bioavailable in humans (Cheng et al 2005) and is likely to contribute the fruit's in vivo antioxidant effects. Bioavailability of zeaxanthin from freeze-dried wolfberries can be greatly enhanced when consumed in hot skimmed milk compared to hot water or warm milk (Benzie et al 2006).

Antidiabetic
A study by Zhao et al demonstrated that diabetic animals treated with LBP for 3 weeks resulted in a significant decrease in the concentration of plasma triglyceride and weight in non insulin dependent diabetes mellitus (NIDDM) rats. Furthermore, LBP markedly decreased the plasma cholesterol levels, fasting plasma insulin levels and postprandial glucose levels at 30 min during oral glucose tolerance test and significantly increased the Insulin Sensitive Index in NIDDM rats (Zhao et al 2005b). The fruit extract of goji has also shown hypoglycaemic and lipid-lowering activities in diabetic animals whilst not affecting healthy animals (Luo et al 2004). It

appears that the polysaccharides and vitamin antioxidants are responsible for these particular effects.

Neuroprotective

Goji berry extract and LBP display neuroprotective activity in several different experimental models.

An aqueous extract isolated from *L. barbarum* exhibited significant protection on cultured neurons against harmful chemical toxins (A beta and dithiothreitol) by reducing the activity of both caspase-3 and -2, but not caspase-8 and -9 (Yu et al 2007). A new arabinogalactan-protein (LBP-III) was isolated from LBP, which appeared to have the strongest effect.

LBP demonstrates neuroprotective effects in the retina in several experimental models of glaucoma (Chan et al 2007, Chang & So 2008, Yu et al 2007). The polysaccharide-containing extract (LBP) from *L. barbarum* exhibited neuroprotective effects in the retina against ocular hypertension in a laser-induced glaucoma animal model (Yu et al 2007). Chang and So confirmed that LBP protects retinal ganglion cells in vivo (Chang & So 2008).

LBP protects neurons against beta-amyloid peptide toxicity in neuronal cell cultures (Chang & So 2008).

Reduces chemotherapy- and radiotherapy-induced toxicity

LBP elicited a typical cardioprotective effect on doxorubicin (DOX)-related oxidative stress in an experimental model (Xin et al 2007). Furthermore, in vitro cytotoxic study showed the antitumour activity of DOX was not compromised by LBP.

Interestingly, another animal study identified that LBP promotes the peripheral blood recovery of irradiation or chemotherapy-induced myelosuppressive mice (Gong et al 2005). Compared to controls, 50 mg/kg LBP significantly ameliorated the decrease of peripheral white blood cells and peripheral red cells in irradiated myelosuppressive mice. Higher doses significantly enhanced peripheral platelet counts.

Immune modulation

LBPs have been known to have a variety of immunomodulatory functions including activation of T cells, B cells and NK cells (Chen et al 2008, Zhu et al 2007).

A polysaccharide–protein complex isolated from *L. barbarum* (LBP) activated macrophages in vivo (Chen et al 2009). The mechanism may be through activation of transcription factors NF-kappaB and AP-1 to induce TNF-alpha production and up-regulation of major histocompatibility complex (MHC) class II co-stimulatory molecules. LBP also activates T cells.

Sexual behaviour and male reproductive function

Studies with experimental models suggest the polysaccharides in goji berries may improve sexual behaviour and reproductive function (Luo et al 2006). LBP improved the copulatory performance and reproductive function of hemicastrated male rats, such as shortened penis erection latency and mount latency, regulated secretion of sexual hormones and increased hormone levels, raised accessory sexual organ weights, and improved sperm quantity and quality (Luo et al 2006).

Studies with LBP indicate a protective effect on testicular cells against a variety of insults. Luo et al (2006) demonstrated a dose-dependent protective effect for LBP against DNA oxidative damage of mouse testicular cells in vivo. LBP also inhibits time- and hyperthermia-induced structural damage in murine seminiferous epithelium, in vitro (Wang et al 2002). Moreover, LBP delays apoptosis in this system, both at normothermic and hyperthermic culture conditions. Considering the oxidative stress is suspected to be a major cause of structural degradation and apoptosis in hyperthermic testes, the protective effect of LBP may be mediated by an antioxidant mechanism of action.

OTHER ACTIONS

One of *L. barbarum* glycoconjugates promoted the survival of human fibroblasts cultured in suboptimal conditions and demonstrated important skin-protective properties (Zhao et al 2005a).

CLINICAL USE

Goji has become more popular for the last few years due to its public acceptance as a 'super food' with highly advantageous nutritive and antioxidant properties. It is touted as being able to improve wellbeing and protect against cancer and other serious diseases. Most investigation with goji has been conducted in China and there is little clinical research information available in English language journals.

Improved wellbeing

A randomised, double-blind, placebo-controlled clinical trial examined the general effects of orally consumed goji berry, *L. barbarum*, as a standardised juice (GoChi; FreeLife International LLC, Phoenix, AZ) to healthy adults for 14 days (Amagase & Nance 2008). The study was designed to measure multiple outcomes based on the traditionally understood properties of the product. Comparisons between day 1 and day 15 revealed that goji treatment significantly increased ratings for energy level, athletic performance, quality of sleep, ease of awakening, ability to focus on activities, mental acuity, calmness, and subjective feelings of general wellbeing. Furthermore, goji significantly reduced fatigue and stress, and improved regularity of gastrointestinal function. In contrast, the placebo group ($n = 18$) showed only two significant changes, heartburn and elevated mood.

Aphrodisiac and increased male fertility

Traditional evidence and animal studies provide some support for its use; however, well-controlled clinical studies are not available to determine the effectiveness of goji in this capacity.

OTHER USES

Goji is broadly marketed as a 'super food' with significant health-promoting qualities. The high concentration of antioxidants, vitamins and minerals in

the fruit makes it a nutritious substance; however, claims that it cures major diseases are not founded on sound clinical evidence.

The high concentration of zeaxanthin in the berries makes it a good dietary source of this carotenoid. As such, indications which respond to increased zeaxanthin intake may also respond to an equivalent dose from goji berries. (See Lutein/zeaxanthin monograph for further information.)

DOSAGE RANGE

Daily dose: 6–15 g daily.

ADVERSE REACTIONS

Not known.

SIGNIFICANT INTERACTIONS

Warfarin

Two case reports exist in the literature, suggesting an interaction between warfarin and goji is possible. One case was of an 80-year-old Chinese woman on a chronic stable dose of warfarin, who experienced two episodes of an elevated international normalised ratio (INR) after drinking herbal tea containing goji (Leung et al 2008). Another case describes a 61-year-old Chinese woman, previously stabilised on anticoagulation therapy (INR 2–3) who had an elevated INR of 4.1 as a result of drinking a concentrated Chinese herbal tea made from *L. barbarum* L. fruits (3–4 glasses daily). No changes in her other medications, lifestyle or dietary habits were revealed (Lam et al 2001). Until confirmation from controlled trials is available, caution is advised.

CONTRAINDICATIONS AND PRECAUTIONS

None known.

PREGNANCY USE/PATIENT COUNSELLING

The fruit is likely to be safe when taken in typical dietary doses; however, the safety of higher doses is unknown.

PATIENTS' FAQs

What will this herb do for me?

Goji fruits are a nutritious source of vitamins, minerals and antioxidants. Preliminary tests show that it has multiple health-promoting effects, but little human research is available to confirm activity.

When will it start to work?

As a concentrated source of nutrients, general benefits will start within several days.

Are there any safety issues?

Two case reports suggest a possible interaction between warfarin and goji berry, but this remains to be confirmed.

PRACTICE POINTS/PATIENT COUNSELLING

- Goji berries are a nutritious source of antioxidants, vitamins and minerals.
- The LBPs in the fruit that are considered to be the most important for pharmacological activity are attracting research interest.
- Preliminary studies in test tubes and with animal models indicate the berry and/or polysaccharides enhance immune function, exert neuroprotective effects, reduce lipid and blood glucose levels in diabetic models and improve male fertility; however, human tests are not available to determine whether these effects are significant in humans.
- Use with caution in people taking warfarin.

Goldenrod

HISTORICAL NOTE Goldenrod has been used therapeutically for centuries for bladder conditions and wound healing. The name *Solidago* is from the Latin verb 'to make whole'. In 1934, reports from the US Department of Agriculture suggested that goldenrod was considered as a potential future source of commercially prepared rubber, although it was noted that domestication of the plant would be difficult as it is vulnerable to fungal infection and insect attack.

COMMON NAME
Goldenrod

OTHER NAMES
Aaron's rod, blue mountain tea, sweet goldenrod, woundwort

BOTANICAL NAME/FAMILY
Solidago canadensis (Canadian goldenrod), *Solidago virgaurea* (European goldenrod) (family Asteraceae [Compositae]). There are numerous species of goldenrod.

PLANT PARTS USED
Dried aerial parts — flowers and leaves.

CHEMICAL COMPONENTS
Flavonoids, including rutin, catechol tannins, triterpene saponins, phenol glycosides, phenolic acids, one essential oil, diterpene lactones and polysaccharides.

MAIN ACTIONS
The pharmacology of goldenrod has not been significantly investigated; therefore, evidence of activity derives from traditional, in vitro and animal studies.

Diuretic
Goldenrod is considered an aquaretic medicine, as it promotes fluid loss without an associated disruption to electrolytes. Two animal studies have confirmed diuretic activity (Chodera et al 1991, Leuschner 1995). According to one study, excretion of calcium increases whereas excretion of potassium and sodium decreases (Chodera et al 1991). A review of herbal medicines for the urinary tract concluded that goldenrod is a major diuretic herb (Yarnell 2002).

Antispasmodic and anti-inflammatory
High doses of a commercial preparation of *S. gigantea* extract have demonstrated anti-inflammatory activity in an animal model, comparable to those of the pharmaceutical anti-inflammatory medicine diclofenac (Leuschner 1995). Other tests with an extract of *S. virgaurea* have also produced similar results (el Ghazaly et al 1992).

The herbal combination consisting of *Populus tremula*, *S. virgaurea* and *Fraxinus excelsior* has demonstrated dose-dependent anti-inflammatory, analgesic and antipyretic effects comparable to those of NSAIDs in several animal models (Okpanyi et al 1989). Although encouraging, the role of *Solidago* in this study is uncertain.

OTHER ACTIONS
Traditionally believed to have an effect on the micro-architecture of the kidney.

Antifungal
Inhibitory effects on human pathogenic yeasts such as *Candida* and *Cryptococcus* spp have been demonstrated for triterpenoid glycosides isolated from *S. virgaurea* (Bader et al 1990).

Antibacterial
A moderate antibacterial activity in vitro against certain strains of bacteria, including species of *Bacillus*, *Proteus* and *Staphylococcus* has been demonstrated from an extract of *S. virgaurea* (Thiem & Goslinska 2002).

Anticancer effects
An extract of *S. virgaurea* has demonstrated antineoplastic activity in vitro using a variety of cell lines, including prostate, breast, small cell lung carcinoma and melanoma, and in vivo in a mouse model of prostate cancer (Gross et al 2002).

CLINICAL USE
Goldenrod has not been significantly investigated under controlled study conditions, so most evidence is derived from traditional use, in vitro and animal studies.

Cystitis
The most common use of goldenrod is in the treatment of bladder infections. Both the Commission E (Blumenthal et al 1998) and ESCOP (2003) have approved its use for irrigation of the urinary tract, with ESCOP also indicating usefulness as adjunctive treatment for bacterial urinary tract infections (UTIs).

Arthritis (in combination)
The product Phytodolor contains alcoholic extracts of *Populus tremula*, *Fraxinus excelsior* and *S. virgaurea* and is standardised to 0.14 mg/mL of isofraxidine, 1 mg/mL salicine and 0.07 mg/mL of total flavonoids. As part of this combination, goldenrod has been investigated in patients with rheumatoid arthritis (RA), osteoarthritis and back pain. Pain was significantly reduced by treatment with Phytodolor in a placebo-controlled study of 47 patients (Weiner & Ernst 2004). Symptom relief was equally effective amongst patients receiving half-strength, normal (60 drops three times daily) or double-strength treatment. A shorter placebo-controlled study of 2 weeks duration found that Phytodolor reduced the

need for conventional drug doses in subjects with 'at least one rheumatological diagnosis' (Weiner & Ernst 2004). Similarly, Phytodolor reduced requirements of diclofenac compared to placebo in a smaller study of 30 patients (Weiner & Ernst 2004). A 2-week placebo-controlled study of 30 subjects with osteoarthritis demonstrated that treatment with Phytodolor significantly reduced pain and improved grip strength (Weiner & Ernst 2004). A recent review found that Phytodolor may be a suitable alternative to NSAIDs and COX2 inhibitors for the treatment of rheumatic disease (Gundermann & Muller 2007). The role of goldenrod in achieving these results is unclear.

Inflammation of the nasopharynx with catarrh

Goldenrod is also used to relieve symptoms in this condition. The astringent activity of the tannin components provides a theoretical basis for its use.

OTHER USES

In many countries, goldenrod is used to prevent urolithiasis and eliminate renal calculi (Skidmore-Roth 2001). It is also used in children with otitis media and nasal catarrh.

Traditional uses

Goldenrod is used both internally and externally for a variety of conditions. Internally it is used to treat upper respiratory tract catarrh, arthritis, menorrhagia and urological complaints, vomiting and dyspepsia, and externally it is used to support wound healing and as a mouth rinse for inflammatory conditions of the mouth and gums.

DOSAGE RANGE

- Infusion of dried herb: 0.5–2 g in 150 mL of boiled water for at least 10 minutes.
- Fluid extract (1:1) (g/mL): 0.5–2 mL taken 2–4 times daily between meals.

ADVERSE REACTIONS

Handling the plant has been associated with allergic reactions ranging from allergic rhinoconjunctivitis and asthma to urticaria. There is one study of a cohort predominantly comprising florists who had presented with complaints relating to the handling of plants which found the extensive cross-sensitisation to pollen of several members of the Asteraceae family (e.g. *Matricaria*, *Chrysanthemum* and *Solidago*) and to pollen of the Amaryllidaceae family (*Alstroemeria* and *Narcissus*) (de Jong et al 1998).

SIGNIFICANT INTERACTIONS

None known

CONTRAINDICATIONS AND PRECAUTIONS

Commission E cautions against use as irrigation therapy when heart or kidney disease is also present (Blumenthal et al 1998).

People with known allergy to goldenrod or who are allergic to the Asteraceae (Compositae) family of plants should avoid this herb.

PREGNANCY USE

From limited use in pregnant women, it appears that no increase in frequency of malformation or other harmful effects have been reported, although animal studies are lacking (Mills & Bone 2005).

PRACTICE POINTS/PATIENT COUNSELLING

- Goldenrod has a long history of use, but has not been tested in humans to any significant extent.
- Traditionally, it has been used internally to reduce upper respiratory catarrh, arthritis, menorrhagia, urological complaints and dyspepsia, and externally to promote wound healing and as a mouth rinse for inflammatory conditions of the mouth and gums.
- In Europe, goldenrod is a popular herb for treating lower UTIs and preventing kidney stones.
- When used as part of the commercial preparation, Phytodolor, it provides effective symptom relief in RA and osteoarthritis according to several clinical studies.
- It is considered an aquaretic herb, which induces diuresis but not potassium and sodium loss.
- Preliminary studies in animal models suggest anti-inflammatory activity comparable to that of NSAIDs, but human studies are not available to confirm the clinical significance of these findings.

PATIENTS' FAQs

What will this herb do for me?

Goldenrod has diuretic and anti-inflammatory activity, which may be useful in cases of bladder inflammation, although clinical testing has not yet been conducted to confirm this.

When will it start to work?

This is unknown.

Are there any safety issues?

People who are allergic to goldenrod or the Asteraceae family of plants should avoid taking this herb.

Goldenseal

HISTORICAL NOTE Goldenseal is indigenous to North America and was traditionally used by the Cherokees and then by early American pioneers. Preparations of the root and rhizome were used for gastritis, diarrhoea, vaginitis, dropsy, menstrual abnormalities, eye and mouth inflammation and general ulceration. In addition to this, the plant was used for dyeing fabric and weapons. Practitioners of the eclectic school created a high demand for goldenseal around 1847. This ensured the herb's ongoing popularity in Western herbal medicine, but unfortunately led to it being named a threatened species in 1997. Today, most high-quality goldenseal is from cultivated sources.

COMMON NAME
Goldenseal

OTHER NAMES
Eye root, jaundice root, orange root, yellow root.

BOTANICAL NAME/FAMILY
Hydrastis canadensis (family Ranunculaceae)

PLANT PARTS USED
Root and rhizome

CHEMICAL COMPONENTS
Isoquinoline alkaloids, including hydrastine (1.5–5%), berberine (0.5–6%) and canadine (tetrahydroberberine, 0.5–1.0%). Other related alkaloids include canadaline, hydrastidine, corypalmine and isohydrastidine.

MAIN ACTIONS
A wealth of empirical data exists for the medicinal use of goldenseal; however, much of the research has been conducted using the chief constituent berberine. It is recommended that goldenseal products be standardised to contain at least 8 mg/mL of berberine and 8 mg/mL of hydrastine (Bone 2003).

Antimicrobial
In vitro testing has demonstrated antibacterial activity of both the whole extract of goldenseal and the major isolated alkaloids (berberine, beta-hydrastine, canadine and canadaline) against *Staphylococcus aureus*, *Streptococcus sanguis*, *Escherichia coli* and *Pseudomonas aeruginosa* (Scazzocchio et al 2001). In a study, two flavonoids isolated from goldenseal were shown to exhibit antibacterial activity against the oral pathogens *Streptococcus mutans* and *Fusobacterium nucleatum* (Hwang et al 2003). An added antimicrobial effect against *S. mutans* was noted with the addition of berberine.

Clinical note — Isoquinoline alkaloids
Isoquinoline alkaloids are derived from phenylalanine or tyrosine and are most frequently found in the Ranunculaceae, Berberidaceae and Papaveraceae families (Pengelly 2004). This is a very large class of medicinally active compounds that include the morphinane alkaloids (morphine, thebaine and codeine), the ipecac alkaloids (emetine and cephaeline), the atropine alkaloid (boldine) and the protoberberines (berberine and hydrastine). Many other plants contain berberine, including *Berberis vulgaris* (barberry), *Mahonia aquifolium*/*Berberis aquifolium* (Oregon mountain grape), *Berberis aristata* (Indian barberry), *Coptis chinensis* (Chinese goldthread), *Coptis japonica* (Japanese goldthread) and *Thalictrum minus*.

The methanolic extract of the rhizome inhibited the growth of 15 strains of *Helicobacter pylori* in vitro (Mahady et al 2003). The authors identified berberine and beta-hydrastine as the main active constituents.

Berberine alone, and in combination with both ampicillin and oxacillin, has demonstrated strong antibacterial activity against all strains of methicillin resistant *Staphylococcus aureus* (MRSA) in vitro (Yu et al 2005); 90% inhibition was demonstrated with 64 microgram/mL or less of berberine. Berberine was also found to enhance the effectiveness of ampicillin and oxacillin against MRSA in vitro.

Many of the *Berberis* spp contain the flavonolignan 5′-methoxyhydnocarpin, which inhibits the expression of the multidrug-resistant efflux pumps (Musumeci et al 2003; Stermitz et al 2000a, 2000b); however, it is unknown whether goldenseal contains this compound.

Berberine inhibits the adherence of streptococci to host cells by aiding the release of an adhesin

lipoteichoic acid (an acid that is responsible for the adhesion of the bacteria to the host tissue) from the streptococcal cell surface (Sun et al 1998). Berberine is also able to dissolve lipoteichoic acid–fibronectin complexes once they have been formed. Berberine displays well-defined antimicrobial properties against certain bacteria and such data suggest that it may also be able to prevent adherence and destroy already-formed complexes.

Berberine may also possess antifungal and antiviral properties. Berberine was shown to destroy cell wall and sterol biosynthesis in *Candida* spp. in vitro (Park et al 1999). A study demonstrated the antiviral activity of berberine to be as effective as the DNA polymerase inhibitor ganciclovir in human cytomegalovirus (Hayashi et al 2007). It appeared to work via a different mechanism and may prove useful if used in conjunction to prevent tolerance and reduce toxicity.

Antidiarrhoeal

Berberine decreases intestinal activity by activating alpha-2-adrenoceptors and reducing cyclic adenosine monophosphate (cAMP) (Hui et al 1991). Berberine also inhibits intestinal ion secretion and inhibits toxin formation from microbes (Birdsall & Kelly 1997).

Berberine has demonstrated efficacy in vitro for many bacteria that cause infective diarrhoea, including *E. coli*, *Shigella dysenteriae*, *Salmonella paratyphi*, *Clostridium perfringens* and *Bacillus subtilis* (Mahady & Chadwick 2001). It has also demonstrated activity in vitro against parasites that cause diarrhoea, including *Entamoeba histolytica*, *Giardia lamblia* and *Trichomonas vaginalis*.

The effects of berberine on cholera toxin-induced water and electrolyte secretion were investigated in an experimental in vivo model (Swabb et al 1981). Secretions of water, sodium and chlorine were reduced 60–80 min after exposure to berberine.

Berberine did not alter ileal water or electrolyte transport in the control model. It produced a significant reduction in fluid accumulation caused by infection with *E. coli* in vivo (Khin-Maung & Nwe Nwe 1992). Oral doses of berberine before the toxin was introduced and intragastric injection after infection were both effective. Berberine was shown to inhibit by approximately 70% the secretory effects of *Vibrio cholerae* and *E. coli* in a rabbit ligated intestinal loop model (Sack & Froehlich 1982). As in the other study, the drug was effective when given either before or after enterotoxin binding. In an investigation using pig jejunum, berberine demonstrated a reduction in water and electrolyte secretion after intraluminal perfusion with *E. coli* (Zhu & Ahrens 1982).

Berberine significantly slowed small intestine transit time in an experimental in vivo model (Eaker & Sninsky 1989). Berberine inhibited myoelectric activity, which appears to be partially mediated by opioid and alpha-adrenergic receptors. The antidiarrhoeal properties of berberine may be partially due to the constituents' ability to delay small intestinal transit time.

Cardiovascular actions

Berberine may be effective for congestive heart failure and arrhythmia, as it has demonstrated positive inotropic, negative chronotropic, antiarrhythmic and vasodilator properties (Lau et al 2001).

After 8 weeks of treatment, oral doses of berberine (10 mg/kg) improved cardiac function and prevented development of left ventricular hypertrophy induced by pressure overload in rats (Hong et al 2002, 2003). Berberine was found to reduce left ventricular end-diastolic pressure, improve contraction and relaxation and decrease the amount of the atrophied heart muscle.

Berberine has also been found to increase cardiac output in dogs with left ventricular failure due to ischaemia (Huang et al 1992). Over 10 days, intravenous administration of berberine (1 mg/kg, within 3 min) followed by a constant infusion (0.2 mg/kg/min, 30 min) increased the cardiac output and decreased left ventricular end-diastolic pressure, diastolic blood pressure (DBP) and systemic vascular resistance, but did not affect heart rate. This study shows that berberine may be able to improve impaired left ventricular function by exerting positive inotropic effects and mild systemic vasodilatation. These results, although interesting, should be evaluated cautiously as the method of administration was intravenous. The hypotensive effects of the berberine derivative, 6-protoberberine (PTB-6), were studied in spontaneously hypertensive rats (Liu et al 1999). PTB-6 lowered systolic blood pressure (SBP) in a dose-dependent manner (5 mg/kg: -31.1 ± 1.6 mmHg; 10 mg/kg: -42.4 ± 3.1 mmHg). The berberine derivative also reduced cardiac output and heart rate. The authors conclude that the antihypertensive effect of PTB-6 is probably caused by a central sympatholytic effect.

Hypocholesterolaemic/anti-atherogenic

Berberine upregulates the LDL receptor (LDLR) by stabilising the LDLR mRNA (Abidi et al 2005, Kong et al 2004). A follow-up study confirmed this and went on to demonstrate that the whole root preparation of goldenseal was more effective in up-regulating liver LDLR expression and reducing plasma cholesterol and LDL cholesterol in hyperlipidaemic hamsters than the pure berberine compound (Abidi et al 2006). The authors also noted that canadine effectively upregulated LDLR expression and unlike berberine was not affected by MDR1-mediated efflux from liver cells. In another study, hamsters fed a high-fat diet for 2 weeks, followed by treatment with oral doses of berberine (100 mg/kg) for 10 days, demonstrated a 40% reduction of cholesterol, including a 42% reduction in LDL cholesterol (Kong et al 2004). No effect on HDL cholesterol was noted.

Despite these positive results, a current study found that berberine alone did not lower cholesterol but when combined with plant sterols significantly reduced both total cholesterol and non-HDL cholesterol (Jia et al in press). Rats being fed a high-sucrose, high-fat diet were given berberine (100 mg/kg), plant sterols (1% of total diet), a combination of both or a control mixture for 6 weeks. Whilst

berberine on its own made no appreciable difference, the combination reduced total cholesterol by 41% and non-HDL cholesterol by 59%. Berberine also reduced plasma triglycerides by 31%, which was of marginal statistical significance ($P = 0.054$).

Berberine may have potential as an anti-atherosclerotic agent because of a demonstrated inhibition of lysophosphatidylcholine (lysoPC)-induced DNA synthesis and cell proliferation in vascular smooth muscle cells (VSMCs) in vivo (Cho et al 2005). Berberine also inhibited the migration of lysoPC-stimulated VSMCs and the activity of extracellular signal-regulated kinases, reduced transcription factor AP-1 and intracellular reactive oxygen species. This suggests that berberine may be useful for the prevention of atherosclerosis.

Antidiabetic

A glucose-lowering effect similar to metformin was observed in vitro for berberine; however, no effect was seen on insulin secretion (Yin et al 2002).

Blood glucose, blood lipids, muscle triglycerides and insulin sensitivity were measured before and after the ingestion of berberine or metformin in rats fed a high-fat diet (Gao et al 1997). In this trial, berberine and metformin improved insulin resistance and liver glycogen levels, but had no effect on blood glucose, insulin, lipid and muscle triglyceride levels. The study was able to demonstrate that berberine was as effective as metformin for improving insulin sensitivity in the rats.

Similarly, fasting blood glucose, total cholesterol and triglyceride levels significantly decreased after 8 weeks of treatment with 187.5 or 562.5 mg/kg of berberine in an experimental model of glucose intolerance (Leng et al 2004). An additional in vitro study using insulin secreted from pancreatic cells, incubated with berberine for 12 h, concluded that berberine increased insulin production. The relationship of these trials to oral doses in humans is unknown. In another in vivo test, diabetic rats were treated with berberine (100 or 200 mg/kg) via intragastric means for 21 days (Tang et al 2006). The researchers found that berberine demonstrated hypoglycaemic, hypolipidaemic and antioxidant effects.

Berberine inhibits alpha-glucosidase and therefore reduces the transport of glucose through the intestinal epithelium (Pan et al 2003). Berberine also appears to stimulate glucose uptake through the AMP-AMPK-p38 MAPK pathway, which may be at least partly responsible for its hypoglycaemic effects (Cheng et al 2006).

Berberine may be able to attenuate the renal complications of diabetes. Streptozotocin-induced diabetic rats were fed berberine (200 mg/kg) for 12 weeks in order to examine the effects on kidney function (Liu et al 2008). The results showed significant reductions in fasting blood glucose, blood urea nitrogen, protein and creatinine over 24 h as compared to control animals.

Anti-inflammatory

Berberine inhibits cyclo-oxygenase 2 (COX-2) transcriptional activity (Fukuda et al 1999, Kuo et al 2005) and reduces prostaglandin (PG) synthesis in vitro and in vivo (Kuo et al 2004). Berberine also inhibits kappa B-alpha phosphorylation and degradation, therefore reducing certain inflammatory mediators such as induced tumour necrosis factor (TNF)-alpha and interleukin (IL)-1beta productions in human lung cells (Lee et al 2007). The compound has also been found to reduce proliferation of human lymphocytes in vitro by inhibiting DNA synthesis in activated cells (Ckless et al 1995).

Immune activity

Intragastric administration of the crude extract of goldenseal for 6 weeks increased the production of IgM in vivo (Rehman et al 1999). Berberine has also been found to induce IL-12 p40, a large subunit of IL-12, through the activation of p38 mitogen-activated protein kinase in mouse macrophages (Kang et al 2002). Interleukin-12 is crucial for the development of the Th1 immune response and thus may also have a therapeutic effect in reducing Th2 allergic disorders. A follow-up study demonstrated that pretreatment with berberine induced IL-12 production in stimulated macrophages and dendritic cells (Kim et al 2003). Macrophages pretreated with berberine had an increased ability to induce interferon (IFN)-gamma and a reduced ability to induce IL-4 in antigen-primed $CD4^+$ T-cells. Increased levels of IL-12 appear to deviate $CD4^+$ T-cells from the Th2 to the Th1 pathway. This inhibition of type 2 cytokine responses indicates that berberine may be an effective anti-allergic compound.

The immunosuppressive effects of berberine were investigated in an induced autoimmune model in vivo (Marinova et al 2000). Berberine was administered daily (10 mg/kg) for 3 days before intravenous induction of tubulo-interstitial nephritis (TIN).

Significantly less damage and an increase in renal function were demonstrated in the animals pretreated with berberine as compared to controls after 2 months. Berberine decreased CD3, CD4 and CD8 lymphocytes in comparison with the non-treated animals. These results suggest that berberine may exert an immunosuppressive effect in a TIN model. Clinical trials in human kidney autoimmune diseases are warranted.

Anticancer

Berberine has demonstrated cytotoxic activity in vitro against many strains of human cancer cells (Hwang et al 2006, Kettmann et al 2004, Kuo et al 2005, Meeran et al 2008, Piyanuch et al 2007, Serafim et al 2008, Wang et al in press). This is due in part to the reduction of COX-2 enzymes (Kuo et al 2005, Tai & Luo 2003), damage to the cytoplasmic membrane and DNA fragmentation (Letasiova et al 2005).

The antitumour effects of berberine were investigated on malignant brain tumours in an in vitro and in vivo model (Zhang et al 1990). Berberine (150 mg/mL) demonstrated an ability to kill 91% of cells in six human malignant brain tumour cell lines and 10 mg/kg exhibited an 80.9% cell-kill rate against solid brain tumours in vivo. The addition of

berberine to 1,3-bis(2-chloroethyl)-1-nitrosourea increased cytotoxicity.

Neuroprotective

An in vivo study was designed to investigate the neuroprotective effects of berberine in ischaemic brain injury (Zhou et al in press). Berberine (20 mg/kg) was intragastrically administered 30 minutes before and 1 day after middle cerebral artery occlusion (MCAO) was performed. After 48 hours, infarct size and neurological deficits were significantly reduced in the treatment group as compared to control. The authors were interested in discovering the mechanisms of action and designed a follow-up in vitro study. They found that berberine inhibited reactive oxygen species and protected PC12 cells against glucose and oxygen deprivation.

Berberine may also be effective in Alzheimer's disease according to early in vitro data (Asai et al 2007). Berberine significantly reduced extracellular amyloid-beta peptide levels by modulating amyloid precursor proteins in human neuroglioma H4 cells.

Antidepressant

Oral doses of berberine (10 and 20 mg/kg) were shown to possess antidepressant effects in both the forced swim and tail suspension tests (Peng et al 2007). It was found to be slightly weaker than the positive control desipramine, a tricyclic antidepressant. In the forced swim test, however, berberine was shown to have additive benefits when used with desipramine, fluoxetine (a selective 5-HT reuptake inhibitor) and moclobemide (a monoamine oxidase inhibitor). The authors also noted that noradrenaline and serotonin levels were increased in the frontal cortex and hippocampus of animals in the berberine group (20 mg/kg).

Another in vivo study used the same models and gave animals either 5, 10 or 20 mg/kg of berberine i.p. (Kulkarni & Dhir 2008). They also found that animals in the berberine group demonstrated a reduced immobility period. Berberine (5 mg/kg, i.p.) also improved the efficacy of subeffective doses of standard antidepressant medications in the forced swim test. The acute administration of berberine (5 mg/kg, i.p.) increased noradrenaline (31%), serotonin (47%) and dopamine (31%) in the brain. The authors add that the mechanism may at least in part involve the nitric oxide pathway and/or sigma receptors.

OTHER ACTIONS

Anticatarrhal, astringent, bitter, choleretic, depurative, mucus membrane tonic, vulnerary and oxytocic.

CLINICAL USE

Goldenseal has not been significantly investigated under clinical trial conditions, so evidence is derived from traditional, in vitro and animal studies. Many of these have been conducted on the primary alkaloids. All results are for the isolated compound berberine, and although this compound appears to have various demonstrable therapeutic effects, extrapolation of these results to crude extracts of goldenseal is premature. It should also be noted that equivalent doses of the whole extract of goldenseal are exceptionally high.

Diarrhoea

A double-blind, placebo-controlled, randomised trial examined the effect of berberine alone (100 mg four times daily) and in combination with tetracycline for acute watery diarrhoea in 400 patients (Khin-Maung et al 1985). Patients were divided into four groups and given tetracycline, tetracycline plus berberine, berberine or placebo; 185 patients tested positive for cholera and those in the tetracycline and tetracycline plus berberine groups achieved a significant reduction in diarrhoea after 16 hours and up to 24 hours. The group given berberine alone showed a significant reduction in diarrhoea volume (1 L) and a 77% reduction in cAMP in stools. Noticeably, fewer patients in the tetracycline and tetracycline plus berberine groups excreted vibrios in their stool after 24 hours and interestingly no statistically significant improvements for patients with non-cholera diarrhoea in the tetracycline or berberine group were shown. A later randomised, double-blind clinical trial compared 200 mg of berberine four times daily plus tetracycline, with tetracycline alone in 74 patients with diarrhoea resulting from *V. cholerae* (Khin-Maung et al 1987). There were no statistically significant differences between the two groups.

A randomised controlled trial (RCT) evaluated the effect of berberine sulfate in 165 men with *E. coli*- or *V. cholerae*-induced diarrhoea as compared to tetracycline (Rabbani et al 1987). Patients with *E. coli* were given a single 400 mg dose and those with *V. cholerae* were given either a single 400 mg dose or 1200 mg (400 mg every 8 hours), combined with tetracycline. Berberine reduced mean stool volumes by 48% in the *E. coli* group as compared to control over 24 hours. Patients in the *V. cholerae* group who received 400 mg of berberine as a single dose also had a reduction in stool volume after 16 hours as compared to placebo. The combination of berberine and tetracycline did not show any statistical improvement over tetracycline alone in the *V. cholerae* group.

A follow-up randomised, placebo-controlled trial was designed to evaluate the antisecretory and antimicrobial potential of various antidiarrhoeal agents including berberine in patients with active diarrhoea due to *Vibrio cholerae* or enterotoxic *E. coli* (Rabbani 1996). Berberine at a lower dose of 200 mg resulted in a reduction in stool volume of between 30% and 50% without significant side effects. Berberine was again shown to be more effective in the treatment of diarrhoea resulting from *E. coli* than in cholera.

Berberine may also be effective in the treatment of giardiasis. A comparison-controlled study of 359 children aged between 4 months and 14 years compared berberine (10 mg/kg/day) with metronidazole (20 mg/kg/day) for up to 10 days (Gupte 1975). Negative stool samples were evident in 90% of children receiving berberine after 10 days with

83% remaining negative after 1 month's duration. The results were comparative with the metronidazole (Flagyl) group (95% after 10 days and 90% after 1 month), without side effects. In a similar study, 40 children aged 1–10 years with giardiasis were given berberine (5 mg/kg/day), metronidazole (10 mg/kg/day) or placebo (vitamin B syrup) for 6 days (Choudry et al 1972). In the berberine group, 48% of children were symptom-free after 6 days and 68% had no giardia cysts on stool analysis as compared to the metronidazole group who experienced a 33% reduction in symptoms and a 100% clearance rate for cysts. These results show that berberine may be more effective than Flagyl for symptom relief, but not as effective for clearing the organism from the gastrointestinal tract. The aforementioned study (Gupte 1975) used a higher dose of berberine (10 mg/kg/day), which produced better results; however, the equivalent amount of goldenseal for either dose would be exceedingly high based on an average berberine content of 5%, which would be inappropriate.

Small intestinal transit time was evaluated in 30 healthy subjects in a controlled study (Yuan et al 1994). Transit time was significantly delayed from 71.10 ± 22.04 min to 98.25 ± 29.03 min after oral administration of 1.2 g of berberine. These results suggest that the antidiarrhoeal effect of berberine might be partially due to its ability to delay small intestinal transit time.

Eye infection

A controlled clinical trial of 51 patients with ocular trachoma infections investigated the effectiveness of berberine over 3 weeks with a 1-year follow-up (Babbar et al 1982). Subjects who used the 0.2% berberine either by itself or combined with sulfacetamide demonstrated significant symptom improvement and tested negative for *Chlamydia trachomatis*, with no relapse after 1 year.

A later comparison-controlled clinical study also evaluated the effectiveness of the topical treatment of berberine for trachoma in 32 microbiologically confirmed patients (Khosla et al 1992). A 0.2% berberine solution (2 drops in each eye, three times daily) was found to be more effective than sulfacetamide (20%) in reducing both the course of the trachoma and the serum antibody titres against *C. trachomatis*. Berberine eyedrops were compared to berberine plus neomycin ointment, sulfacetamide and placebo in a double-blind, controlled clinical trial in 96 primary school children (Mohan et al 1982). Patients in the berberine group were asked to use 2 drops (0.2% berberine) of the solution in each eye, three times daily and to additionally apply a berberine ointment (0.2%) at night for 3 months. Children treated with only the berberine had an 87% clinical response rate, compared to 58% in the berberine and neomycin group; however, only 50% tested negative in follow-up microbiological tests.

A study addressed safety concerns about berberine eye products (Chignell et al 2007). They concluded that caution should be taken when eyes are exposed to strong sunlight.

Hypercholesterolaemia

In an RCT, oral doses of 0.5 g of berberine, given twice daily for 3 months in 32 hypercholesterolaemic patients, resulted in a 29% reduction in serum cholesterol, a 35% reduction in triglycerides and a 25% reduction in LDL cholesterol (Kong et al 2004). HDL cholesterol levels remained unchanged. Berberine also significantly improved liver function, as noted by liver enzyme levels. A later trial compared berberine, simvastatin and a combination of both (Kong et al 2008). Patients (n = 63) diagnosed with hypercholesterolaemia (total cholesterol over 5.2 mmol/L) were randomised into three groups and given either berberine (1 g/day), simvastatin (20 mg/day) or both. After 2 months of oral treatment, the results were as follows: monopreperation of berberine reduced LDL cholesterol by 23.8% and triglycerides by 22.1%; simvastatin reduced LDL cholesterol by 14.3% and triglycerides by 11.4%; combination therapy reduced LDL cholesterol by 31.8% and triglycerides by 38.9%. Total cholesterol reductions were similar to LDL reductions and HDL cholesterol did not change significantly in any group. All preparations were found to be safe.

Chronic congestive heart failure

The efficacy and safety of berberine in chronic congestive heart failure were studied in a randomised, double-blind, controlled study in 156 patients with chronic heart failure (Zeng et al 2003). All patients received conventional treatment and 79 patients in the treatment group also received 1.2–2.0 g/day of berberine for 8 weeks. Quality of life was greatly improved in the berberine group in comparison to controls, as measured by a significant increase in left ventricular ejection fraction, less fatigue and a greater capacity to exercise. A significant reduction in mortality was also noted during the 24-month follow-up (7 in the treatment group as compared to 13).

The acute cardiovascular effects of intravenous berberine (0.02 and 0.2 mg/kg/min for 30 min) were studied in 12 patients with refractory congestive heart failure (Marin-Neto et al 1988). At the lower dose, a 14% reduction in heart rate was noted, whereas 0.2 mg/kg resulted in a 48% decrease in systemic vascular resistance and a 41% decrease in pulmonary vascular resistance. Right atrium and left ventricular end-diastolic pressures were reduced by 28% and 32%, respectively. Cardiac index, stroke index and left ventricular ejection fraction were also significantly enhanced.

Diabetes

A pilot study was designed to determine the safety and efficacy of berberine in patients with type 2 diabetes mellitus (Yin et al 2008). Eighty-four subjects were divided into two groups. Study A consisted of 36 newly diagnosed type 2 diabetics who received either berberine (500 mg 3 times daily) or metformin (500 mg 3 times daily) for 13 weeks. The second group (study B) consisted of 48 diabetics who were poorly controlled on their current medication. They all stayed on their current regimen

and half also received berberine (500 mg 3 times daily) for 13 weeks.

Results for study A: Participants in the berberine group had very similar results to the metformin group. Haemoglobin A_{1c} reduced by 2%, fasting blood glucose reduced by 3.8 mmol/L and postprandial blood glucose reduced by 8.8 mmol/L. Fasting insulin levels and postprandial insulin were also the same as the metformin group. Total cholesterol (reduced by 0.57 mmol/L) and triglycerides (reduced by 0.24 mmol/L) were significantly lower after 13 weeks as compared to the metformin group ($P = 0.05$).

Results for study B: Participants in the combination group had reductions in haemoglobin A_{1c} from 8.1% to 7.3% ($P = 0.001$). Fasting blood glucose and postprandial blood glucose also improved significantly ($P = 0.001$). Fasting insulin was reduced by 29.0% and LDL cholesterol, total cholesterol and triglycerides were also significantly lower than baseline after 13 weeks.

Radiation-induced lung injury (RILI)

A prospective, randomised, placebo-controlled, double-blind trial was designed to determine whether berberine might reduce RILI in patients receiving radiation treatment for non-small cell lung cancer (Liu et al 2008). Ninety patients were randomised to receive either 20 mg/kg/day of berberine or placebo for 6 weeks during three-dimensional conformal radiation therapy. At 6 weeks, 45.2% of patients in the treatment group developed RILI as compared to 72.1% in the placebo group. At 6 months, 35.7% of patients in the berberine group experienced RILI as compared to 65.1% in the control group. Significant improvements in lung function were also demonstrated.

OTHER USES

Menorrhagia, dysmenorrhoea, peptic ulcer, gastritis, dyspepsia, skin disorders, sinusitis, chronic inflammation of mucous membranes and topically for ulceration and infection.

Traditionally, it is used as a bitter digestive stimulant that improves bile flow and liver function.

DOSAGE RANGE

Internal

- Tincture (1:3): 2.0–4.5 mL/day or 15–30 mL/week (Bone 2003).
- Tincture (1:10): 6–12 mL/day (Mills & Bone 2005).
- Dried rhizome and root: 1.5–3 g/day by decoction (Mills & Bone 2005).

External

- Eyewash: 0.2% berberine solution, 2 drops in each eye, three times daily (Khosla et al 1992).

ADVERSE REACTIONS

Goldenseal is generally regarded as safe in recommended doses (Blumenthal 2003). Doses higher than 0.5 g of pure berberine may cause lethargy, dizziness, dyspnoea, skin and eye irritation, gastrointestinal irritation, nausea, vomiting, diarrhoea, nephritis and kidney irritation (Blumenthal et al 1998).

Clinical note — Berberine absorption

Berberine is poorly absorbed, with up to 5% bioavailability (Pan et al 2002). In vitro data have clearly demonstrated that berberine is a potent antibacterial; however, in vivo data have established low bioavailability. Berberine has been shown to upregulate the expression and function of the drug transporter P-glycoprotein (Pgp) (Lin et al 1999). Pgp belongs to the super family of ATP-binding cassette transporters that are responsible for the removal of unwanted toxins and metabolites from the cell (Glastonbury 2003). It appears that Pgp in normal intestinal epithelia greatly reduces the absorption of berberine in the gut. In vivo and in vitro methods have been used to determine the role of Pgp in berberine absorption by using the known Pgp inhibitor cyclosporin A (Pan et al 2002). Co-administration increased berberine absorption sixfold and clearly demonstrated the role of Pgp in absorption.

Increased expression of Pgp can lead to cells displaying multidrug resistance (Glastonbury 2003). As previously reported, a certain flavonolignan in many *Berberis* spp. has the ability to inhibit the expression of multidrug-resistant efflux pumps (Stermitz et al 2000a, 2000b), allowing berberine and certain antibiotics to be more effective.

SIGNIFICANT INTERACTIONS

Because controlled studies are not available, interactions are currently speculative and based on evidence of pharmacological activity. Many studies have shown that extracts of goldenseal significantly inhibit cytochrome P450 enzymes (Budzinski et al 2000, 2007, Etheridge et al 2007, Gurley et al 2005, 2008a, 2008b, Raner et al 2007). The inhibitory effects of berberine on CYP3A4/5, CYP2C8, CYP2D6 and CYP2E1 have been reported in vitro with one study finding that CYP2D6 and CYP3A4/5 were each down-regulated by 40% (Gurley et al 2005). Two studies in healthy volunteers demonstrated that CYP3A4 and CYP2D6 were significantly down-regulated (Gurley et al 2008a, 2008b). Theoretically, these findings suggest that any drug metabolised using this pathway may be affected. The clinical relevance of this possible interaction is unknown.

Cyclosporin A

Berberine increased the blood concentration of cyclosporin A in renal transplant patients in an RCT (Wu et al 2005): 52 patients received 0.2 g of berberine orally three times daily for 3 months. The final blood concentration in the berberine/cyclosporin A group was 29.3% higher than the group given cyclosporin A only. The relevance of this to oral ingestion of goldenseal is unknown — caution advised.

Digoxin

Twenty healthy volunteers took 3210 mg of goldenseal and 0.5 mg digoxin daily for 14 days (Gurley

et al 2007). There was no change in the pharmacokinetics of digoxin suggesting that this dose of goldenseal is not a potent modulator of Pgp.

CONTRAINDICATIONS AND PRECAUTIONS

Goldenseal is contraindicated in kidney disease because of inadequate excretion of the alkaloids (Blumenthal 2003). Berberine has been found to be a potent displacer of bilirubin (Chan 1993). A review published in 1996 stated that berberine can cause severe acute haemolysis and jaundice in babies with glucose-6-phosphate dehydrogenase deficiency (Ho 1996). Goldenseal is therefore not recommended in pregnancy, lactation or cases of neonatal jaundice. Goldenseal is also contraindicated in hypertension (BHMA 1983) as large amounts of hydrastine have been reported to restrict peripheral blood vessels and cause hypertension (Genest & Hughs 1969). The dose required to induce this effect is unknown and the ability to reach this threshold using the whole extract is unlikely; however, until this is clarified goldenseal is best avoided in hypertension.

PREGNANCY USE

Contraindicated in pregnancy and lactation.

In addition to the preceding concerns about bilirubin, berberine has caused uterine contractions in pregnant and non-pregnant experimental models (Mills & Bone 2005). An in vivo study using 65-fold the average human oral dose of goldenseal investigated effects on gestation and birth and found no increase in implantation loss or malformation (Yao et al 2005). The authors conclude that the low bioavailability of goldenseal from the gastrointestinal tract was likely to explain the differences between in vitro and in vivo effects in pregnancy. Hydrastine (0.5 g) has also been found to induce labour in pregnant women (Mills & Bone 2005). Until more pharmacokinetic studies are done, goldenseal is best avoided in pregnancy.

PRACTICE POINTS/PATIENT COUNSELLING

- Goldenseal has been used traditionally as an antidiarrhoeal agent and digestive stimulant.
- It has been used topically as a wash for sore or infected eyes and as a mouth rinse.
- Goldenseal is a bitter digestive stimulant that improves bile flow and liver function.
- Most clinical evidence has been conducted using the chemical constituent berberine. These data have shown effectiveness against diarrhoea, congestive heart failure, infection and cholesterol.
- Goldenseal is not to be used in pregnancy or during breastfeeding.
- Use with caution in patients who have hypertension or taking cyclosporin.

PATIENTS' FAQs

What will this herb do for me?

Goldenseal may be used in the treatment of diarrhoea, dyspepsia, infection, diabetes and cholesterol. Most of the available research has been done on the alkaloid berberine. More clinical trials of the whole extract are needed to determine if the same effect will be seen.

When will it start to work?

Antibacterial and antidiarrhoeal activities should be apparent quite quickly. The lipid-lowering effects of goldenseal have been reported within 12 weeks.

Are there any safety issues?

The herb should not be taken during pregnancy or lactation and may interact with some medications.

Grapeseed extract

HISTORICAL NOTE Since the time of Ancient Greece, grape leaves, fruit and sap have been used medicinally to treat a variety of ailments, such as skin and eye irritation, varicose veins, diarrhoea, bleeding and cancer. In the 1500s, a French expedition in North America found itself trapped in ice and forced to survive on salted meat and stale biscuits. After a time, the crew began to show signs of what we now recognise as scurvy. It is believed that the men survived because a Native American Indian showed them how to make a tea from the bark and needles of pine trees. The French explorer wrote of this encounter in a book that was subsequently read by researcher Jacques Masquelier, also a Frenchman, in the 20th century. Intrigued by the story, he began to investigate the chemistry and properties of pine bark and identified oligomeric proanthocyanidin complexes (OPCs). Several years later, he extracted OPCs from grapeseed extract (GSE), which is now considered the superior source of OPCs (Murray & Pizzorno 1999).

COMMON NAME
Grapeseed extract

BOTANICAL NAME/FAMILY
Vitis vinifera/Vitaceae

PLANT PARTS USED
Seeds, grape skins

CHEMICAL COMPONENTS
The skin of the grapeseed is a rich source of proanthocyanidins (also referred to as procyanidins). Mixtures of procyanidins are referred to as OPCs. Grapeseed extract contains OPCs made up of dimers or trimers of (+)-catechin and (–)-epicatechin (Fine 2000) and also trimers and polymers of proanthocyanidins. *Vitis vinifera* also contains stilbenes (resveratrol and viniferins) (Bavaresco et al 1999); however, it is unclear whether significant amounts are present in the seeds.

MAIN ACTIONS
Most evidence of activity derives from in vitro and animal studies for OPCs or GSE; however, some clinical studies are also available. The stilbene resveratrol (3,4′,5 trihydroxystilbene) has also been the focus of much investigation and exhibits anti-inflammatory, antithrombotic, anticarcinogenic and antibacterial activities, but it is uncertain whether significant amounts are present in the seeds and GSE (Fremont 2000).

Antioxidant

Grapeseed PC extract has demonstrated excellent free radical scavenging abilities, in both test tube and animal models, and provided significantly greater effects than vitamins C, E and beta-carotene (Bagchi et al 1997, 1998, 2000, 2001, Castillo et al 2000, Facino et al 1999, Fauconneau et al 1997, Maffei et al 1994, 1996). In vitro tests have further identified a vitamin E sparing effect, in which PCs prevent vitamin E loss and cause alpha-tocopherol radicals to revert to their antioxidant form (Maffei et al 1998).

Inhibits platelet aggregation

Grapeseed extract has been shown to inhibit platelet aggregation, and combining extracts of grapeseed and grape skin produces a far greater antiplatelet effect in test tube and ex vivo tests (Shanmuganayagam et al 2002). Inhibition of platelet function was confirmed more recently (Sano et al 2005, Vitseva et al 2005).

Stabilises capillary walls and enhances dermal wound healing

In vivo studies have found that PCs stabilise the capillary wall and prevent increases in capillary permeability when chemically induced in tests, such as carrageenan-induced hindpaw oedema (Zafirov et al 1990) and dextran-induced oedema (Robert et al 1990). Components in GSE have the ability to cross-link collagen fibres, thereby strengthening the collagen matrix (Tixier et al 1984). Clinical studies confirm that grapeseed extract improves capillary resistance when used at a dose of 150 mg daily (Lagrue et al 1981). Not unexpectedly, research has also identified wound-healing properties.

A 2002 study in mice found that topical application of grapeseed PCs considerably accelerated wound contraction and closure and provided additional support during the wound healing process (Khanna et al 2002). It has been shown that a GSE preparation containing 5000 ppm resveratrol facilitates oxidant-induced vascular endothelial growth factor expression in keratinocytes in vitro, which may account for its beneficial effects in promoting dermal wound healing and resolution of related skin disorders (Khanna et al 2001).

Anticarcinogenic, antimutagenic

Most tests have been conducted with PCs from grapeseed extract and show significant activity.

Several in vitro studies have demonstrated that PCs from *Vitis vinifera* strongly suppress tumour growth and have cytotoxic activity against a range of cancer cells, including breast, lung, prostate, colon and gastric adenoma cells (Bagchi et al 2000, Engelbrecht et al 2007, Joshi et al 2001, Kaur et al 2006, Tyagi et al 2003, Ye et al 1999). More specifically, PCs from grapeseeds exerted antitumour properties in several animal models (Kim et al 2004, Martinez Conesa et al 2005, Nomoto et al 2004, Ray et al 2005, Raina et al 2007, Zhang et al 2005). One study also found that grapeseed PCs enhanced the growth and viability of human gastric mucosal cells at the same time (Ye et al 1999).

Tests with GSE showed that it induced apoptosis in acute myeloid leukaemic cells (Hu & Qin 2006). A recent in vitro study identified gallic acid within GSE to be effective against human prostate carcinoma cells (Agarwal et al 2006). In breast cancer cells, its mechanism of action is to inhibit aromatase activity and expression (Kijima et al 2006). A phase 1 chemoprevention trial in postmenopausal women is being carried out which hypothesises that breast cancer risk will be reduced with GSE due to the antiaromatase activity (Palomares et al 2006).

Clinical note — Proanthocyanidins

Proanthocyanidins (PCs) are a group of naturally occurring polyphenolic bioflavonoids that are present in many fruits (e.g. apples, pears, grapes and peaches), vegetables, nuts, beans (e.g. cocoa), seeds, flowers and bark (e.g. pine) (Bavaresco et al 1999). Grapeseeds are a particularly rich source of PCs, containing more than any other grape products, such as red, white or rose wine or grape juice, and more than most commonly available foods (Rasmussen et al 2005). Proanthocyanidins are also found in many medicinal herbs, such as *Ginkgo biloba*, *Camellia sinensis*, *Hypericum perforatum* and *Crataegus monogyna*; however, GSE is considered the superior source. Proanthocyanidins demonstrate a wide range of biological actions according to various in vitro, in vivo and clinical studies. However, in recent years, bioavailability studies have demonstrated that not all orally ingested PCs are absorbed. In particular, PC polymers have negligible absorption from the gastrointestinal tract, whereas low-molecular-weight PCs (monomers, dimers and trimers) are absorbed (Rasmussen et al 2005). In addition, some PCs are degraded by microflora in the caecum and large intestine into low-molecular-weight phenolic acids, chiefly hydroxyphenylpropionic acid and 4-O-methylgallic acid (Ward et al 2004), which are likely to contribute to the biological effects. These findings have implications when interpreting in vitro data because this method of testing does not take into account the variations in bioavailability and metabolism in the body.

Anti-inflammatory

In vitro evidence suggests that GSE has anti-inflammatory activity (Sen & Bagchi 2001). Two compounds isolated from *Vitis vinifera* exhibit non-specific inhibitory activity against COX-1 and -2 (Waffo-Teguo et al 2001). Inhibition of the pro-inflammatory 5-lipoxygenase is another mechanism identified recently for GSE (Leifert & Abeywardena 2008). Rats fed on a hyperlipidic diet and GSE had a reduction in proinflammatory markers such as CRP, IL-6 and TNF-alpha (Terra et al in press).

Cardioprotective effects

Considering that GSE demonstrates antioxidant, antiplatelet and anti-inflammatory actions, it may have a role in the prevention of cardiovascular disease. A number of researchers have investigated this issue further, mainly using animal models. One series of studies was conducted by Bagchi et al (2003) using a natural, standardised, water–ethanol

extract made from California red grapeseeds, which contained approximately 75–80% oligomeric PCs and 3–5% monomeric PCs. According to in vivo research, treatment with GSE provided resistance to myocardial ischaemia-reperfusion injury, better postischaemic ventricular recovery and reduced incidence of reperfusion-induced ventricular fibrillation and ventricular tachycardia, as compared with corresponding control animals. Another study using a hamster atherosclerosis model found that 50 and 100 mg GSE/kg body weight led to a 49% and 63% reduction in foam cells, respectively. Additionally, cholesterol and triglyceride lowering activity has been reported (Yu et al 2002). One animal study identified that GSE significantly reduced total cholesterol by 42%, LDLs by 56% and elevated HDL cholesterol by 56% (El-Adawi et al 2006).

A more recent study with hyperlipidaemic rabbits showed that GSE administered over 15 weeks produced a significant reduction in aortic atherosclerosis in males, although no effect was observed in females (Frederiksen et al 2007).

Cognition enhancer/neuroprotective

Grapeseed proanthocyanidin (GSPE) demonstrated neuroprotective effects in vivo and an increase in superoxide dismutase with the highest test dose (Devi et al 2006). Some in vivo studies have identified that GSE reduces age-related oxidative DNA damage and improves memory performance and cognitive enhancement, most likely achieved via an antioxidant mechanism (Balu et al 2005, 2006, Sarkaki et al 2007, Sreemantula et al 2005). Interestingly, along with GSE's antioxidant action, one study demonstrated a neurorescue effect when GSE was given to rats 3 hours after neurotoxic injury (Feng et al 2005, 2007).

The ability of GSE to protect critical proteins in the brain that are most affected in Alzheimer's disease suggests a potential clinical application (Kim et al 2005, 2006).

Reducing drug-induced toxicity

Protection against chemically induced multiorgan toxicity has also been reported (Bagchi et al 2001). Hepatoprotection was demonstrated in studies where rats were exposed to a hepatotoxin. It is thought that this effect was due to inhibiting lipid peroxidation via antioxidant activity (Dulundu et al 2007, Jamshidzadeh et al 2008). GSE demonstrated potent antioxidant activity and protected kidneys from gentamicin-induced nephrotoxicity in an experimental model. The same study found that bone marrow chromosomes were also protected (El-Ashmawy et al 2006). GSE was also protective in rats from toxicity due to radiation exposure (Enginar et al 2007, Saada et al 2009).

GSE protected against the cardiotoxic side effects of the chemotherapy drug doxorubicin in vivo. It is thought that the antioxidant properties of GSE protecting cardiomyocytes was chiefly responsible (Du & Lou 2008). Protection against chemotherapy-induced small intestine mucositis was observed in another animal study where rats were administered with 400 mg/kg of GSE before and during chemotherapy (Cheah et al 2008).

OTHER ACTIONS

There is preliminary evidence from many other studies indicating a range of pharmacological effects. Results from a clinical study suggest that GSE increases the rhodopsin content of the retina or accelerates its regeneration after exposure to bright light (Boissin et al 1988). Reduced incidence of cataract development and cataract progression was also observed in an experimental model using grapeseed proanthocyanidin extract (GSPE) (Durukan et al 2006). GSE shows evidence of antibacterial and antifungal actions specifically against *Candida albicans* (Han 2007, Furiga et al 2008). GSE has also been shown in vitro to have an anti-venom action against the saw-scaled viper (Mahadeswaraswamy et al 2008). Antinociceptive effects demonstrated in vivo for GSE show a reduction in pain and a potentiating effect of morphine (Uchida et al 2008). An animal study demonstrated anti-ageing potential due to GSE maintaining the erythrocyte membrane integrity that is often impaired in the elderly (Sangeetha et al 2005).

CLINICAL USE

Free radical damage has been strongly associated with virtually every chronic degenerative disease, including cardiovascular disease, arthritis and cancer. Clearly, due to the potent antioxidant activity of grapeseed, its therapeutic potential is quite broad. Most clinical studies have been conducted in Europe using a commercial product known as Endotelon®. Due to the poor bioavailability of high-molecular-weight PCs, it is advised that products containing chiefly low-molecular-weight PCs be used in practice.

Fluid retention, peripheral venous insufficiency and capillary resistance

There is good supportive evidence from clinical studies that have investigated the use of GSE in fluid retention, capillary resistance or venous insufficiency (Amsellem et al 1987, Delacroix 1981, Constantini et al 1999, Henriet 1993, Lagrue et al 1981).

Hormone replacement therapy and fluctuations in hormone levels can produce symptoms of venous insufficiency in some women. One large study involving 4729 subjects with peripheral venous insufficiency due to hormone replacement therapy (HRT) showed that GSE decreased the sensation of heaviness in the legs in just over half the subjects by day 45, whereas 89.4% of subjects experienced an improvement by day 90 (Henriet 1993). According to an open multicentre study of women aged 18–50 years with oedema due to premenstrual syndrome, GSE (Endotelon®) administered from day 14 to 28 improved various symptoms of fluid retention such as abdominal swelling, weight gain and pelvic pain and also venous insufficiency (Amsellem et al 1987). The treatment was taken for four cycles, with most women (60.8%) responding after two cycles and 78.8% responding after four cycles.

An open study involving 24 patients with non-complicated chronic venous insufficiency found that over 80% of subjects receiving OPCs (100 mg/day) reported lessened or no symptoms after

10 days. Symptoms of itching and pain responded best, completely disappearing during the course of treatment in 80% and 53% of the patients, respectively (Costantini et al 1999). A double-blind study of 50 patients with symptoms of venous insufficiency found that GSE (Endotelon® 150 mg daily) improved both subjective and objective markers of peripheral venous insufficiency, such as pain (Delacroix 1981).

In some pathological conditions, such as inflammation or diabetes, vascular permeability can be abnormally increased (Robert et al 1990). Two studies investigated the effects of GSE on capillary resistance in hypertensive and diabetic patients under both open and double-blind, placebo-controlled conditions with treatment producing significant improvements in both groups (Lagrue et al 1981). The studies used a daily dose of 150 mg (Endotelon®).

Diabetes

Diabetic retinopathy

Grapeseed extract (Endotelon® 150 mg) was found to stabilise diabetic retinopathy in 80% of subjects compared to 47% with placebo, under double-blind test conditions (Arne 1982). These results were obtained by measuring objective markers such as visual acuity, muscular tone and ocular tone.

Diabetic nephropathy

Preliminary in vitro research indicates that grapeseed polyphenols have a protective effect against cell damage, including renal cell damage, caused by high glucose levels (Fujii et al 2006). Other in vitro research also points to possible therapeutic benefits in preventing and treating vascular problems and diabetic complications (Zhang et al 2007).

A study with diabetic rats given grapeseed proanthocyanidins extracts (GSPE) identified nephroprotection, which might be related to the free radical scavenging activity of GSPE (Liu et al 2006). Further research would be required to confirm a clinical application.

Eye strain

A double-blind study involving 75 patients with eye strain caused by viewing a computer screen found that a dose of GSE 300 mg daily significantly improved objective and subjective measures (Bombardelli & Morrazzoni 1995). Grapeseed extract (Endotelon®) has also been shown to significantly improve visual adaptation to and from bright light in a dual centre study involving 100 volunteers (Boissin et al 1988, Corbe et al 1988). A dose of 200 mg daily over 5 weeks was used. It has been proposed that GSE increases rhodopsin content of the retina or accelerates its regeneration after exposure to bright light.

Hyperlipidaemia/atherosclerosis

A recent single-blind, placebo study where 61 healthy subjects took 200 or 400 mg GSE over 12 weeks showed that active treatment significantly lowers oxidised LDL levels at the end of the test period. The group receiving the higher dose experienced results at the earlier 6-week point as well as at 12 weeks (Sano et al 2007). A randomised, double-blind study of 40 subjects with hypercholesterolaemia compared the effects of placebo, chromium polynicotinate (400 microgram/day), GSE (200 mg/day) or a combination of both. Over 2 months, the combination treatment decreased total cholesterol and LDL levels significantly but did not significantly alter homocysteine, HDL or blood pressure among the four groups (Preuss et al 2000). The role of GSE in achieving this result is unclear.

Enhances dermal wound healing

A 2002 study in mice found that topical application of grapeseed PCs considerably accelerate wound contraction and closure and provided additional support during the wound healing process (Khanna et al 2002).

Chloasma

Chloasma is a condition characterised by hyperpigmentation and is generally considered recalcitrant to treatment. Proanthocyanidin-rich GSE successfully reduced hyperpigmentation in women with chloasma after 6 months of oral treatment, according to an open study involving 12 subjects (Yamakoshi et al 2004). The study continued for another 6 months but failed to find an additional improvement with further use. The researchers suggested that a preventative effect may be possible with long-term oral GSE when used in the months prior to summer.

Pancreatitis

It is believed that the oxygen-derived free radicals mediate tissue damage in acute and chronic pancreatitis. Therefore, antioxidant treatment is being investigated. A small, open study of three patients with difficult-to-treat chronic pancreatitis found that a commercially available IH636 GSE produced a reduction in the frequency and intensity of abdominal pain, as well as resolution of vomiting in one patient.

Preventing reperfusion injury

Procyanidin administration reduced the adverse effects of myocardial ischaemia-reperfusion injury during cardiac surgery in several in vivo studies (Facino et al 1999, Maffei et al 1996). This appears to be positively associated with an increase in plasma antioxidant activity. An animal model also suggests that a proanthocyanidin-rich extract from GS was protective against renal damage from ischaemia-reperfusion injury (Nakagawa et al 2005). Another animal model showed protection against hepatic ischaemia/reperfusion injury by regulating the release of inflammatory mediators and by its antioxidant action (Sehirli et al 2008).

Reduces sun burn

Topical application of GSE has been shown to enhance sun protection factor in human volunteers (Bagchi et al 2000). A recent study, with a GSE supplement, topical cream and a topical lotion (both Anthogenol products), assessed 42 individuals randomised into two groups with one group taking

the dietary supplement. UV radiation-induced erythema was treated and it was found that both the topical applications decreased erythema formation with slightly better results for those volunteers also taking the oral supplements. Application of the topical lotion produced the best results (53% reduction) and the lotion plus the GSE supplement added a further 13% reduction in skin inflammation while all groups found improved skin hydration (Hughes-Formella et al 2007).

Protection against multi-organ drug and chemical toxicity

The results from a number of in vivo studies have suggested that pre-exposure to grapeseed extract can provide multiorgan protection against damage caused by various drugs, such as paracetamol, amiodarone, doxorubicin, cadmium chloride and dimethylnitrosamine treatment (Bagchi et al 2000, 2001).

OTHER USES

Some preliminary in vitro research suggests a potential use for periodontal diseases and oral hygiene for prevention of periodontitis. This is due to GSE's antimicrobial effect against specific oral bacteria and its strong antioxidant action (Houde et al 2006, Furiga et al in press).

An in vitro study suggests a promising use for GSE as active against *Candida albicans* and a possible synergistic action with the drug amphotericin B, which would enable this strong drug dose to be reduced by 75% when given in conjunction with GSE. Clinical studies are needed to confirm this potential use (Han 2007).

DOSAGE RANGE

- Fluid extract 1:1 (g/mL): 20–40 mL per week.
- Solid dose forms: 12,000 mg of GSE standardised to OPCs taken 2–3 times daily in order to provide 150–300 mg of OPCs daily. Due to the poor bioavailability of high-molecular-weight PCs, it is advised that products containing chiefly low-molecular-weight PCs be used in practice.

According to clinical studies:

- Chloasma: 162 mg/day GSE.
- CVD: 200–300 mg/day GSE.
- Hypercholesterolaemia: 200–400 mg/day GSE.
- Chronic pancreatitis: ActiVin® 200–300 mg/day.
- Oedema due to premenstrual syndrome: GSE (Endotelon®) 150–400 mg taken from day 14 to 28.
- Oedema due to injury or surgery: 200–400 mg/day GSE (Endotelon ®).
- Diabetic retinopathy: 150–400 mg/day GSE (Endotelon®).
- Vascular fragility: 150–400 mg/day GSE (Endotelon®).
- Venous insufficiency and poor leg circulation: GSE (Endotelon®) 150–300 mg/day.
- Vision problems: GSE (Endotelon®) 200 mg/day.

TOXICITY

Tests in animal models have found GSE to be extremely safe (Bentivegna & Whitney 2002).

ADVERSE REACTIONS

Studies using doses of 150 mg/day have found it to be well tolerated. Side effects are generally limited to gastrointestinal disturbances, including nausea and indigestion.

SIGNIFICANT INTERACTIONS

Controlled studies are not available; therefore, interactions are theoretical and based on evidence of pharmacological activity.

Antiplatelet drugs

Additive effect theoretically possible — observe patient.

Anticoagulant drugs

Increased risk of bleeding theoretically possible — monitor patient for increased bruising or bleeding.

Iron and iron-containing preparations

Decreased iron absorption. Tannins can bind to iron, forming insoluble complexes — separate doses by 2 hours.

CONTRAINDICATIONS AND PRECAUTIONS

None known.

PREGNANCY USE

Safety has not been scientifically established.

PRACTICE POINTS/PATIENT COUNSELLING

- Grapeseed extract has considerable antioxidant activity and appears to regenerate alpha-tocopherol radicals to their antioxidant form.
- Grapeseed extract also has anti-inflammatory actions, reduces capillary permeability, enhances dermal wound healing and reduces photodamage, inhibits platelet aggregation and may enhance rhodopsin regeneration or content in the retina.
- It is popular in Europe as a treatment for venous insufficiency and capillary fragility, both of which are supported by clinical evidence. It is also used to relieve eye strain, stabilise diabetic retinopathy and connective tissue disorders.
- Preliminary research has identified cardioprotective effects due to a variety of mechanisms. Possible benefits in pancreatitis and multiorgan protection against damage caused by several pharmaceutical drugs, including several chemotherapy drugs, and radiation. Anticarcinogenic activity has also been reported.
- It shows promise for neurodegenerative disorders in preliminary studies.
- Most clinical research has been conducted in Europe with a commercial grapeseed product known as Endotelon®.
- Due to concerns with bioavailability, it is recommended that only preparations containing low-molecular-weight PCs be used.

PATIENTS' FAQs

What will this herb do for me?

There is evidence that GSE is a useful treatment for venous insufficiency, poor leg circulation and

capillary fragility and has considerable antioxidant activity. It is also used to treat eye strain, diabetic retinopathy and enhance wound healing when applied locally.

When will it start to work?

It appears to relieve symptoms of venous insufficiency within 10 days and eye strain within 5 weeks. Other uses may take longer before results are seen.

Are there any safety issues?

Research suggests that it is well tolerated and generally safe; however, people taking anticoagulant medicines should refer to their healthcare professional before taking this substance.

Green tea

HISTORICAL NOTE Tea has been a popular beverage for thousands of years and was originally grown in China, dating back 5000 years, where it has been used as part of various ceremonies and to maintain alertness. Green tea and the partially fermented oolong tea have remained popular beverages in Asia since that time, whereas black tea is the preferred beverage in many English-speaking countries. Tea was introduced to the Western culture in the 6th century by Turkish traders (Ulbricht & Basch 2005). Second to water, tea is now considered to be the world's most popular beverage.

COMMON NAME
Green tea

OTHER NAMES
Chinese tea, camellia tea, gruner tea, Matsu-cha, Green Sencha Tea, Japanese tea, Yame tea

BOTANICAL NAME/FAMILY
Camellia sinensis (family Theaceae)

PLANT PART USED
Leaf

CHEMICAL COMPONENTS
The composition of green tea varies according to the growing and harvesting methods, but the most abundant components are polyphenols, which are predominantly flavonoids (e.g. catechin, epicatechin, epicatechin gallate, epigallocatechin gallate, proanthocyanidins). Caffeine content in green tea varies but is estimated at about 3%, along with very small amounts of the other common methylxanthines, theobromine and theophylline (Graham 1992). It also contains many other constituents, such as tannin, diphenylamine, oxalic acid, trace elements and vitamins.

Epigallocatechin gallate is one of the most abundant polyphenols in tea and is regarded as the most important pharmacologically active component.

MAIN ACTIONS
It is suspected that the polyphenol content is chiefly responsible for the chemoprotective, antiproliferative, antimicrobial and antioxidant activity of green tea. The caffeine content is predominantly responsible for central nervous system activity and an interaction between both appears necessary for increasing thermogenesis.

Antioxidant
Green tea has consistently demonstrated strong antioxidant activity. In a controlled human trial, 24 healthy women consumed two cups of green tea (250 mg catechins/day) for 42 days (Erba et al 2005). The results showed a significant increase in plasma antioxidant status, reduced plasma peroxides and reduced LDL cholesterol when compared with controls. Several other in vitro animal and human studies have also demonstrated that green tea inhibits lipid peroxidation and scavenges hydroxyl and superoxide radicals (Leenen et al 2000, Rietveld & Wiseman 2003, Sung et al 2000).

Clinical note — The difference between teas
Black, green and oolong tea are produced from the same plant (*Camellia sinensis*) but differ in polyphenol content according to the way the leaves are processed. Black tea is made from oxidised leaves, whereas oolong tea is made from partially oxidised leaves and green tea leaves are not oxidised at all. Because the oxidising process converts many polyphenolic compounds into others with less activity, green tea is considered to have the strongest therapeutic effects and the highest polyphenol content (Lin et al 2003). Caffeine concentrations also vary between the different teas: black tea > oolong tea > green tea > fresh tea leaf (Lin et al 2003). Variation in caffeine content is further influenced by growing conditions, manufacturing processes and size of the tea leaves (Astill et al 2001). The highest quality leaves are the first spring leaf buds, called the 'first flush'. The next set of leaf buds produced is called the 'second flush' and considered to be of poorer quality. Tea varieties also reflect the area they are grown in (e.g. Darjeeling in India), the form produced (e.g. pekoe is cut, gunpowder is rolled) and processing method (black, oolong or green) (Ulbricht & Basch 2005).

Antibacterial activity
Green tea extract has moderate and wide-spectrum inhibitory effects on the growth of many types of pathogenic bacteria, according to in vitro tests, including seven strains of *Staphylococcus* spp, seven strains of *Streptococcus* spp, one strain of *Corynebacterium suis*, 19 strains of *Escherichia coli* and 26 strains of *Salmonella* spp (Ishihara et al 2001). Green tea was effective against most of the 111 bacteria tested including two genera of gram-positive and seven genera of gram-negative bacteria. It was also confirmed that in vivo it could protect against *Salmonella typhimurium* (Bandyopadhyay et al 2005). Green tea has also been found to inhibit *Helicobacter pylori* in an animal model (Matsubara et al 2003). According to one study, which compared the antibacterial activity of black, green and oolong tea, it seems that fermentation adversely affects antibacterial activity, as green tea exhibited the strongest effects, and black tea the weakest (Chou et al 1999). An in vitro study has demonstrated that green tea can significantly lower bacterial endotoxin-induced cytokine release and therefore may reduce mortality from sepsis.

Oral pathogens

Both in vitro and in vivo tests have identified strong antibacterial activity against a range of oral pathogens, such as *Streptococcus mutans*, *S. salivarius* and *E. coli* (Otake et al 1991, Rasheed & Haider 1998). The mechanism of action appears to involve anti-adhesion effects, with the strongest activity associated with epigallocatechin gallate and epicatechin gallate. Green tea catechins (GTCs) have also showed an antibacterial effect against *Porphyromonas gingivalis* and *Prevotella* spp in vitro (Hirasawa et al 2002). Furthermore, green tea polyphenols, especially epigallocatechin gallate, have been found to completely inhibit the growth and adherence of *P. gingivalis* on buccal epithelial cells (Sakanaka et al 1996).

Antiviral activity

A number of in vitro studies have shown that epigallocatechin gallate strongly inhibits HIV replication (Chang et al 1994, Fassina et al 2002, Liu et al 2005, Tao 1992, Williamson et al 2006). The theaflavins from black tea have shown even stronger anti-HIV activity in vitro by inhibiting viral entry into target cells (Liu et al 2005). Antiviral activity has also been identified against Epstein–Barr virus, Herpes simplex virus 1 (HSV-1), influenza A and B, rotavirus and enterovirus (Chang et al 2003, Imanishi et al 2002, Isaacs et al 2008, Mukoyama et al 1991, Tao 1992, Weber et al 2003). EGCG and epicatechin gallate (ECG) show antiviral activity inhibiting influenza virus replication in vitro with differences in the strength of the antiviral activity depending on the strain of influenza (Song et al 2005). Antiviral activity seems to be attributable to interference with virus adsorption (Mukoyama et al 1991).

Antimalarial

Antimalarial properties have been shown in vitro with crude extract of green tea, EGCG and ECG strongly inhibiting *Plasmodium falciparum* growth (Sannella et al 2007).

Anticarcinogenic

Several in vitro studies have shown a dose-dependent decreased proliferation and/or increased apoptosis in a variety of cancer cell lines (lung, prostate, colon, stomach, pancreatic, bladder, oral, leukaemia, breast, cervical and bone) (Berger et al 2001, Garcia et al 2006, Gupta et al 2003, Hafeez et al 2006, Kavanagh et al 2001, Kinjo et al 2002, Pianetti et al 2002, Qanungo et al 2005, Qin et al 2007, Sadava et al 2007, Shimizu et al 2005, Srinivasan et al 2008, Valcic et al 1996, Wang & Bachrach 2002, Yoo et al 2002, Zhang et al 2002). Additionally, photochemopreventative effects for green tea and epigallocatechin gallate have been demonstrated in vitro, in vivo and on human skin (Afaq et al 2003) and apoptosis of skin tumour cells (Mantena et al 2005).

The mechanism of action by which tea polyphenols exert antimutagenic and antitumourigenic effects is still largely speculative. However, the following has been observed: inhibition of the large multicatalytic protease and metalloproteinases, which are involved in tumour survival and metastasis, respectively, and inhibition of many tumour-associated protein kinases, while not affecting kinase activity in normal cells (Kazi et al 2002, Wang & Bachrach 2002). Tea polyphenols have also been found to inhibit some cancer-related proteins that regulate DNA replication and transformation. There is increasing evidence that catechins possess anti-angiogenic properties (Sachinidis & Hescheler 2002). Inhibition of angiogenic factors and antitumour immune reactivity including an increase in cytotoxic T lymphocyte cells was found to be the mechanism of action in preventing photocarcinogensis (Mantena et al 2005). Recent work suggests tea polyphenols may inhibit microsomal aromatase and 5 alpha-reductase, so suppressing prostate carcinogenesis. Tea catechins may work to suppress proteasomal activities thereby inhibiting breast cancer cell proliferation (Ho et al 2009).

Antihypertensive

In vitro experiments using green tea extracts have identified angiotensin-converting enzyme inhibition (Persson et al 2006). Animal experiments have also shown that a green tea extract protected against arterial hypertension induced by Angiotensin II (Antonello et al 2007) and green tea lowered blood pressure that had been elevated by a high-cholesterol diet (Song et al 2008). Blood pressure lowering effects have not been demonstrated in humans according to a meta-analysis of parallel group or crossover studies (Taubert et al 2007).

Neuroprotective/neurorescue

Neuroprotective activity refers to the use of an agent before exposure to a neurotoxin which prevents toxicity. Neurorescue is a different term which refers to the use of an agent after exposure to a neurotoxin, which is able to reverse toxicity effects. New in vitro and animal research indicates that (-)-epigallocatechin-3-gallate (EGCG) found in green tea has the ability to act as both a neuroprotective and a neurorescue agent (Hou et al 2008, Guo et al 2007, Jeong et al 2007). In vitro tests reveal EGCG reduces apoptosis of human neuroblastoma cells (Avramovich-Tirosh et al 2007). Additionally, in vivo studies have found a neuroprotective effect for EGCG on dopamine neurons, which is being further investigated as a potential preventative treatment in Parkinson's disease (Guo et al 2007, Jeong et al 2007).

Two animal studies found that EGCG reduced beta-amyloid deposition — one study reported 60% reduction in the frontal cortex and 52% in the hippocampus over the 3 months of the study (Li et al 2006, Rezai-Zadeh et al 2008). This may have implications in the development and progression of Alzheimer's dementia and is being further investigated in other models.

Several different mechanisms of action appear to be responsible for neuroprotective and neurorescue activity including: antioxidant, iron chelating, anti-inflammatory, cell apoptosis, signal transduction, gene regulation and an effect on amyloid precursor protein (APP) (Ostrowska et al 2007, Mandel et al 2006).

Iron chelation

EGCG has been shown to chelate metals such as iron, zinc and copper (Guo et al 1996, Kumamoto et al 2001). Since the accumulation of iron has been implicated in the aetiology of both Alzheimer's dementia and Parkinson's disease and in vivo research shows EGCG's iron-chelating effect penetrates the brain barrier, it may offer neuroprotective and neurorescue effects in these diseases. EGCG has further been shown to reduce APP and beta-amyloid peptide, most likely due to its iron chelating activity (Reznichenko et al 2006). It is possible that iron chelation effects enabling iron to be removed from the brain may provide a novel therapy to prevent progression in neurodegenerative diseases (Mandel et al 2007).

Thermogenic activity

Although the thermogenic activity of green tea is often attributed to its caffeine content, an in vivo study has shown that stimulation of brown adipose tissue thermogenesis occurs to a greater extent than would be expected from the caffeine content alone (Dulloo et al 2000). The interaction between catechin polyphenols and caffeine on stimulating noradrenaline release and reducing noradrenaline catabolism may be responsible. Clinical investigation has produced similar results, with green tea consumption significantly increasing 24-hour energy expenditure and urinary noradrenaline excretion, whereas an equivalent concentration of caffeine had no effect on these measures (Dulloo et al 2000).

OTHER ACTIONS

Green tea exhibits a variety of other pharmacological actions, such as anti-inflammatory activity, central nervous system (CNS) stimulation, inhibition of platelet aggregation, stimulation of gastric acid secretion and diuresis, increased mental alertness, relaxation of extracerebral vascular and bronchial smooth muscle, and reduced cholesterol, triglyceride and leptin levels (Fassina et al 2002, Sayama et al 2000). It has multiple mechanisms that have an impact on the cardiovascular system including lipid lowering, hypocholesterolaemic, anti-inflammatory, antithrombogenic, antioxidant, antihypertensive and anti-atherosclerotic (Babu & Liu 2008). Some animal studies suggest that EGCG activates gamma amino butyric acid (GABA) A receptors causing sedative and hypnotic effects (Adachi et al 2006, Vignes et al 2006). A number of rat experiments have shown memory improvement in older animals. Improved spatial cognition learning ability in rats was demonstrated after the administration of long-term GTCs (Haque et al 2006). Significant improvement in memory and learning was found in older rats administered with green tea extract over 8 weeks (Kaur et al 2008)

EGCG and other tea polyphenols

Catechins are the most important flavanols in green tea and EGCG is the catechin thought to be the most pharmacologically active phytochemical. EGCG and the other green tea polyphenols have gained world-wide attention because they have multiple mechanisms of action and are extremely safe. So far, research has confirmed they are strongly antioxidant, anticarcinogenic, chemoprotective, antiproliferative, anti-angiogenic and apoptotoic on multiple cancer cell types, antithrombotic, anti-inflammatory, hypolipidaemic, antihypotensive, antidiabetic, thermogenic, antibacterial, antiviral, UV-protective, neuroprotective, neurorescue, anti-amyloidogenic and have iron- and metal-chelating activities.

As a result, there is a lot of work being conducted to determine whether EGCG and green tea can be part of an effective therapeutic strategy for the prevention and treatment of a number of the major diseases affecting the Western world. Conditions currently being studied include cardiovascular disease, cancers, neurodegenerative diseases such as Alzheimer's disease, Parkinson's disease and dementia, and diabetes.

CLINICAL USE

Evidence is largely based on epidemiological studies with few clinical studies available.

Cancer prevention

It is still unclear whether green tea consumption reduces the incidence of all cancers or has any effect on mortality; however, studies of individual cancers show some protective effects. Supportive evidence is most consistent for breast and prostate cancers, with some supportive evidence for endometrial cancer and leukaemia and less consistent evidence for gastric cancers.

All cancers

A 2001 prospective study in Japan found no association between green tea consumption and cancer incidence (Nagano et al 2001) whereas a 2003 study using 13-year follow-up data found increased green tea consumption was associated with an apparent delay of cancer onset and death, and all cause deaths (Nakachi et al 2003).

Alternately, the Ohsaki National Health Insurance Cohort study in Japan followed a population of 40,530 Japanese adults and did not find a significant correlation between green tea consumption and reduced mortality due to cancer (Kuriyama et al 2006).

Breast cancer

A meta-analysis of three cohort studies from Japan and one population case control study from the US concluded that green tea consumption reduced the risk of breast cancer (Sun et al 2006). Similar protective effects were observed in a case–control study in China, which found that regular drinking of green tea reduced breast cancer risk (Zhang et al 2007).

Endometrial cancer

Green tea drinking was found to be mildly protective of endometrial cancer risk in a population-based case–control study in China where 995 cases were interviewed. This protective effect might be limited to pre-menopausal women (Gao et al 2005).

Prostate cancer

A case–control study in China with 130 prostate cancer patients found that green tea was protective against prostate cancer with lower risk associated with an increase in the frequency, duration and quantity of green tea consumed (Jian et al 2004). Drinking green tea was also associated with a reduction in the risk of advanced prostate cancer in 49,920 men aged 40–69 years who completed questionnaires over a 10-year period in the Japan Public Health Centre-based Prospective Study. The effect was dose dependent and strongest for men drinking five or more cups/day compared with less than 1 cup/day (Kurahashi et al 2008).

Gastric cancer

A meta-analysis of 14 epidemiological studies found that green tea was not associated with a reduced risk of gastric cancer (Zhou et al 2008). In contrast, in the same year a systematic review of 43 epidemiological studies, four randomised trials and one meta-analysis concluded that green tea consumption may reduce incidence of gastrointestinal cancers but inconsistencies in the evidence meant further long-term clinical trials are required (Liu et al 2008).

Colorectal cancer

A meta-analysis of studies investigating green tea consumption and colorectal cancer risk evaluated eight studies and found that using the available epidemiological data it could not be concluded that green tea was protective (Sun et al 2006). A year later, a large prospective study of 69,710 Chinese women reported regular tea drinking reduced the risk of both colon and rectal cancers (Yang et al 2007).

Liver cancer

According to a placebo-controlled, randomised study, green tea polyphenols may reduce the incidence of hepatocellular carcinoma (HCC) in high-risk patients (Yu et al 2006). The study involved 1209 males, who tested positive for hepatitis B virus and then allocated to the control group or active treatment with green tea polyphenols (two capsules daily of 500 mg). The trial lasted 3 years with a further 2-year follow-up period. Ten cases of HCC were reported in the green tea group and 18 cases in the placebo group.

Leukaemia

Leukaemia risk may be reduced with drinking sufficient amounts of green tea. The protective effect was significant in the 16–29-year age range with higher amounts of green tea consumption; there was no significant relationship to green tea drinking and leukaemia risk in younger people in the 0–15-year age range. These findings were from a population-based study in Taiwan (Kuo et al 2009).

Cancer treatment

Studies have been conducted with various doses of green tea and GTCs in different cancers producing mixed results.

Overall, the current evidence does not support the use of green tea as a cancer treatment; however, there are some exceptions, which suggest an adjunctive role. Green tea increased the survival rate of patients with epithelial ovarian cancer in a cohort of 309 Chinese women (Zhang et al 2004). Most (77.9%) of the women in the treatment group were alive at the 3-year follow-up as compared with 47.9% of the control group.

In a randomised controlled trial (RCT), 90 patients with cervical lesions infected with human papilloma virus were given either a capsule containing 200 mg of (-)-epigallocatechin-3-gallate (EGCG) and/or an ointment containing 200 mg of Polyphenon E to be applied daily (Ahn et al 2003). There was a 69% responder rate when compared with placebo, with the ointment showing the best effects.

Several studies have been conducted in men with established prostate cancer. GTCs may have a role in arresting disease development in prostate cancer according to a double-blind, placebo-controlled study (Bettuzzi et al 2008). Sixty volunteers with high-grade prostate intraepithelial neoplasis (HG-PIN) and therefore at high risk of prostate cancer were treated with GTCs (three capsules of 200 mg/day) or placebo over 12 months. Of the 30 men in the GTC group, only one tumour was diagnosed as opposed to nine cases in the placebo group. The GTC group also scored higher on the quality of life scores, had reduced lower urinary tract symptoms and no side effects were detected (Bettuzzi et al 2006). An update for this trial was undertaken 2 years later to see if the prostate cancer was merely delayed rather than prevented in the green tea group. Half the original subjects (equal numbers from placebo and green tea cohorts) agreed to further investigations which detected one more tumour in the GTC group and two more in the placebo group. These results suggest that GTC given for a year may offer long-term protection within this at-risk group and might be useful as first line preventative therapy

In contrast, a small study testing green tea (6 g/day) in patients with pre-existing androgen independent prostate cancer found little effect on prostate specific antigen (PSA) levels (Jatoi et al 2003). Similar results were obtained in a small study of 19 patients with hormone refractory prostate cancer given a lower dose of 250 mg capsules of green tea twice a day (Choan et al 2005). It is likely that this last study did not use a green tea treatment with sufficient concentrations of catechins.

Cardiovascular protection

Epidemiological studies suggest that green tea consumption is associated with a reduced risk of cardiovascular disease (Maeda et al 2003). A 2000 prospective cohort study of 8552 people in Japan found that those consuming more than 10 cups/day, compared with those consuming fewer than three cups, had a decreased relative risk of death from cardiovascular disease (Nakachi et al 2000). The Ohsaki National Health Insurance Cohort Study was a population-based study in Japan, spanning

11 years (1995–2005) with 40,530 Japanese adults aged 40–79 years. At baseline, no participants had cancer or coronary heart disease. The study identified an inverse association between green tea consumption and mortality due to cardiovascular disease (especially mortality due to stroke) as well as all other causes. A significant protective effect was shown at a dose of five cups or more daily for men and three or more cups daily for women. Overall, the protective effects were greatest for women compared to men (Kuriyama et al 2006). The investigators suggested higher smoking levels in men may have reduced potential benefits in this group (Cheng 2007). A review of the literature looking at green tea and stroke prevention suggested that epidemiological studies in countries where green tea consumption was prevalent showed promising results. Further clinical trials were recommended to confirm the findings (Fraser et al 2007).

Lipid lowering

A meta-analysis evaluating the association between cardiovascular risk and flavonoid-rich nutrients drew from four studies to conclude that green tea reduced LDL cholesterol (between 0.12 and 0.34 mmol/L) (Hooper et al 2008). A significant reduction in LDL cholesterol and triglycerides and marked increase in HDL cholesterol was also found for green tea consumption (400 mg given three times daily) in a double-blind, placebo, RCT of 78 obese women conducted over 12 weeks (Hsu et al 2008). Similar results were obtained in an early cross-sectional study involving 1371 men aged over 40 years (Imai & Nakachi 1995). The study showed that increased green tea consumption was associated with decreased serum concentrations of total cholesterol and triglyceride and an increase in HDL, together with a decrease in LDL and very low density lipoproteins (VLDL) cholesterols.

In contrast, the inclusion of 3 g/day of green tea to a cholesterol lowering diet provided no further lipid lowering effects according to a study of 100 hypercholesterolaemic patients (Bertipaglia de Santana et al 2008). Whilst green tea increased antioxidant potential there was no significant reduction in any cholesterol parameters.

Dental caries and gingivitis

Green tea extract tablets and chewable oral preparations have been investigated for effects on dental plaque formation and gingival health under RCT conditions, overall producing favourable results (Liu & Chi 2000).

A double-blind study investigated the effects of GTCs and polyphenols on the gingiva when used in the form of chewable oral sweets (Krahwinkel & Willershausen 2000). Compared with placebo, the green tea product chewed eight times a day significantly decreased gingival inflammation and improved periodontal structures before the 21-day test period was complete.

Another study investigated Chinese green tea polyphenol tablets for effects on plaque formation in 150 volunteers (Liu & Chi 2000). The randomised, controlled crossover study showed that green tea polyphenol tablets used for 2 weeks were able to reduce the plaque index compared with placebo treatment.

Sunburn protection

More than 150 in vitro and in vivo studies have reported the benefits of green tea for the skin (Hsu 2005). Many mechanisms appear to be responsible; green tea protects against UV and psoralen + ultraviolet A (PUVA)-induced carcinogenesis and DNA damage and is a potent antioxidant, anti-inflammatory, anticarcinogenic and vulnerary (Hsu 2005). Research with human volunteers has found that topical application of green tea to skin half an hour before UV exposure protects against the development of sunburn and epidermal damage (Elmets et al 2001). The effect is dose dependent and strongest for the epigallocatechin gallate and epicatechin gallate polyphenols.

Weight loss

Animal studies have found that green tea consumption reduces food intake, decreases leptin levels and body weight and increases thermogenesis. However, little clinical evidence is available to determine whether similar effects are seen in humans (Sayama et al 2000).

Clinical studies investigating the effects of green tea on weight loss have produced mixed results.

One open study found that a green tea extract AR25 (80% ethanolic dry extract standardised at 25% catechins) taken by moderately obese patients resulted in a 4.6% decrease in body weight and 4.5% decrease in waist circumference after 3 months' treatment (Chantre & Lairon 2002). Both groups lost the same amount of weight and displayed similar metabolic parameters at the end of the study period. An RCT study in Thailand was undertaken over 12 weeks with 60 obese individuals all given a similar diet of three meals a day with 65% carbohydrates, 15% protein and 20% fat. There was no significant difference in weight loss at week 4 but at weeks 8 and 12 weight reduction was significantly greater in the green tea group than the placebo group. The difference in weight loss between the groups was 2.70 kg at 4 weeks, 5.10 kg at 8 weeks and 3.3 kg at 12 weeks. Researchers suggested the effects were due to changes in resting energy expenditure and fat oxidation (Auvichayapat et al 2008). However, two other studies produced negative findings. One double-blind, placebo-controlled parallel trial, with 46 women attempting a weight-loss program over 87 days, showed no difference between the green tea group and the placebo group (Diepvens et al 2005). Another double-blind, placebo, RCT, with 78 obese women, also showed no significant difference in body weight, body mass index (BMI) or waist circumference after taking a green tea extract capsule of 400 mg three times a day for 12 weeks (Hsu et al 2008).

Liver disease

A systematic review of 10 studies showed that increased green tea consumption is associated with a reduced risk of liver disease. The studies were published between the years 1995 and 2005, with

numbers of subjects ranging from 52 to 29,090. Of the 10 studies, four were RCTs, two cohort, one case–control and three cross-sectional studies. Among them, eight studies were conducted in China, one in Japan and the other in the USA. Most of the studies used adjustments such as age, sex, smoking, drinking to control potential confounders and the study periods varied from less than 6 months to more than 6 years. Eight studies yielded statistically significant results showing a protective role of green tea against liver disease whereas two studies only showed a partial tendency. Also, four studies showed a positive association between green tea intake and attenuation of liver disease. When considering the protective effects of green tea against subgroups of liver diseases, it seems that they are more effective in fatty liver disease and liver disorders than in liver cancer as two studies involving liver cancer did not show a significant protective effect (Jin et al 2008). Despite these promising results, more rigorous double-blind studies are still required to confirm the results as the studies used in the review were heterogeneous and differed in the design, outcome, tea dosage and other aspects.

OTHER USES

Green tea has many other uses, based on results of animal or in vitro tests or on the known pharmacological activity of constituents such as tannin and caffeine. Some of these other uses are treatment of diarrhoea, Crohn's disease, dyspepsia and other digestive symptoms, promoting alertness and cognitive performance, reducing symptoms of headache and promoting diuresis.

Colitis

Animal studies have shown anti-inflammatory activity in colitis (Varilek et al 2001, Westphal et al 2008).

Dementia/cognitive impairment

Several in vivo studies have demonstrated memory improvement in older animals for green tea extract and improvements in spatial cognition learning ability after long-term administration of GTCs (Haque et al 2006, Kaur et al 2008). A community-based self-administered questionnaire of 1003 Japanese geriatric people found that greater ingestion of green tea was associated with lower cognitive impairment (Kuriyama et al 2006). Green tea intake was significantly associated with better cognitive performance in a 2-year follow-up study of Japanese elderly (Hasegawa et al 2005).

Beta-thalassaemia

An in vitro research shows green tea chelates iron which should be investigated further to determine whether there are benefits in the management of iron overload in conditions such as beta-thalassaemia (Srichairatanakool et al 2006).

Renal failure

Green tea extract blocks the development of cardiac hypertrophy in experimental renal failure and reduces oxidative stress, according to the results of investigation with animal models (Priyadarshi et al 2003, Yokozawa et al 1996).

Urinary stones

Two in vivo and in vitro studies have shown that green tea's antioxidant action may inhibit kidney stone formation (Itoh et al 2005, Jeong et al 2006).

Diabetes

Animal studies have identified that green tea polyphenols reduce serum glucose levels and improve kidney function in diabetes (Sabu et al 2002, Rhee et al 2002). Other in vivo studies have confirmed that green tea may have a therapeutic use in diabetes (Juskiewicz et al 2008). However, one animal study found that fasting blood glucose levels were increased in diabetic rats fed green tea (Islam & Choi 2007). Evidence from human trials has been contradictory. One double-blind RCT with 49 individuals with type 2 diabetes mellitus found no significant hypoglycaemic effects for green tea given at 375 mg or 750 mg/day (MacKenzie et al 2007). Another RCT of 66 diabetic patients found 500 mg/day of green tea polyphenols had no clear effect on blood glucose or insulin resistance markers (Fukino et al 2005). An epidemiological study of 542 men and women, aged over 65 years, from the Mediterranean islands found that tea consumption (green and black) was associated with reduced levels of fasting glucose but this was only in the non-obese subjects (Polychronopoulos et al 2008).

Genital warts

A number of recent trials have shown good effectivity for a topical treatment (Polyphenon E by Medigene EU) containing a fixed amount of GTCs in the treatment of genital warts. The product is marketed as Veregen™ in the USA.

Healing of genital warts occurred in 54.9% of patients using Polyphenon E ointment compared with 35.4% of patients receiving placebo in three placebo clinical studies of 1400 patients (Gross 2008). Another trial with the same Polyphenon E topical treatment evaluated 503 patients, with external genital and perianal warts, who were randomised to be treated with a 15% or 10% ointment or a placebo. Treatment was applied three times a day for up to 16 weeks. After follow-up, 12 weeks later, 53% of patients with the 15% strength ointment had complete clearance, 51% for the 10% ointment and 37% for the control vehicle. A greater number of women experienced total clearance of all warts (with the Polyphenon E treatment compared to men, 60% compared to 45% [Stockfleth et al 2008]) Another double-blind, placebo, RCT, with 502 patients with genital and perianal warts used a topical treatment of sinecatechins (a defined green tea extract), which was found to be effective and well tolerated. The findings were significant at weeks 4, 6 and subsequent visits over the 16-week trial. Complete clearance of warts was obtained in 57% of patients compared with only 33% with the control group (Tatti et al 2008).

DOSAGE RANGE

The dose varies depending on the indication it is being used for. Some research suggests 8–10 cups of green tea/day are required for effects whereas others indicate only 3–5 cups of green tea/day are required. It is likely the dose also depends on the quality of the green tea and the concentration of GTCs in the preparation.

- For external genital and perianal warts: Polyphenon E 15% strength ointment applied three times daily.
- For reduced risk of cancers: five or more cups daily.
- For cardiovascular disease protection: 3–10 cups daily.

ADVERSE REACTIONS

Due to the caffeine content of the herb, CNS stimulation and diuresis are possible when consumed in large amounts.

One clinical study found an absence of any severe adverse effects when 15 green tea tablets were taken daily (2.25 g green tea extracts, 337.5 mg EGCG and 135 mg caffeine) for 6 months (Fujiki et al 1999). One trial with high-dose green tea (600 mg/day) reported adverse effects in 69% of the patients with a range of adverse effects including insomnia, fatigue, nausea, vomiting, diarrhoea, abdominal pain and confusion (Jatoi et al 2003).

SIGNIFICANT INTERACTIONS

Controlled studies are not available for green tea, so interactions are speculative and based on evidence of pharmacological activity. Therefore, clinical significance is unknown.

Anticoagulants

Antagonistic interaction — a case of excessive consumption (2.25–4.5 L of green tea/day) was reported to inhibit warfarin activity and decrease the international normalised ratio (INR) (Taylor & Wilt 1999). Exercise caution with intake of large quantities of green tea.

Hypoglycaemic agents

Caffeine-containing beverages can increase blood sugar levels when used in sufficient quantity (200 mg of caffeine); however, hypoglycaemic activity has been reported for green tea, which could theoretically negate this effect (Ulbricht & Basch 2005) — the outcome of this combination is uncertain, therefore observe patient.

Iron

Tannins found in herbs such as *Camellia sinensis* can bind to iron and reduce its absorption — separate doses by at least 2 hours. Protein and iron have also been found to interact with tea polyphenols and decrease their antioxidant effects in vitro (Alexandropoulou et al 2006). The clinical significance of this is as yet unknown.

CNS stimulants

Based on the caffeine content of the herb, high intakes of green tea can theoretically increase the CNS stimulation effects of drugs such as nicotine and beta-adrenergic agonists (e.g. salbutamol); however, the clinical significance of this is unknown — observe patient.

CNS depressants

Based on the caffeine content of the herb, high intakes of green tea can theoretically decrease the CNS depressant effects of drugs such as benzodiazepines; however, the clinical significance of this is unknown — observe patient.

Bortezomib (BZM) and other boronic acid-based proteasome inhibitors

EGCG was tested in vitro and in vivo to investigate whether combining it with the proteasome inhibitor BZM, commonly used in the treatment of multiple myeloma, would result in an increase in the drugs antitumour activity (Golden et al 2009). Green tea extract almost completely blocked the effects of BZM both in vitro and in vivo — avoid.

Diuretics

Based on the caffeine content of the herb, high intakes of green tea can theoretically increase the diuretic effects of drugs such as frusemide; however, the clinical significance of this is unknown — observe patient.

Drugs metabolised by CYP1A2

The inhibitory effect of caffeine on CYP1A2 may cause other interactions, but this is speculative for green tea. A small trial with 42 volunteers giving 800 mg of green tea a day suggested that drugs metabolised by the CYP enzymes were unlikely to be significantly affected (Chow et al 2006).

CONTRAINDICATIONS AND PRECAUTIONS

Excessive intake will increase the likelihood of adverse effects due to the caffeine content and therefore is not recommended for people with hypertension, cardiac arrhythmias, severe liver disease, anxiety disorders or insomnia.

PREGNANCY USE

Usual dietary intakes appear safe; however, excessive use is not recommended due to the caffeine content of green tea.

PATIENTS' FAQs

What will this herb do for me?

Green tea has strong antioxidant effects and some population studies suggest that regular consumption may reduce the risk of cancer and cardiovascular disease. Early research has found it may be useful for sunburn protection, reducing dental plaque formation, colitis, diabetes, renal disease, improving memory and cognition and as an antiseptic. However, further research is required.

When will it start to work?

This will depend on the reason it is being used. Preventative health benefits are likely to take several years of regular daily tea consumption. Effects on

PRACTICE POINTS/PATIENT COUNSELLING

- Green tea is made from the same plant as black tea, but it contains greater amounts of polyphenols and generally less caffeine.
- Green tea has been found to have significant antioxidant activity and protects against sunburn when applied topically.
- It has antibacterial activity and is used in oral preparations to reduce plaque and improve gingival health.
- Several in vitro and animal studies have shown anticarcinogenic activity for a range of cancers and some epidemiological evidence further suggests cancer protective effects may occur; however, further research is required. Patients with a high risk of prostate or liver cancer (due to hepatitis B) may benefit from regular green tea drinking.
- Epidemiological evidence suggests green tea may reduce cardiovascular disease especially stroke risk and LDL cholesterol.
- Preliminary evidence from animal studies has shown that it increases thermogenesis, decreases appetite, reduces inflammation in colitis, reduces glucose levels in diabetes, may be useful in renal failure, and has potential to improve cognitive function in the elderly and be used in Alzheimer's and Parkinson's diseases.
- It is not known whether the use will promote weight loss in humans as research results are inconsistent.
- A proprietary ointment made from a fixed concentration of GTCs is effective in the treatment of genital warts.

oral health care appear to develop more quickly, within 2 weeks.

Are there any safety issues?

Research suggests that green tea is a safe substance when used in usual dietary doses, but excessive consumption may produce side effects, chiefly because of the caffeine content.

Guarana

HISTORICAL NOTE Guarana has been used by the Amazonian Indians of South America for centuries to enhance energy levels, suppress appetite, increase libido and protect them from malaria. More recently, hot guarana beverages have been adopted by the greater population as a tonic to enhance wellbeing, in much the same way coffee is drunk in Australia.

COMMON NAME
Guarana

OTHER NAMES
Brazilian cocoa, guarana gum, guarana paste, quarana, quarane, uabano, uaranzeiro, zoom

BOTANICAL NAME/FAMILY
Paullinia cupana (family Sapindaceae)

PLANT PART USED
Seeds

CHEMICAL COMPONENTS
Guarana seeds are a rich source of caffeine, containing 3–6% on a dry weight basis (Saldana et al 2002). Other major compounds include theobromine, theophylline, tannins, resins, protein, fat and saponins (Duke 2003).

MAIN ACTIONS
A review of the scientific literature reveals that guarana itself has only recently been the subject of clinical studies. As such, studies pertaining to caffeine are sometimes used to explain the herb's action, an approach that presupposes the other constituents are either inactive or of such weak effect they need not be recognised. Although this approach is convenient and provides us with some understanding of the herb's pharmacological effects, the results of four recent clinical studies suggest that guarana's effects on cognitive function are due to more than its caffeine content. It has also been suggested that the effects of guarana are longer lasting than caffeine, possibly due to the saponin and tannin content (Babu et al 2008).

CNS stimulant
Although guarana has not been clinically investigated for its effects on the CNS, there is a great deal of evidence to show that caffeine is an antagonist of the adenosine receptor, which produces a net increase in CNS activity because the inhibitory action of adenosine is blocked (Smith 2002). This results in the release of a variety of neurotransmitters (e.g. noradrenaline, acetylcholine, dopamine, and the GABA/benzodiazepine system).

OTHER ACTIONS

Inhibits platelet aggregation
Guarana inhibits platelet aggregation both in vitro and in vivo (Bydlowski et al 1988, 1991). Decreased thromboxane synthesis may in part explain this activity.

Gastric effects
Guarana may increase gastric acid secretion and delay gastric emptying. This has been demonstrated in a clinical study using a herbal combination known as 'YGD', which contains yerba mate (leaves of *Ilex paraguayensis*), guarana (seeds of *Paullinia cupana*) and damiana (leaves of *Turnera diffusa* var. *aphrodisiaca*) (Andersen & Fogh 2001). Whether stand-alone treatment with guarana will produce similar effects is unknown.

Chemoprotective
Guarana has been shown to be chemoprotective in a mouse hepatocarcinogenesis model (Fukumasu et al 2005). The herb was found to reduce the cellular proliferation of preneoplastic cells. It has also been demonstrated that guarana is protective against chemically induced DNA damage in mouse liver. This effect was attributed to the tannin content of the herb (Fukumasu et al 2006). A later mouse experiment observed a decrease in proliferation and an increase in apoptosis of melanoma lung metastases resulting in a reduction in tumour size (Fukumasu et al 2008).

Antibacterial
In vitro data has demonstrated the antibacterial and antioxidant effects of the ethanolic extract of guarana, thought to be due to the phenolic compounds (Basile et al 2005). Guarana was shown to be effective against many pathogens of the digestive tract including *Escherichia coli*, *Salmonella typhimurium* and *Staphylococcus aureus.* This adds weight to the traditional use of guarana for diarrhoea. More recently in vitro research has demonstrated antibacterial activity against *Streptococcus mutans* which could have applications in preventing dental plaque (Yamaguti-Sasaki et al 2007). Antimicrobial activity was further confirmed in vitro when testing guarana seed extracts against food-borne fungi and bacteria. This may have applications in food preservation (Majhenic et al 2007).

Antioxidant
A strong antioxidant activity has been demonstrated in vitro for guarana seeds (Majhenic et al 2007).

Other actions relating to caffeine content
Although these have not been tested for guarana directly, the caffeine content, which is well absorbed from the herb, may cause mild dilation of the blood vessels; an increase in blood pressure, renin and catecholamine release, urine output, metabolic rate, lipolysis, respiration and intestinal peristalsis; and inhibition of CYP1A2. Caffeine also possesses thermogenic properties (Astrup 2000).

CLINICAL USE

Mood enhancing

For several years anecdotal evidence has suggested that guarana produces similar effects to caffeine on subjective feelings of wellbeing, energy, motivation and self-confidence (Mumford et al 1994). Tests with animal models indicate guarana exerts a mild antidepressant effect thereby providing some support for the observed mood elevating effects (Campos et al 2005, Otobone et al 2007).

Mood elevation was further demonstrated in a recent double blind, placebo-controlled, multi-dose clinical study involving 26 volunteers which tested a low caffeine containing guarana extract (PC-102) (Haskell et al 2007). Four strengths were investigated (37.5 mg, 75 mg, 150 mg and 300 mg). Treatment at each dose level produced a significant effect on mood. As there were low levels of caffeine measured in the guarana extract, mood elevation cannot be explained by the caffeine content alone.

Enhanced cognitive function and alertness

At least six clinical studies have been conducted to investigate whether guarana affects cognitive function, producing mixed results thus far. Four double-blind studies report that guarana has significant effects on cognitive function and provides evidence that these effects are not just mediated by the herb's caffeine content (Haskell et al 2005, Haskell et al 2007, Kennedy et al 2004, Kennedy et al 2008). In contrast, two double-blind studies failed to identify significant effects for guarana on cognitive function (Galduroz & Carlini 1994, 1996).

One double-blind, placebo-controlled study assessed the effects of four different doses of guarana (37.5 mg, 75 mg, 150 mg, and 300 mg) in 22 subjects (Haskell et al 2005). Cognitive performance and mood were assessed at baseline and again 1, 3 and 6 hours after each dose using the Cognitive Drug Research computerised assessment battery, serial subtraction tasks, a sentence verification task and visual analogue mood scales. All doses improved picture and word recognition, results on the Bond–Lader visual analogue scales and caffeine research visual analogue scales showing improvements in alertness and reduced ratings of headache. The two lower doses produced better results than the two higher doses, which were associated with impaired accuracy of choice reaction and one of the subtraction tests. Several observations suggest that these effects were not due to caffeine alone. Firstly, effects were still apparent 6 hours after administration and secondly, better results were obtained with a dose of 37.5 mg than 300 mg with a caffeine content of less than 5 mg in the lowest dose. The study was replicated 2 years later, with a double-blind, counterbalanced, placebo-controlled study (Haskell et al 2007). In this study, 26 participants were given the same four doses of a standardised guarana extract. All doses improved mood however cognitive improvements were greatest for the two lower doses, with the 75 mg dose most effective. As there was only 9 mg of caffeine in this dose it is unlikely that the effects can be attributed solely to the caffeine content.

Another double-blind, placebo controlled study investigated the effects of a single dose of guarana (75 mg) on cognition, in combination with and in comparison to ginseng (*Panax ginseng* 200 mg) in 28 healthy volunteers (Kennedy et al 2004). Guarana was shown to produce comparable effects to ginseng in improved task performance with all three treatments better than placebo. However, guarana was superior to ginseng in improving the speed of performed tasks. Once again, given the low caffeine content (9 mg) of the guarana extract used in this study, the effects are unlikely to be attributable to its caffeine content alone, particularly as the dose was shown to be as effective as a 16-fold dose of pure caffeine. A later double-blind, randomised, placebo-controlled study of 129 adults tested a multi-vitamin and mineral supplement with added guarana (Berocca Boost with 222 mg guarana and 40 mg caffeine) and found it supported the previous findings that guarana improves cognitive performance. A single dose of the supplement also reduced mental fatigue after sustained mental effort (Kennedy et al 2008).

Two other randomised, double-blind studies have investigated the effects of guarana on cognitive function (Galduroz & Carlini 1994, 1996). One study involving 45 healthy elderly volunteers found that guarana treatment was ineffective (Galduroz & Carlini 1996), which confirmed the findings of a previous study conducted by the same authors (Galduroz & Carlini 1994). Studies in some animal models have produced positive results for both single-dose and long-term administration of guarana, observing a positive effect on memory acquisition and memory maintenance (Espinola et al 1997).

Ergogenic aid

Guarana is also used as an ergogenic aid by some athletes, most likely because caffeine and theophylline have been used in this way, to improve performance in training and competition (Graham 2001). No human studies testing guarana for effects on physical performance could be located. Referring to caffeine studies, it appears that ergogenic effects are observed under some conditions but not under others (Doherty et al 2002, Hunter et al 2002, Ryu et al 2001). Testing guarana in several animal models has also produced contradictory results. Significant increases in physical capacity have been observed with a dose of 0.3 mg/mL of a guarana suspension after 100 and 200 days' treatment. However, the same effect was not seen with a concentration of 3.0 mg/mL nor with a solution of caffeine 0.1 mg/mL (Espinola et al 1997).

Appetite suppressant and weight loss aid

Weight-loss products often contain guarana, in the belief that it suppresses appetite and may have thermogenic and diuretic activities. An animal study designed to evaluate the effects of guarana and decaffeinated guarana found that only the caffeinated herb was effective for weight loss (Lima et al 2005).

To date, most clinical studies have investigated the effects of guarana in combination with other herbs.

In combination

A double-blind RCT testing a combination of yerba mate (leaves of *Ilex paraguayensis*), guarana (seeds of *Paullinia cupana*) and damiana (leaves of *Turnera diffusa* var. *aphrodisiaca*) found that the preparation significantly delayed gastric emptying, reduced the time to perceived gastric fullness and induced significant weight loss over 45 days in overweight patients (Andersen & Fogh 2001).The same herbal combination (Zotrim) was tested in an open study of 73 overweight health professionals, over six weeks. Active treatment resulted in a significant reduction in self-reported weight and waist and hip measurements, and increased satiety after meals. Significant weight loss was reported by 22% of volunteers.

Another randomised double-blind placebo-controlled trial evaluated the effects of guarana in combination with Ma Huang (*Ephedra* spp) and concluded that the formula was effective for weight loss in overweight men after 8 weeks of treatment (Boozer et al 2001). A more recent double-blind, placebo-controlled, randomised study tested a multi-component herbal combination containing extracts from asparagus, green tea, black tea, guarana, mate, kidney beans, Garcinia cambogia and chromium yeast and found that over a 12-week period there was a significant change in the Body Composition Improvement Index and decreased body fat compared to placebo (Opala et al 2006). The formula was more effective for those participants who were undertaking an exercise program at the same time than for those who remained sedentary.

A short-lived increase in metabolic rate was observed in a small double-blind, placebo-controlled, crossover study of 16 healthy subjects (Roberts et al 2005). A product containing primarily black tea (*Camellia sinensis*) and guarana extract providing 36% caffeine (plus vitamin C and some other trace nutrients and herbs) increased metabolic rate after 1 hour with no significant difference at the 2 hour check.

Although encouraging, the effects of guarana as a stand-alone treatment need to be confirmed.

OTHER USES

Traditionally, guarana has been used as an aphrodisiac, a treatment for diarrhoea, a diuretic and as a beverage in some cultures.

DOSAGE RANGE

According to clinical trials

- Cognition, alertness and mood: doses between 37.5 and 75 mg are sufficient to provide effects for at least 6 hours.
- For other indications, guarana has not been significantly researched. Based on its caffeine content, it is advised that doses should not exceed that amount that will provide approximately 250 mg of caffeine daily. This is equivalent to 2.5–4 g guarana/day, depending on the caffeine content of the preparation.

TOXICITY

Animal tests have shown that high doses of 1000–2000 mg/kg (intraperitoneal and oral) do not induce significant alterations in parameters for toxicological screening, suggesting an absence of toxicity (Mattei et al 1998).

ADVERSE REACTIONS

Due to a lack of clinical studies testing guarana as a stand-alone treatment, it is difficult to determine what adverse reactions may exist.

Based on caffeine content, the following adverse effects may theoretically occur at high doses: agitation, tremor, anxiety, restlessness, headache, seizures, hypertension, tachycardia and premature ventricular contractions, diarrhoea, gastrointestinal cramping, nausea and vomiting and diuresis.

SIGNIFICANT INTERACTIONS

Controlled studies are not available, therefore interactions are theoretical and based on evidence of pharmacological activity with uncertain clinical significance.

Clinical note — Popular energy drinks and caffeine content

Adolescents in particular are high consumers of energy drinks with a reported 30% of teens in the US using these drinks in 2006 (Babu et al 2008). They often contain a mixture of caffeine, guarana, taurine, other herbs and vitamins. According to product labels and websites, the following drinks contain varying amounts of caffeine:

Coca Cola	34 mg per 355 mL can
Diet Coke	45.6 mg per 355 mL
Diet Pepsi	36 mg per 355 mL
Diet Pepsi Max	69 mg per 355 mL
Red Bull	80 mg per can
Mother	80 mg per 250 mL
V	78 mg per 250 mL
Brewed coffee	100 mg per cup

A large intake of these drinks can produce adverse effects based on their caffeine content such as headache, agitation, insomnia, anxiety, tremor, restlessness, seizures, tachycardia, and nausea and other gastrointestinal disturbances. Four independent cases associating high consumption of energy drinks with seizures have been reported (Iyadurai & Chung 2007). It is possible that these four individuals may have been genetically susceptible and the high consumption of these drinks may have reduced the seizure threshold. It has been found that caffeine excess lowers the threshold to seizures so the caffeine content of the energy drink is the most likely cause. A prudent suggestion would be to avoid a high intake of these drinks. There has been one reported case of intractable ventricular fibrillation in a young woman with a pre-existing mitral valve prolapse. This occurred after consuming an energy drink with guarana and high caffeine content (Cannon et al 2001).

Clinical note — Is caffeine safe in pregnancy?

There have been numerous studies investigating the effects of caffeine in pregnancy with inconsistent results. A meta-analysis of 32 case-control or cohort-design studies found that there was a small statistically significant increase in the risk of spontaneous abortion and of low birth weight babies where the pregnant mother consumed more than 150 mg of caffeine per day (equivalent to about 1.5 cups of freshly brewed coffee) (Fernandes et al 1998). Confounders such as maternal age, smoking and alcohol use could not be excluded. More recent studies have produced varying results with one cohort study in Denmark concluding that high levels of coffee consumption were associated with a higher risk of fetal death, especially after 20 weeks (Bech et al 2005). A population-based case-control study in Uruguay also showed a significantly increased risk of fetal death when more than 300 mg caffeine per day is consumed (Matijasevich et al 2006). An increased risk of repeated miscarriage with high caffeine intake was reported in a Swedish study (George et al 2006) and a more recent study found an increased miscarriage risk even allowing for pregnancy-related symptoms (Weng et al 2008). The risk of small-for-gestational-age (SGA), especially for boys, was nearly doubled for mothers with high rather than low caffeine intake in the third trimester (Vik et al 2003).

In contradiction to these findings other studies showed caffeine consumption was unlikely to be a major risk factor for SGA or low birthweight babies (Infante-Rivard 2007), and a systematic review showed no association between moderate caffeine consumption and fetal growth (Pacheco et al 2007). Another large prospective study confirmed that there was no clinical importance demonstrated looking at fetal growth except for women consuming 600 mg caffeine daily (Bracken et al 2003).

It therefore seems prudent that caffeine intake should be avoided or limited throughout pregnancy and that the caffeine content of guarana products should be checked before use.

CNS stimulants

Additive stimulant activity is theoretically possible, so use with caution.

CNS sedatives

Antagonistic effects are theoretically possible due to the herb's CNS stimulant activity. However, one in vivo study found no interaction with pentobarbital. Observe patients taking this combination.

Diuretics

Additive diuretic effects are theoretically possible — use this combination with caution.

Anticoagulants

Increased bleeding is theoretically possible, as in vitro and in vivo research has identified antiplatelet activity for guarana. Use this combination with caution.

Antiplatelet drugs

Additive effects are theoretically possible as in vitro and in vivo research has identified antiplatelet activity for guarana. Observe patients taking this combination.

Digoxin

Long-term use of high-dose supplements can result in reduced potassium levels, which lowers the threshold for drug toxicity. Avoid long-term use of high-dose guarana preparations.

Drugs metabolised by CYP1A2

The inhibitory effect of caffeine on CYP1A2 may cause other interactions, but this is highly speculative for guarana.

CONTRAINDICATIONS AND PRECAUTIONS

Contraindicated in moderate to severe hypertension and cardiac arrhythmias.

Use with caution in anxiety states, hypertension, diabetes, gastric ulcers and chronic headache. Adverse reactions may be dose dependent. Suspend use of concentrated extracts 1 week before major surgery.

Under the World Anti-Doping Code 2007 Prohibited List caffeine is not classified as a prohibited stimulant, unless specified by particular sports. Therefore athletes are recommended to check with their own sports federation about the status of caffeine containing substances.

PREGNANCY USE

The use of caffeine-containing preparations should be limited during pregnancy and breastfeeding as it has the ability to cross the placenta and can be found in breast milk. Caffeine clearance is also delayed in the second and third trimesters with the half-life of caffeine increasing to 10.5 hours from 2.5-4.5 hours in a non-pregnant woman. It also appears that the fetus has a reduced capacity to metabolise caffeine.

PRACTICE POINTS/PATIENT COUNSELLING

- Guarana has mild CNS stimulant properties and increases alertness, cognitive function and mood.
- Current evidence is inconclusive as to whether guarana also enhances physical stamina.
- It has been used in combination with other herbs as a weight-loss aid with some degree of success. However, it is unknown what role guarana played in achieving these results.
- In some sensitive individuals, guarana may produce CNS stimulant-related side effects, such as elevated heart rate and blood pressure, tremor, restlessness and excitability.

PATIENTS' FAQs

What will this herb do for me?

Guarana is a herbal stimulant that increases alertness, cognitive function and possibly mood.

How quickly does it start working?

Effects are expected 1–2 hours after ingestion, although this will vary depending on the individual and the current level of wakefulness.

Are there any safety issues to be aware of?

Used in small amounts, it is likely to have a degree of stimulant activity and decrease fatigue; however, as with all stimulants, excessive use or long-term use can be detrimental to health. Guarana should be used with caution in people with hypertension, anxiety states, gastric ulcers, diabetes and some types of cardiovascular disease. It may also interact with a variety of medicines and therefore it is recommended to consult your healthcare professional if you are currently taking pharmaceutical medication.

Gymnema sylvestre

HISTORICAL NOTE Gymnema has been called the sugar destroyer because the leaf suppresses the ability to taste sweet on the tongue. It has been used to treat diabetes, as well as to aid metabolic control when combined with other herbal medicines.

COMMON NAME
Gymnema

OTHER NAMES
Asclepias geminate, gurmar (sugar destroyer), gemnema melicida, gokhru, gulrmaro, gurmar, gurmara, gurmarbooti, kar-e-khask, kharak, merasingi, meshasringi, masabedda, *Periploca sylvestris*, sirukurinjan

BOTANICAL NAME/FAMILY
Gymnema sylvestre (family Asclepiadaceae)

PLANT PART USED
Leaf

CHEMICAL COMPONENTS
Gymnema contains gymnemasaponins, gymnemasides, gymnemic acids and gypenosides (Duke 2003), oleanane-type triterpenic acid (Peng et al 2005) and flavonol glycosides (Liu et al 2004), as well as a range of nutrients, including ascorbic acid, beta-carotene, chromium, iron, magnesium and potassium. The main active chemical components appear to be the gymnemic acids, gymnemasaponins and the polypeptide gurmarin.

MAIN ACTIONS

Sweet-taste suppression
The constituent, gymnemic acid, inhibits the ability to taste sweetness in animal models (Fushiki et al 1992, Harada & Kasahara 2000, Kurihara 1969, 1992) and humans (Frank et al 1992). In humans, the administration of 5 mmol/L gurmarin to the tongue raised the threshold ability to taste sucrose from 0.01 mol/L to 1 mol/L for several hours. It is suggested that gurmarin acts on the apical side of the taste cell, possibly by binding to the sweet taste receptor protein (Miyasaka & Imoto 1995).

Antidiabetic
Gymnema's antidiabetic activity appears to be due to a combination of mechanisms, including reduction of intestinal absorption of glucose (Shimizu et al 2001), inhibition of active glucose transport in the small intestine (Yoshioka 1986), suppression of glucose-mediated release of gastric inhibitory peptide (Fushiki et al 1992), increased activity of the enzymes responsible for glucose uptake and use (Shanmugasundaram et al 1983), stimulation of insulin secretion (Persaud et al 1999, Sugihara et al 2000) and increasing the number of islets of Langerhans and number of pancreatic beta cells (Prakash et al 1986, Shanmugasundaram et al 1990). *Gymnema montanum* (a related species) has also been shown to have antidiabetic, antiperoxidative and antioxidant effects in diabetic rats (Ananthan et al 2003) and antioxidant activity evident in the liver, kidney (Ananthan et al 2004) and brain tissues (Ramkumar et al 2004).

Animal studies suggest that gymnema will reduce blood sugar levels in response to a glucose load in streptozotocin-induced mildly diabetic rats (Okabayashi et al 1990) and alloxan-induced diabetic rats (Shanmugasundaram et al 1983, Srivastava et al 1985), but will not affect blood sugar levels in normal or spontaneously hypertensive rats (Preuss et al 1998). Gymnema extract has been found to return blood sugar and insulin levels to normal in streptozotocin-induced diabetic rats after 20–60 days and to double the number of pancreatic islet and beta cells (Shanmugasundaram et al 1990), as well as maintain stable blood glucose levels in rats given beryllium nitrate (Prakash et al 1986). A recent experimental rat model using streptozotocin to induce type 1 diabetes found that a standardised extract of gymnema, containing 70% of gymnemic acids, produced a significant decrease in blood sugar levels progressing for each of the 3 weeks of the experiment (Jain 2006).

There are currently two negative studies. One study using a dose of 120 mg/kg/day oral gymnema did not find improvements in insulin resistance in insulin-resistant, streptozotocin-induced diabetic rats (Tominaga et al 1995) and the other study, from Brazil using dried powdered leaves of gymnema, found no effect on blood glucose, body weight or food or water consumption in non-diabetic and alloxan-diabetic rats (Galletto et al 2004).

Gymnemic acids have demonstrated hypoglycaemic activity in dexamethasone-induced hyperglycaemic mice (Gholap & Kar 2005) and gymnema, together with other Ayurvedic herbs, has been shown to have hypoglycaemic activity in streptozotocin-induced diabetic mice (Mutalik et al 2005) and rats (Babu & Prince 2004). Gymnema has also been shown to protect the lens against sugar-induced cataract by multiple mechanisms (Moghaddam et al 2005) and protect against the adverse effects of lipid peroxidation on brain and retinal cholinesterases, suggesting a use in preventing the cholinergic neural and retinal complications of hyperglycaemia in diabetes (Ramkumar et al 2005).

Used in combination
A combination of gymnema, *Acacia catechu* and *Pterocarpus marsupium* was found to significantly elevate serum insulin levels in an animal model (Wadood et al 2007). The effect was thought to be due to beta cell regeneration. A polyformula of 18 herbs (Diabegon), including gymnema, was administered to rats resulting in improvement in insulin resistance and

dyslipidaemia (Yadav et al 2007). Another polyherbal formula (Diakyur) also demonstrated significant hypoglycaemic activity and antilipidperoxidative effect (Joshi et al 2007). Whilst these studies demonstrate the success of these specific herbal formulas, it is unclear what role gymnema had in producing these results.

Reduces cholesterol levels

Gymnema extract reduces fat digestibility and increases faecal excretion of cholesterol, neutral sterols and acid steroids, as well as reducing serum cholesterol and triglyceride levels, according to two animal studies (Nakamura et al 1999, Shigematsu et al 2001). Nakamura et al also found that oral administration of gymnema decreased body weight and food intake.

Antimicrobial, antibacterial and antiviral

The ethanolic extract of *Gymnema sylvestre* leaves demonstrated antimicrobial activity against *Bacillus pumilis*, *B. subtilis*, *Pseudomonas aeruginosa* and *Staphylococcus aureus* (Satdive et al 2003). This finding was confirmed in a later in vitro study which found that gymnemic acid extract exerted strong antibacterial activity against *Bacillus subtilis*, *Staphylococcus aureus*, *Klebsiella pneumoniae*, *Pseudomonas aeruginosa*, *Escherichia coli* and *Salmonella typhi* (Poonkothai et al 2005). Antiviral activity has also been reported (Porchezhian & Dobriyal 2003). A larvicidal effect has also been demonstrated for a 5% concentration of aqueous extract of *Gymnema sylvestre* leaves against *Culex quinquefasciatus* larvae (Gopiesh 2007). The treatment was 100% effective.

OTHER ACTIONS

Gymnema has been found to contain an ATPase inhibitor, which has been shown to block the effect of ATPase from snake venom (Manjunatha & Veerabasappa 1982). According to one animal study, oral administration of gymnema reduces body weight and food intake (Nakamura et al 1999). A significant anti-inflammatory activity was discovered for an aqueous extract of gymnema leaves, which was comparable to that of the drug phenylbutazone in a carrageenan-induced paw oedema animal model (Malik 2008).

CLINICAL USE

Sweet-taste suppression and weight loss

A controlled trial of normal volunteers found that an aqueous gymnema extract with concentrated gymnemic acid reduced sweetness perception by 50%, resulting in reduced caloric consumption 1.5 hours after the sweetness-numbing effect stopped (Brala & Hagen 1983). This result supports the findings of animal studies. In a 6-week randomised, double-blind, placebo-controlled study, a multiherbal formula that included gymnema was found to significantly reduce body weight and fat loss in obese adults after 6 weeks (Woodgate & Conquer 2003); however, the role of gymnema in achieving these results is unknown. A double-blind, placebo-controlled, RCT compared (−)-hydroxycitric acid (HCA-SX) with HCA plus a combination of chromium and *Gymnema sylvestre* extract. In this study, a group of 29 volunteers, in the obese BMI range, were divided into three groups and given the supplements or placebo for 8 weeks and all subjects were provided with a 2000 kcal diet per day and a supervised 30-minute walk for 5 days each week. The study combined data from two previous double-blind, placebo-controlled RCTs and reported that both the HCA-SX group and, to a greater degree, the group with the added chromium and gymnema experienced weight loss, decreased appetite, improvement in blood lipids, higher serum leptin and serotonin levels plus an increase in fat oxidation (Preuss et al 2005).

Type 1 and type 2 diabetes

Orally, gymnema leaf is used to treat both type 1 and type 2 diabetes and hyperglycaemia. There are two clinical trials that suggest that gymnema may be useful in reducing blood glucose levels in both type 1 and type 2 diabetes. In one study, the ability of the GS4 extract (400 mg/day) to supplement the use of conventional oral hypoglycaemic agents (glibenclamide or tolbutamide) was studied in 22 patients with type 2 diabetes over 18–20 months. Treatment resulted in a significant reduction in fasting blood glucose (174 ± 7 vs 124 ± 5 mg/dL), HbA_{1c} (11.91 ± 0.3 vs 8.48 ± 0.13%) and glycosylated plasma protein levels (3.74 ± 0.07 vs 2.46 ± 0.05 microgram hexose/mg protein) and raised insulin levels, whereas no changes were observed in the control group. This allowed for a decrease in conventional drug dosage and in five cases, blood glucose homeostasis was maintained with GS4 alone, suggesting that beta-cell function may have been restored (Baskaran et al 1990). In a second study, 27 patients with type 2 diabetes were treated with 400 mg of an aqueous extract of gymnema in addition to insulin. Insulin requirements were reduced, as were fasting blood sugar levels, HbA_{1c}, glycosylated plasma protein levels and serum lipids (Shanmugasundaram et al 1990).

A small, double-blind, randomised, placebo-controlled trial of a multiherbal Ayurvedic formula containing gymnema showed significantly improved glucose control and reduced HbA_{1c} levels in patients with type 2 diabetes within the 3-month test period (Hsia et al 2004).

A systematic review only found two randomised controlled trials with a mono-preparation of *Gymnema sylvestre* and both were open-label comparative studies so no statistical summary was conducted. The review's findings were limited by the lack of rigorous trials but suggested that gymnema may have a combination of actions that can assist with diabetic complications as well as its aetiology — these effects include anti-inflammatory, weight loss and improving pancreatic beta cell function. As there is no other single drug with such a wide range of actions, gymnema has potential to treat the disease (Leach 2007).

In the light of this comprehensive review of the literature, it seems that gymnema has shown great potential, in trials to date, as a diabetic herbal medication, but more rigorous, well-designed trials are warranted.

Clinical note — Herbs and diabetes
Diabetes has been recognised since ancient times, and as early as 700–200 BC two types of diabetes were recorded in India, one of which was diet related and the other was described as genetic. Diabetes has also been recognised in China for thousands of years, where it is attributed to yin deficiency and treated with an integrated approach that involves more than lowering blood glucose. At least 30 different herbal medicines are used in the management of diabetes and its complications, with several of these having outstanding beneficial potential.

Hypercholesterolaemia and hypertriglyceridaemia

Short-term animal studies have shown that gymnema extracts are able to reduce serum cholesterol and triglyceride levels in experimentally induced hyperlipidaemic rats (Bishayee & Chatterjee 1994) and in spontaneously hypertensive rats (Preuss et al 1998), as well as in humans with type 2 diabetes (Shanmugasundaram et al 1990). These results have not yet been established by long-term studies. A recent rat experiment demonstrated reduced hyperlipidaemia and weight loss without rebound effect after the treatment was withdrawn for 3 weeks (Luo et al 2007).

OTHER USES

Gymnema has been used as a snakebite cure because it inhibits venom ATPase (Manjunatha & Veerabasappa 1982), and has also been used as a leaf paste to treat toe mycosis.

An insecticide against mosquitos may be another use due to its larvicidal properties (Gopiesh et al 2007).

In Ayurvedic medicine, gymnema is used as an antimalarial, digestive stimulant, laxative and diuretic and as a treatment for cough, fever, urinary conditions and diabetes.

DOSAGE RANGE

The typical therapeutic dose of an extract, standardised to contain 24% gymnemic acids, is 400–600 mg/day. When used to regulate blood sugar, gymnema may best be administered in divided doses with meals.

Diabetes

- Liquid extract (1:1): 25–75 mL/week or 3.6–11.0 mL/day.
- 6–60 g/day of dried leaf infusion.

Sweet craving and reducing sweet perception

- Liquid extract (1:1): 1–2 mL dropped onto the tongue and rinsed off — repeat every 2–3 hours as required.

ADVERSE REACTIONS

Theoretically, gastric irritation can occur, because of the saponin content. There are two case reports of hepatotoxicity resulting from the consumption of a weight-loss formula containing gymnema and other herbs, including *Garcinia cambogia*, willow bark, glucomannan, green tea and guarana (Stevens et al 2005). In one study, gymnema was found to have a toxic effect in mice, producing increased lipid peroxidation at doses of 26.8 mg/kg, but was safe and antiperoxidative at doses of 13.4 mg/kg (Gholap & Kar 2005). In another study it was concluded that there was no toxic effect in rats treated with gymnema at doses of more than 500 mg/kg for 52 weeks (Ogawa et al 2004).

SIGNIFICANT INTERACTIONS

Controlled studies are not available; therefore, interactions are based on evidence of activity and are largely theoretical and speculative.

Hypoglycaemic agents and insulin

Gymnema may enhance the blood glucose-lowering effects of insulin and hypoglycaemic agents, and so should be used with caution. In practice, the interaction may be useful, as a reduction in the drug dose could theoretically be achieved under professional supervision.

CONTRAINDICATIONS AND PRECAUTIONS

Blood glucose levels should be monitored closely when used in conjunction with insulin and hypoglycaemic agents.

PREGNANCY USE

There is insufficient reliable information available about the safety of gymnema in pregnancy.

PRACTICE POINTS/PATIENT COUNSELLING

- Gymnema suppresses the ability to taste sweet on the tongue.
- It may be useful as a weight-loss aid.
- Clinical studies have shown that gymnema can be used to help control blood sugar levels in diabetes.
- When used with hypoglycaemic medications, blood sugar levels need to be monitored to prevent hypoglycaemia.
- Preliminary research suggests that it may also have a role in elevated cholesterol and triglyceride levels.

PATIENTS' FAQs

What will this herb do for me?
Gymnema has the uncanny ability to reduce the tongue's perception of sweetness. It can also stabilise blood sugar levels and may be useful as a weight-loss aid.

When will it start to work?
It reduces the taste of sweetness rapidly, lasting for several hours, but effects on blood sugar develop with long-term use.

Are there any safety issues?
Diabetic patients on medication should carefully monitor their blood sugar levels when taking this herb, because it may further reduce levels.

Hawthorn

HISTORICAL NOTE The name 'hawthorn' comes from 'hedgethorn', after its use as a living fence in much of Europe. Dioscorides and Paracelsus praised hawthorn for its heart-strengthening properties and it is also known in TCM. It has since been shown to have many different positive effects on the heart and is a popular prescription medicine in Germany for heart failure (Rigelsky & Sweet 2002).

COMMON NAME
Hawthorn

OTHER NAMES
Aubepine, bianco spino, crataegi (azarolus, flos, folium, folium cum flore [flowering top], fructus [berry], nigra, pentagyna, sinaica boiss), English hawthorn, Chinese hawthorn, fructus oxyacanthae, fructus spinae albae, hagedorn, hedgethorn, maybush, maythorn, meidorn, oneseed hawthorn, shanzha, weissdorn, whitehorn

BOTANICAL NAME/FAMILY
Crataegus laevigata, *C. cuneata*, *C. oxyacantha*, *C. monogyna*, *C. pinnatifida* (family Rosaceae [Rose])

PLANT PARTS USED
Extracts of the leaf and flower are most commonly used, although the fruit (berries) may also be used.

CHEMICAL COMPONENTS
Leaves and flowers contain about 1% flavonoids, such as rutin, quercetin, vitexin, hyperoside, 1–3% oligomeric procyanidins including catechin and epicatechin, triterpenes, sterols, polyphenols, coumarins, tannins (Blumenthal et al 2000). Although the therapeutic actions cannot be attributed to single compounds, the herb has been standardised to flavonoid content (hyperoside as marker) and procyanidins (epicatechin as marker). RP WS 1442 is a hydro-alcoholic extract of hawthorn prepared from leaves and blossoms and standardised to 18.75% oligomeric procyanidins. It has been found that bioequivalent extracts as determined by noradrenaline-induced contraction of isolated guinea pig aorta rings can be obtained using 40–70% ethanol or methanol as the extraction solvent, whereas aqueous extracts had markedly different constituents and pharmacological effects (Vierling et al 2003). In vivo absorption studies found that oral administration of hawthorn phenolic extract resulted in detectable plasma levels of epicatechin whereas no hyperoside and isoquercetin were detected, indicating poor bioavailability of these compounds (Chang et al 2005). A year later the same authors, who used in vitro and in vivo experiments, showed that all three constituents have limited permeabilities and co-occurring extract components seem to have no significant effect on their intestinal absorption (Zuo et al 2006). A recent study investigating another important constituent, vitexin-2"-*O*-rhamnoside, showed that passive diffusion dominates its absorptive transport behaviour, and that the absorption and secretion are mediated by the efflux transport system P-glycoprotein (Xu et al 2008).

MAIN ACTIONS

Cardiovascular effects
The mechanisms of action for hawthorn have been extensively studied in vitro and in vivo. There is good research evidence to support cardiovascular actions that include increasing the force of myocardial contraction (positive inotropic action), increasing coronary blood flow, reducing myocardial oxygen demand, protecting against myocardial damage, improving heart rate variability and stroke volume, as well as hypotensive and anti-arrhythmic effects (Mills & Bone 2000, Garjani et al 2000, Popping et al 1995).

Positive inotrope
One study suggested that phosphodiesterase inhibition may underlie the myocardial action of hawthorn (Schussler et al 1995), whereas a later study found that Crataegus extract's positive inotropic effect is not caused by phosphodiesterase inhibition or a beta-sympathomimetic effect (Muller et al 1999).

Anti-arrhythmic effect and negative chronotropic effect
Crataegus extract blocks repolarising potassium currents in ventricular myocytes, an effect similar to the action of class III anti-arrhythmic drugs, which might be the basis for its observed anti-arrhythmic effects (Muller et al 1999). Hawthorn therefore differs from other inotropic agents, which reduce the refractory period and increase the risk of arrhythmias (Joseph et al 1995). Additionally, hawthorn extract does not cause beta-adrenergic receptor blockade at concentrations which cause negative chronotropic effects (Long et al 2006). A recent study elucidated that the decreased chronotropic effect in rat cardiomyocytes may be mediated via muscarinic receptors (Salehi et al 2009).

Cardioprotective effect
Interestingly, hawthorn treatment modifies left ventricular remodelling and counteracts myocardial dysfunction in animal models of cardiac hypertrophy (Hwang et al 2008). Furthermore, in vitro and in vivo studies on rats report a significant cardioprotective effect during cardiac ischaemia (Al Makdessi et al 1996, 1999, Jayalakshmi & Devaraj 2004, Min et al 2005, Veveris et al 2004). For example, pretreatment with alcohol-based hawthorn extract maintained mitochondrial status, and prevented mitochondrial lipid peroxidative damage and decrease in Kreb's cycle enzymes following induced myocardial infarction in rats (Jayalakshmi et al 2006).

Coronary blood flow

Dose-dependent increases in coronary blood flow have been shown in isolated human coronary arteries and it has been suggested that this is caused by membrane hyperpolarisation of vascular smooth-muscle cells due to potassium channel activation (Siegel et al 1996). When testing hawthorn extract WS 1442 for its effect on relaxation of rat aorta and human mammalian artery, researchers discovered that the extract induces an endothelium dependent, NO-mediated vasorelaxation (Brixius et al 2006).

Much of hawthorn's cardiovascular activity is attributed to its flavonoid constituents (Nemecz 1999) and hawthorn extract is classified as a flavonoid drug in Germany. Studies using isolated guinea pig hearts suggest that the oligomeric procyanidins contribute to the vasodilating and positive inotropic effects of hawthorn (Schussler et al 1995), and ischaemia–reperfusion studies in rats suggest that these compounds are also responsible for cardioprotective effects (Chatterjee et al 1997).

It has been reported that hawthorn extracts prepared from dried leaves and those made from dried berries have similar chronotropic activities and that the extracts may contain multiple dissimilar cardioactive components, because following various chromatographic steps several fractions retained multiple cardiac activities (Long et al 2006).

Several procyanidins have shown ACE inhibition in vitro, in a reversible and non-competitive manner (Uchida et al 1987). Although the original study identifying this activity tested isolated procyanidins from another herb, they are found in relatively high concentration in hawthorn extracts (Murray 1995).

Antioxidant

It has been suggested that the part of the mechanism for hawthorn's cardiovascular protective effects may be due to protection against human LDL from oxidation or indirect protection via maintenance of alpha-tocopherol (Zhang et al 2001), as hawthorn extract has been found to possess antioxidant activity in vitro (Periera et al 2000, Rajalakshmi et al 2000) with effective inhibition of oxidative processes, efficient scavenging of O_2 and possible enhancement of glutathione biosynthesis (Ljubuncic et al 2005). Along those lines newer research shows that ethanolic hawthorn extract restores glutathione and the activity of antioxidant enzymes such as superoxide dismutase, catalase and glutathione peroxidase (Akila & Devaraj 2008).

Hawthorn's free radical scavenging capacity is considered to relate to its total phenolic proanthocyanidin and flavonoid content (Bahorun et al 1996, Rakotoarison et al 1997, Kiselova et al 2006). This is supported by a study that demonstrated that the capacity of hawthorn extracts to inhibit Cu^{2+}-induced LDL oxidation is linked to their content of total polyphenols, proanthocyanidins (global and oligomeric forms), as well as to their content of two individual phenolics: a flavonol, the dimeric procyanidin B2, and a flavonol glycoside, hyperoside (Quettier-Deleu et al 2003). The highest antioxidant activity appears to be found in the flower buds, which are high in proanthocyanidin content, and the leaves, which are high in flavonoid content (Bahorun et al 1994). Recent research has confirmed these findings, with fresh and dried fruits possessing less antioxidant activity and, amongst all other classes of phenols in hawthorn, proanthocyanidins are most clearly related to the antioxidant activity of hawthorn extracts (Froehlicher et al in press). Epicatechin was found to be more efficient as an antioxidant than hyperoside or chlorogenic acid (Bernatoniene et al 2008, Froehlicher et al in press, Sokól-Letowska et al 2007). Bernatoniene et al found that both aqueous and ethanolic hawthorn extracts have antiradical activity, but that the effect displayed by the ethanolic extract was stronger (Bernatoniene et al 2008). Moreover, the radical scavenging properties were higher for both extracts when a combination rather than individual constituents were used (Bernatoniene et al 2008, Sokól-Letowska et al 2007).

Lipid-lowering

The monomeric catechins and oligomeric procyanidins are thought to contribute to a hypocholesterolaemic effect. This may occur through a variety of mechanisms including an upregulation of hepatic LDL receptors, enhanced degradation of cholesterol to bile acids, and suppression of cholesterol biosynthesis (Rajendran et al 1996), as well as inhibition of cholesterol absorption mediated by downregulation of intestinal acyl CoA:cholesterol acyltransferase activity (Zhang et al 2002). Moreover, in mice hawthorn flavonoids increased lipoprotein lipase expression in muscular tissue and decreased it in adipose tissue (Fan et al 2006). Hawthorn extract, when fed to rats on an atherogenic diet (4% cholesterol, 1% cholic acid, 0.5% thiouracil), prevented the elevation of lipids in the serum and heart, and also significantly decreased lipid accumulation in the liver and aorta, thus reversing the rats' hyperlipidaemic conditions (Akila & Devaraj 2008).

A traditional multi-herbal Chinese formula containing hawthorn has been found to prevent experimental hypercholesterolaemia in rats, probably due to its choleretic function (Cheng et al 2004). A different multi-herbal Chinese formula was also found to protect vascular endothelial cells from excess cholesterol in vivo (Tu et al 2003).

Antiviral

The *O*-glycosidic flavonoids and the oligomeric proanthocyanidins exhibited significant inhibitory activity against herpes simplex virus type 1 in vitro (Shahat et al 2002).

Antimicrobial

Hawthorn extracts showed moderate bactericidal activity, especially against gram-positive bacteria *Micrococcus flavus*, *Bacillus subtilis* and *Lysteria monocytogenes*. Hawthorn was ineffective against *Candida albicans* (Tadic et al 2008).

Anti-inflammatory

Flavonoids from hawthorn have demonstrated anti-inflammatory and hepatoprotective activity in vitro and in vivo. It is thought that this is achieved by reducing the release of PGE_2 and NO in vitro, as

well as decreasing the serum levels of the hepatic enzyme markers, reducing the incidence of liver lesions, such as neutrophil infiltration and necrosis, and decreasing the hepatic expression of iNOS and COX-2 in vivo (Kao et al 2005).

A hydro-alcoholic extract from the flower heads of *C. oxyacantha* has also been found to inhibit thromboxane A2 biosynthesis in vitro (Nemecz 1999).

Chemopreventative effects have been postulated after the inhibition of skin tumour formation, a decrease in the incidence of tumour, inhibition of NF-kappa B and suppressed expression of COX 2 and iNOS were detected when using the polyphenol fraction of hot water extracts from dried fruits of *C. pinnatifida* (Kao et al 2007).

A dry extract of leaves and flowers of *C. laevigata* inhibited N-formyl-Met-Leu-Phe (FMLP)-induced superoxide anion generation, elastase release and chemotactic migration in human neutrophils. It also reduced FMLP-induced leukotriene B(4) production and LPS-induced generation of TNF-alpha and IL-8 (Dalli et al 2008).

In a study using 62 male rats no effect on IL-1ss, IL-6, IL-10 and leptin could be detected. However, there was a trend suggesting suppression of IL-2 plasma concentrations (Bleske et al 2007).

Hawthorn fruit has been shown to be protective in experimental models of inflammatory bowel disease in mice with restoration of body weight and colon length, increased haemoglobin count, reduced signs of inflammation, such as infiltration by polymorphonuclear leukocytes and multiple erosive lesions, along with improved survival (Fujisawa et al 2005). In a model of carrageenan-induced rat paw oedema, orally administered hawthorn extract showed dose-dependent anti-inflammatory effects. Compared to an indomethacin dose producing 50% reduction of rat paw oedema, a dose of 200 mg/kg hawthorn extract produced 72.4% of anti-inflammatory activity (Tadic et al 2008).

Radioprotective

A study using mouse bone marrow cells showed that a single intraperitoneal administration of hawthorn extract 1 hour prior to gamma radiation can significantly reduce the frequencies of micronucleated polychromatic erythrocytes and significantly increase the ratio of polychromatic erythrocyte/polychromatic erythrocyte + normochromatic erythrocyte. Such a protective effect against genotoxicity appeared to be related to the antioxidant activity of the extract (Hosseinimehr et al 2007). The significant radioprotective potential of hawthorn was also detected in vitro using human peripheral blood lymphocytes. A reduced incidence of radiation induced micronuclei, reduced levels of lipid peroxidation products and two-fold enhanced apoptosis were observed. A stepwise slow down of cell proliferation was seen as beneficial, thus enabling more time for repair (Leskovac et al 2007).

Protection against ischaemic damage

Hawthorn flavonoids have also been shown to decrease the cytotoxicity of hypoxia to human umbilical vein endothelial cells in vitro (Lan et al 2005), as well as protect against delayed cell death caused by ischaemia/reperfusion brain injury in gerbils (Zhang et al 2004). These effects have been attributed to improving energy metabolism, scavenging oxygen free radicals and inhibiting production of free radicals in ischaemic myocardium (Min et al 2005, Zhang et al 2004).

OTHER ACTIONS

Hawthorn may decrease uterine tone and motility and exert antispasmodic and analgesic effects. The high procyanidin content in the herb provides a theoretical basis for other actions such as anti-allergic and collagen-stabilising effects. Moreover, a hawthorn extract has been shown to produce dose-dependent gastroprotective activity, with the efficacy comparable to ranitidine (Tadic et al 2008).

An aqueous extract of hawthorn leaves exhibited hypoglycaemic activity in streptozotocin-diabetic rats, but not in normal rats, without affecting basal plasma insulin concentrations (Jouad et al 2003). Hawthorn has also been found to have hepatoprotective effects in rats with myocardial infarction, with protection against alterations in tissue marker enzymes of experimentally induced liver injury and a reversal of histological changes (Thirupurasundari et al 2005). A multi-herbal Chinese medicine formula containing hawthorn reversed alcohol-induced fatty liver and liver damage in rats (Kwon et al 2005).

CLINICAL USE

Congestive heart failure

There is considerable experimental and clinical evidence supporting the use of hawthorn as an effective treatment for congestive cardiac failure in patients with slight, mild limitation of activity who are comfortable at rest or with mild exertion (i.e. NYHA class II).

A meta-analysis of rigorous clinical trials of the use of hawthorn extract to treat patients with chronic heart failure (NYHA classes I–III) included eight trials involving 632 subjects. The results of the meta-analysis showed that treatment with standardised hawthorn extracts produced significant improvement in maximal workload, pressure–heart rate product, as well as symptoms such as dyspnoea and fatigue as compared with placebo (Pittler et al 2003). The hawthorn extract most commonly used in these trials was WS 1442, which is standardised to 18.8% oligomeric procyanidins. In some cases, hawthorn extract was used as an adjunct to standard therapy (such as diuretics) and the daily dose ranged from 160 mg to 1800 mg.

A review of the results of 13 clinical trials published from 1981 to 1996, involving over 839 patients, suggests that a daily dose of 900 mg hawthorn extract improves exercise tolerance, anaerobic threshold and ejection fraction, as well as subjective symptoms (Kraft 2000). Studies comparing hawthorn extract LI 132 (Crataegutt novo 450, 1 tablet twice daily) to the ACE inhibitor captopril suggests that the LI 132 extract is comparable in effectiveness to a dose of 37.5 mg captopril, but may be better tolerated (Tauchert et al 1994).

Similarly, a prospective, cohort study involving 952 patients with NYHA stage II heart failure compared the use of the WS 1442 extract of hawthorn either alone or in conjunction with conventional therapy to conventional medication. After 2 years, the hawthorn cohort was found to have similar or more pronounced improvements than the conventional medication group with reduced fatigue, stress dyspnoea and palpitations, along with marked reduction in the use of drugs such as ACE inhibitors, cardiac glycosides, diuretics and beta-blockers (Habs 2004).

In two further double-blind studies of NYHA class II patients, one using the WS 1442 extract in 40 patients (Zapfe 2001) and another using the Rob 10 standardised extract of fresh hawthorn berries in 88 patients (Rietbrock et al 2001), 3 months' treatment with hawthorn led to significantly improved exercise tolerance, reduced subjective symptoms, and was found to be safe and well tolerated. In 2003, another placebo-controlled, randomised, parallel-group, multicentre trial confirmed the efficacy and safety of a standardised extract of fresh berries of *Crataegus oxyacantha* L. and *C. monogyna* Jacq. (crataegisan) in patients with cardiac failure NYHA class II (Degenring et al 2004). This study of 143 patients (mean age 64.8 years) used a dose of 30 drops of the extract taken three times daily for 8 weeks and found a significant increase in exercise tolerance, but no difference in symptoms or blood pressure–heart rate product. Researchers suggested that dyspnoea and fatigue do not occur until a significantly higher wattage had been reached in the bicycle exercise testing and that further improvements were likely to occur if treatment time was extended.

In another RCT of patients with marked limitation of activity, who were comfortable only at rest (NYHA class III), 209 patients received standardised extract WS 1442 at doses of either 900 mg or 1800 mg or placebo in addition to pre-existing diuretic treatment. After 16 weeks, significant dose-dependent improvements in exercise capacity and clinical signs and symptoms were seen with the herbal extract, with patients on the higher dosage experiencing less adverse events such as dizziness and vertigo (Tauchert 2002).

A 2008 Cochrane review of 14 randomised, placebo-controlled, double-blind clinical trials concluded that in patients using hawthorn extract symptoms such as shortness of breath and fatigue significantly improved, exercise tolerance significantly increased, the outcome measure of maximal workload significantly improved and the pressure-heart rate product (index for cardiac oxygen consumption) beneficially decreased. No data on relevant mortality and morbidity such as cardiac events were reported, except for one trial which reported deaths (three in active, one in control) without providing further details (Pittler et al 2008).

A large, international, multicentre, randomised, double-blind, placebo-controlled study investigated the efficacy and safety of WS 1442 extract (900 mg daily) in 2681 patients with NYHA class II or III CHF and reduced left ventricular ejection fraction (LVEF ≤ 35%) over 24 months (Holubarsch et al 2008). The trend for cardiac mortality reduction was not statistically significant. However, in the subgroup with LVEF ≥ 25% WS 1442 significantly reduced sudden cardiac death by 39.7% ($P = 0.025$) in comparison to the placebo group. It seems that WS 1442 can potentially reduce the incidence of cardiac death in patients with less compromised left ventricular function (Holubarsch et al 2008).

A retrospective study, analysing the data from the HERB CHF study in which patients with mild to moderate heart failure (HF) were randomised to 900 mg WS 1442 or placebo, found that patients taking WS 1442 had an increased risk of HF progression (HF death, hospitalisation or increase in diuretics), however, it was also reported that the patients using WS 1442 had already an increased likelihood of HF progression at baseline (Zick et al 2008). In contrast to Holubarsch et al (2008), the authors of this study found that patients with LVEF ≤ 35% who were taking WS 1442 were at significantly greater risk of HF progression than patients in the placebo group (Zick et al 2008).

In an observational cohort study of 212 patients, a homeopathic hawthorn preparation was found to be non-inferior to standard treatment (ACE inhibitor/diuretics) for mild cardiac insufficiency in all parameters except blood pressure reduction (Schroder et al 2003).

As well as being shown to be effective when used alone, hawthorn is effective in reducing symptoms of congestive heart failure when used in combination with other herbs such as camphor. This was demonstrated in an open study of 319 patients (Harder & Rietbrock 1990), as well as in a double-blind study of 190 patients (Schmidt et al 2000).

Commission E supports the use of hawthorn leaf and flower to treat decreased cardiac output (NYHA class II) (Blumenthal et al 2000).

Arrhythmias, hypertension and atherosclerosis

In addition to treating congestive cardiac failure, hawthorn has traditionally been used to treat arrhythmias, hypertension and atherosclerosis, with some evidence to support these uses, although large controlled clinical studies are required (Petkov 1979).

In one double-blind RCT of 92 subjects aged 40–60 years, a hydro-alcoholic extract of Iranian hawthorn (*C. curvisepala* Lind) given three times daily was found to produce a significant decrease in both systolic and diastolic blood pressure after 3 months. Antihypertensive activity was also observed in one uncontrolled study that used hawthorn berry tincture (equivalent to 4.3 g/day of berry) (Mills & Bone 2000), whereas three randomised, double-blind, placebo-controlled clinical trials have shown that a combination of natural D-camphor and an extract from fresh hawthorn berries was effective in treating orthostatic hypotension (Georg Belz & Loew 2003, Hempel et al 2005, Kroll et al 2005). Furthermore, when this combination of natural D-camphor and an extract from fresh hawthorn berries (marketed as Korodin®) was given to hypotensive women in two

randomised, double-blind, placebo-controlled, clinical trials, the treatment led to positive and differential effects on blood pressure and cognitive performance compared to placebo within 5 min (Schandry & Duschek 2008).

One study that focused primarily on mild hypertension compared the hypotensive effect of low dose hawthorn extract (500 mg) and magnesium supplements, individually and in combination, to placebo. Walker et al (2002) found hawthorn treatment significantly reduced resting diastolic blood pressure at week 10 compared with the other groups. In addition, a trend towards a reduction in anxiety was also observed with hawthorn treatment, which is an interesting observation as sedative effects have been observed in animal models.

A recent randomised, placebo-controlled, clinical trial ($n = 79$) focused for the first time on investigating possible hypotensive effects of hawthorn extract (1200 mg daily) in patients with type 2 diabetes while taking their prescription drugs. Hypotensive drugs were used by 71% of the participants with a mean intake of 4.4 hypoglycaemic and/or hypotensive drugs. In general, fat intake met recommendations, whereas sugar intake was higher than recommended, and micronutrient intake was low. The hawthorn group showed significantly greater reduction than the placebo group in mean diastolic blood pressure, but not in systolic blood pressure (Walker et al 2006).

Hyperlipidaemia

Hawthorn fruit extract has been reported to reduce serum lipid levels, as well as to reduce lipid deposits in the liver and aortas of rats (Shanthi et al 1994) and rabbits (Zhang et al 2002) fed a hyperlipidaemic diet. In combination with other traditionally used Chinese herbs, hawthorn has been shown to also reduce serum lipid levels in both animals (He et al 1990, La Cour et al 1995) and humans (Chen et al 1995, Guan et al 1995).

Adjustment disorder

The results of a double-blind trial of 182 people suggest that hawthorn in combination with other herbs such as passionflower and valerian may be beneficial for people with adjustment disorder with anxious mood (Bourin et al 1996). Another double-blind trial of 264 people found that a combination containing *Crataegus oxyacantha* and *Eschscholtzia californica* along with magnesium was effective in treating mild-to-moderate anxiety disorder (Hanus et al 2004).

OTHER USES

As it has a high flavonoid content, hawthorn is also used to strengthen connective tissue, decrease capillary fragility, and prevent collagen destruction of joints and therefore may be beneficial in the treatment of certain connective tissue disorders (Mills & Bone 2000). Hawthorn has been traditionally used as a diuretic and to treat kidney and bladder stones. In practice, it is also used at the first signs of a herpes simplex infection, to prevent lesion formation and halt infection.

DOSAGE RANGE

- Infusion of dried herb: 0.2–2 g three times daily.
- Tincture of leaf (1:5): 3.5–17.5 mL/day.
- Fluid extract (1:2): 3–6 mL/day.
- Dry extract: 900–1200 mg/day.
- Herpes simplex outbreak: 4 mL three times daily at the first sign of infection for a maximum of 2 days.

TOXICITY

No target toxicity to 100-fold the human dose of the WS 1442 extract is defined (Schlegelmilch & Heywood 1994). This is in contrast to inotropic drugs, such as digoxin, which generally have a low therapeutic index. A recent preclinical toxicological assessment for a combination product consisting of hawthorn, passionflower and valerian showed no toxicity at high doses and over a long period of time (180 days) (Tabach et al 2009).

ADVERSE REACTIONS

A systematic review (24 clinical trials, $n = 5577$ patients) concluded that hawthorn extracts (mostly WS 1442, LI 132) were well tolerated at doses between 160 and 1800 mg daily for a duration of 3 to 24 weeks. Overall, 166 adverse events were reported, most of which were mild to moderate. Eight severe adverse effects had been reported with the LI 132 extract. The most frequent adverse effects were dizziness/vertigo ($n = 15$), gastrointestinal complaints ($n = 24$), headache ($n = 9$), migraine ($n = 8$) and palpitation ($n = 11$) (Daniele et al 2006). Similarly, a recent review of 14 clinical trials reported safe use of hawthorn with only infrequent, mild and transient adverse effects such as dizziness, cardiac and gastrointestinal complaints (Pittler et al 2008).

SIGNIFICANT INTERACTIONS

WS 1442 (900 mg daily) was safe to use in patients ($n > 2500$) receiving optimal medication for heart failure (Holubarsch et al 2008). A systematic review (24 clinical trials) on the safety of hawthorn monopreparations found no reports of drug interactions (Daniele et al 2006).

Cardiac glycosides

Hawthorn may theoretically potentiate the effects of cardiac glycosides, as both in vitro and in vivo studies indicate that it has positive inotropic activity. Furthermore, the flavonoid components of hawthorn may also affect P-glycoprotein function and cause interactions with drugs that are P-glycoprotein substrates, such as digoxin. In practice, however, a randomised crossover trial with eight healthy volunteers evaluating digoxin 0.25 mg alone for 10 days and digoxin 0.25 mg with *Crataegus* special extract WS 1442 (hawthorn leaves with flowers) 450 mg twice daily for 21 days found no significant difference to any measured pharmacokinetic parameters, suggesting that hawthorn and digoxin in these doses may be co-administered safely (Tankanow et al 2003). Caution — use under professional supervision and monitor drug requirements.

Antihypertensive drugs

Theoretically, hawthorn may potentiate blood pressure-lowering effects, thereby requiring modified drug doses. However, hawthorn extract (1200 mg daily) was safe to use in patients with type 2 diabetes ($n > 70$) while taking their prescription drugs (mean intake of 4.4 hypoglycaemic and/or hypotensive drugs) (Walker et al 2006). In general, observe patients taking this combination and monitor drug requirements — interaction would be beneficial under professional supervision.

PREGNANCY USE

Hawthorn did not have an adverse effect on embryonic development in vitro and in vivo (Yao et al 2008). However, in vivo and in vitro evidence of uterine activity has been reported, therefore this herb should not be used in pregnancy until safety is established (Newell et al 1996).

PRACTICE POINTS/PATIENT COUNSELLING

- Hawthorn has positive inotropic action, increases coronary blood flow, reduces myocardial oxygen demand, protects against myocardial damage, improves heart rate variability, as well as having hypotensive and anti-arrhythmic effects.
- Although considered relatively effective, heart disease can be a very serious medical condition with a rapidly changing course and should not be treated without close medical supervision. In particular, chest pain and shortness of breath are extremely serious symptoms that require immediate medical attention.
- It may take 2–6 weeks' treatment to notice a benefit of treatment with hawthorn, and heart rate and blood pressure should be monitored.
- Hawthorn also exhibits antioxidant, anti-inflammatory, antiviral and lipid-lowering activity.
- Great care should be exercised if hawthorn is to be combined with other drugs that affect the heart.

PATIENTS' FAQs

What will this herb do for me?

Hawthorn appears to be useful in treating a variety of heart conditions such as high blood pressure, hyperlipidaemia and heart failure.

When will it start to work?

Studies suggest it will start to have effects in 2–6 weeks.

Are there any safety issues?

Heart conditions are potentially serious, therefore professional supervision is required.

Honey

HISTORICAL NOTE Honey has been used since ancient times as a healing agent for wounds and a treatment for gastric complaints. In ancient Greece, Hippocrates recommended honey and vinegar for pain and honey combinations for fever. It is also recommended by the Bible and the Koran as a medicinal agent. Over the past few decades, scientific research has confirmed its role as a successful wound treatment. It is also known as *honig* and *miel blanc*.

CHEMICAL COMPONENTS

Caffeic acids, benzoic acid and its esters, phenolic acid and its esters, flavonoids, beeswax, inhibin, glucose oxidase and catalase, although other as yet unidentified constituents also exist (Aysan et al 2002).

The composition of a particular honey greatly depends on the composition of the nectar it originated from, and therefore the plant species involved in its production.

MAIN ACTIONS

Antibacterial

The type of plant species involved in honey production is significant, as some confer greater antibacterial properties than others. Currently, evidence suggests that honey produced from the tea trees *Leptospermum scoparium* (New Zealand manuka) and *Lipolygalifolium* (Australian jelly bush) are the most effective, but batch testing is still required to verify the antibacterial activity of commercially produced preparations. However, other honeys, not specifically promoted for their antibacterial qualities, may still have antibacterial activity (Lusby et al 2005).

Several mechanisms of action account for the antibacterial effect of honey.

Hydrogen peroxide content

Hydrogen peroxide has antiseptic properties and is naturally produced in honey. The relative levels of two enzymes, glucose oxidase and catalase, within honey influence the amount of hydrogen peroxide produced. Additionally, diluting full-density honey encourages greater hydrogen peroxide and gluconic acid production from glucose (Aysan et al 2002). Differences in antimicrobial activity among honeys from various floral sources may, in part, be a reflection of these natural variations.

High osmolarity

Honey has a high sugar and low water content, with sugar concentration reaching up to 80% in some seasons. Its high osmolarity is considered important because sugar molecules bind to the existing water molecules, thereby reducing the amount of water available to bacteria.

Low pH

Honey is an acidic substance and therefore unfavourable to the growth of certain bacteria. In vitro testing shows that *Leptospermum* honey can inhibit the growth of several important bacterial pathogens, including *Escherichia coli*, *Salmonella typhimurium*, *Shigella sonnei*, *Listeria monocytogenes*, *Staphylococcus aureus*, *Bacillus cereus* and *Streptococcus mutans* (Steinberg et al 1996, Taormina et al 2001).

In a recent open-label, non-randomised prospective study, applying a manuka honey dressing to non-healing wounds was associated with a statistically significant decrease in wound pH and size. A reduction in pH of 0.1 was associated with an 8.1% reduction in wound size (Gethin et al 2008).

The antibacterial action of honey may be enhanced when combined with a synergistic compound. The antibacterial and antifungal activities of honey were increased by the addition of starch to the medium (Boukraa & Bouchegrane 2007, Boukraa & Amara 2008). When Royal Jelly was combined with four different samples of honey, the minimum inhibitory concentration (MIC) against *Staphylococcus aureus* was lowered by 50% (Boukraa et al 2008).

Honey has also been tested for efficacy against a range of drug-resistant bacteria, with positive results (Cooper et al 2002). Eighteen strains of methicillin-resistant *Staphylococcus aureus* and 27 strains of vancomycin-sensitive and -resistant enterococci, isolated from infected wounds and hospital surfaces, were sensitive to concentrations below 10% w/v of manuka honey and pasture honey. Artificial honey was also effective, but concentrations three times greater were required to produce similar results. In a study using a 10%–40% v/v medical-grade honey (Bfactory) applied to the skin of healthy volunteers colonised with antibiotic-susceptible and -resistant isolates of *Staphylococcus aureus*, *Staphylococcus epidermidis*, *Enterococcus faecium*, *Escherichia coli*, *Pseudomonas aeruginosa*, *Enterobacter cloacae* and *Klebsiella oxytoca*, bacterial levels were reduced 100-fold by day 2, and the number of positive skin cultures was reduced by 76% (Kwakman et al 2008).

Honey is effective (in vitro) against community-associated methicillin-resistant *Staphylococcus aureus* (CA-MRSA), which typically infects skin and soft tissues in healthy individuals. Culture counts of 10^6 colony-forming units were reduced to a non-detectable amount in 24 h in the four honey samples tested whilst levels in the control group (no honey) remained unchanged (Maeda et al 2008).

Phenolic compound

The antioxidant activity of honey has been associated with the levels of phenolic compounds found in a range of floral honeys, with antioxidant activity varying between 43.0% and 95.7%. The responsible compounds suggested include p-coumaric acid, kaempferol, chrysin and apigenin (Baltrusaityte et al 2007). The variation in the concentration of the phenolic compounds among different floral honeys is further confirmed through another study, which found that the concentration of millefiori honey is the highest in polyphenols, flavonoids and has a corresponding high antioxidant activity, when compared with *Acacia* honey (Blasa et al 2006).

Antifungal

Honey has an antifungal action against three species of *Candida* in vitro (Irish et al 2006). Isolates of *C. albicans*, *C. glabrata* and *C. dubliniensis* were tested against four samples of honey; Jarrah honey with hydrogen peroxide activity, Medihoney Antibacterial Honey Barrier, a proprietary blend of *Leptospermum* and hydrogen peroxide honeys, Comvita Wound Care, a pure *Leptospermum* honey, and an artificial honey. The natural honeys had a significantly greater antifungal effect compared to the artificial honey against *C. albicans* and *C. glabrata*, but only the Jarrah honey was effective against *C. dubliniensis*.

Deodorises wounds

Bacteria use the glucose found in honey in preference to amino acids, thereby producing lactic acid instead of malodorous products (Molan 2001).

Debriding

The topical application of honey to a wound tends to lift debris to the surface, allowing for easier cleaning, which may be related to its high osmolarity. Honey does not adhere to the surface, allowing for easier and less painful wound dressing changes (Subrahmanyam 1998).

Enhances wound healing

Clinical evidence suggests that the application of honey hastens granulation and epithelialisation of necrotic tissue by various mechanisms. It appears to stimulate the growth of new blood capillaries and cytokine production, thereby stimulating tissue regeneration. The high viscosity of honey and its hygroscopic character allow it to form a physical barrier, creating a moist environment and a reduction in local oedema (Aysan et al 2002). Clinically, it appears that epithelialisation is accelerated between days 6 and 9 (Subrahmanyam 1998), and that honey is more beneficial than Edinburgh University solution of lime (EUSOL) as a wound-dressing agent (Okeniyi et al 2005).

Antioxidant

The phenolic compounds found in honey, namely the flavonoids, render it a good source of antioxidants (Al-Mamary et al 2002, Schramm et al 2003). In vitro tests have confirmed a significant link between absorbance and antioxidant power, with darker, more opaque honeys having stronger antioxidant power than lighter, clearer honeys (Taormina et al 2001). More specifically, manuka honey has been identified to be a specific scavenger of superoxide anions (Inoue et al 2005). A study examining different samples of honey for their ability to reduce reactive oxygen species (ROS) in vitro found significant variation in activity, with buckwheat honey most effective. This is possibly due to its high concentration of phenolic compounds, which have known antioxidant activity. Considering the fact that hydroxyl radicals

and hypochlorite anions formed in the wound site impair wound healing, this honey should have superior wound healing properties (van den Berg et al 2008).

Immunomodulation

An animal study has shown that both immunocompetent and immunodeficient mice had increased humoral immunity following administration with honey (Karmakar et al 2004).

OTHER ACTIONS

An in vitro study showed that honey prevented binding of *Salmonella interiditis* to intestinal epithelial cells (Alanqdy et al 2005) at dilutions of up to 1:8.

Preliminary studies suggest that honey may have an impact on reducing the intoxicating effects of alcohol; however, that research was of questionable quality, and a better standard of research is required to validate this effect (Onyesom 2004, 2005).

Honey may also have an antimutagenic activity against a common food carcinogen and mutagen, Trp-p-1 (Wang et al 2002).

CLINICAL USE

Honey is mainly used topically for wound healing or dermatological conditions; however, it is now being used in mouthwashes, oral syrups and ocular preparations.

Burns

Honey-dressed wounds had a more rapid reduction in local inflammation, better infection control and more rapid healing than for standard treatment with silver sulfadiazine (SSD) in a randomised clinical trial (Subrahmanyam 1998). Of the 25 patients with wounds, 84% treated with honey achieved satisfactory epithelialisation by day 7 and 100% by day 21 compared with 72% and 84%, respectively with SSD. Histological evidence confirmed honey's superiority, with 80% of wounds showing significant reparative activity and decreased inflammation by day 7 compared with 52% with SSD.

Wound healing

Honey applications have been used to treat various types of wounds, such as leg ulcers and bed sores. Honey has also been used to enhance postoperative wound healing and partial-thickness wounds such as split-thickness skin graft donor sites. Numerous studies have evaluated the efficacy of honey for these indications and found that effects are better than placebo. Whether topical honey is better than current treatments is difficult to determine, as studies have produced mixed results, mostly indicating similar effectiveness. Overall, evidence is encouraging; however, there is still a lack of double-blind studies, despite substantial interest in honey as a wound-healing agent. One reason for this may be the difficulty in selecting a suitable placebo topical application (Molan 2006).

In one study, 59 patients with wounds or ulcers not responding to conventional treatment were treated with topical unprocessed honey. Of these, 58 cases were reported as showing remarkable recovery, with all sterile wounds remaining sterile until healed and infected wounds becoming sterile within 1 week. The one case that did not respond involved a malignant ulcer. Clinically, honey promoted rapid debridement of wounds, epithelialisation and reduced oedema surrounding the ulcers (Efem 1988). Vardi et al (1998) found that 5–10 mL of unprocessed honey applied twice daily to infants not responding to at least 2 weeks of conventional treatment was able to produce a marked clinical improvement within 5 days and complete wound closure after 21 days.

A case series of eight consecutive cases examined the efficacy of honey on non-healing lower limb ulcers. After 4 weeks of using a manuka honey dressing, ulcers decreased in size by a mean of 55% and were no longer malodorous. Patients whose ulcers had an arterial component reported the least benefit and also a stinging sensation following application (Gethin & Cowman 2005). One randomised study involving 40 patients with open or infected wounds compared honey to sugar dressings (Mphande et al 2007). In the honey group, 55% of patients had positive wound cultures at the start of treatment and 23% at one week, compared with 52% and 39% respectively in the sugar group. Additionally, the median rate of healing in the first two weeks of treatment was 3.8cm^2/week for the honey group and 2.2cm^2/week for the sugar group and after three weeks of treatment 86% of patients treated with honey had no pain during dressing changes, compared with 72% treated with sugar.

Emsen (2007) used medical honey for the fixation of the split-thickness skin grafts in 11 patients. Oedema and the amount of wound exudate were reduced, and no complications such as graft loss or infection were reported either on fifth day of grafting or at the end of the follow-up period (average 17 months). A honey-medicated dressing was tested for ease of use and efficacy in a study involving 60 patients with chronic, complicated surgical or acute traumatic wounds (Ahmed et al 2003). In 59 patients, the preparation was considered easy to use and helpful in cleaning wounds.

Several studies have compared honey dressings to currently used treatments, finding it is as effective but not necessarily more effective.

A recent open-labelled, randomised controlled trial involving 368 patients with venous ulcers found that honey dressings did not significantly decrease the time needed to heal compared to those treated with usual care (a range of dressings). After 12 weeks, 55.6% of ulcers healed in the honey-treated group and 49.7% in the usual care group. There were no significant differences found in the other parameters, including mean time to healing (63.5 days and 65.3 days in the honey and usual care groups, respectively), reduction in ulcer size, incidence of infections or quality of life between the groups (Jull et al 2008). There were also more adverse events reported in the honey-treated group, with 25% of participants reporting one or more episodes of discomfort.

A non-randomised, prospective, open study compared the effects of honey-impregnated gauze,

paraffin gauze, hydrocolloid dressings and saline-soaked gauzes in 88 patients who underwent skin grafting (Misirlioglu et al 2003). Honey gauzes produced a faster epithelialisation and reduced the sensation of pain compared with paraffin and saline-soaked gauzes. This effect was the same as that observed for hydrocolloid dressings.

The effect of honey on wound healing following toenail surgery was not found to be statistically different from the paraffin-impregnated tulle gras in a double-blind, randomised controlled trial (McIntosh & Thomson 2006). Mean healing times were 40.30 and 39.98 days for the honey group and the paraffin tulle gras group, respectively. Whilst partial avulsion wounds healed statistically and significantly faster with paraffin tulle gras, no significant difference was found in time to total avulsion compared to the honey group.

A RCT of 101 haemodialysis patients compared thrice-weekly application of Medihoney with mupirocin for the healing of catheter exit sites. This study found the honey to be safe, effective and more affordable than mupirocin for this group (Johnson et al 2005).

Fournier's gangrene

In 1996, the effects of topical unprocessed honey together with traditional treatment in a rare condition known as Fournier's gangrene (FG) were investigated (Hejase et al 1996). FG is an extensive fulminant infection of the genitals, perineum or the abdominal wall and is generally regarded as a difficult-to-manage infectious disease. The major gross pathological findings are oedema and necrosis of the subcutaneous tissues when the male genitalia are involved, necessitating aggressive treatment.

In this study, 38 patients admitted with the diagnosis of FG were treated with broad-spectrum triple antimicrobial therapy, broad debridement, exhaustive cleaning and application of unprocessed honey dressings daily for 2 weeks. Rapid changes to wound healing rate occurred after 10 days' honey use — advancing necrosis ceased, wounds became sterile, odour was reduced and fluid was absorbed from wounds. Honey also enhanced the growth and multiplication of epithelial cells from the wound edges and reduced the need for scrotal plastic surgery. As a result of the impressive results obtained, these researchers highly recommend honey dressings in gangrenous wounds, suggesting that it significantly improved patient outcomes.

OTHER USES

Allergic rhinoconjunctivitis

Honey does not reduce symptoms of allergic rhinoconjunctivitis, according to results from a randomised study of 36 volunteers (Rajan et al 2002). The study compared the effects of unpasteurised and unfiltered honey with filtered and pasteurised honey and corn syrup with synthetic honey flavouring and found that an oral dose of 1 tablespoon daily of either honey produced the same results as placebo.

Helicobacter pylori infection

Honey inhibits *H. pylori* in test tube studies (Ali et al 1991, Osato et al 1999), although no controlled studies are available to clarify its effectiveness in humans.

Periodontal disease

In vitro tests show that honey can inhibit the growth of oral bacteria (Steinberg et al 1996). As a follow-up investigation, 10 volunteers were asked to swish 5 mL of honey around their mouths for 4 minutes and then swallow. At 10 minutes after honey use, oral bacterial counts were significantly decreased. A pilot study has also shown that manuka honey has potential in the treatment of gingivitis and periodontal disease (English et al 2004). Thirty subjects were given either a chewable 'honey leather' or a sugarless chewing gum to chew for 10 minutes after each meal for 3 weeks. The honey group had a statistically significant reduction in mean dental plaque scores and gingivitis (assessed by percentage of bleeding sites), with no significant changes in the control group (English et al 2004).

Eczema

Topically applied honey is sometimes used to enhance skin healing and prevent infection in eczema. Although controlled trials are not available, the clinical evidence generally supporting efficacy in wound healing provides a theoretical basis for its use in this condition.

Anal fissures and haemorrhoids

A prospective pilot study examined the use of a topical preparation containing a mixture of honey, olive oil and beeswax in a ratio of 1:1:1(v/v/v) on anal fissure or haemorrhoids. Treatment for up to 4 weeks significantly reduced the bleeding and itching in patients with haemorrhoids and pain, bleeding and itching in patients with anal fissures (Al-Waili et al 2006).

Colon cancer

Preliminary animal studies on experimentally induced colon cancer show the potential for reduced disease development (Duleva & Bajkova 2005), but further study is necessary to validate this for clinical use.

Dysbiosis

Honey may assist in inhibiting the growth of the pathogenic bacteria *Clostridium perfringens* and *Eubacterium aerofaciens*, while not affecting, or possibly promoting, the growth of beneficial *Bifidobacterium* spp. (*B. longum*, *B. adolescentis*, *B. breve*, *B. bifidum* and *B. infantis*) (Shin & Ustunol 2005).

Coughs

In a randomised, partially double-blinded clinical trial involving 105 children, a single dose of buckwheat honey, given 30 minutes before bed, significantly reduced cough severity (47.3% versus 24.7%) and overall symptom score reduction (53.7% versus 33.4%) compared to no treatment (Warren and Cooper 2008). Similarly, Paul et al (2007)

found that a single nighttime dose of buckwheat honey given to children with an upper respiratory infection resulted in greatest symptom improvement in nocturnal cough and sleeping difficulties compared to honey-flavoured dextromethorphan treatment or no treatment.

Pain following tonsillectomy

In a prospective, randomised, placebo-controlled preliminary study involving 60 patients, 5 mL honey combined with paracetamol and antibiotics was found to be more effective in reducing postoperative pain following tonsillectomy than treatment with paracetamol and antibiotics only. The honey combination treatment group also demonstrated increased tonsillary fossa epithelialisation (Ozlugedik et al 2006).

Tear deficiency and meibomian gland disease

Topical application of honey (three times daily) was found to significantly reduce the total ocular bacterial colony-forming units (CFUs) of dry eye subjects caused by tear deficiency and/or meibomian gland disease. After 3 months, antibacterial effect was such that there was no significant difference in the CFUs of the patient groups and the non-dry eye (control) group (Albietz & Lenton 2006).

Radiotherapy and chemotherapy side effects

In a prospective, controlled, randomised study, 21 adult females who had radiotherapy to the breast or thoracic wall resulting in grade 3 skin toxicities greater than 15 mm in diameter were treated daily with either a honey or a paraffin gauze dressing. The honey-treated group reported less pain, itching or irritation as measured through daily visual analogue scale (VAS) (Moolenaar et al 2006)

Two studies examined the prophylactic effect of honey against oral mucositis, which is induced as a consequence from treatment for head or neck cancer. In a single-blind, randomised clinical trial of 40 patients, the honey treatment group swished 20 mL of honey around in their mouth and swallowed gradually 15 minutes before radiation therapy, and again 15 minutes and 6 hours after, whilst the control group rinsed with 20 mL of saline before and after radiation. The level of mucositis measured by the Oral Mucositis Assessing Scale (OMAS) was significantly lower in the honey-treated group compared to the control group (Motallebnejad et al 2008). In the second randomised controlled trial of 40 patients receiving chemotherapy and radiation (involving the oral and/or oropharyngeal mucosa), the treatment group who used a topical application of pure honey had reduced levels of mucositis and less *Candida* or bacterial colonisation compared to the control group (Rashad et al 2008)

Honey may help to reduce the extent of neutropenia experienced as a side effect of chemotherapy and thereby reduce the amount of colony-stimulating factors (CSFs) required. Thirty cancer patients who had undergone chemotherapy and developed grade 4 neutropenia requiring treated with CSFs repeated this schedule of chemotherapy combined with 5 days of treatment with Life-Mel honey. The addition of the honey treatment resulted in improvement in all cell lines with fewer cases of neutropenia (40% of patients did not require treatment with CSFs), 64% of patients retaining haemoglobin levels above 11 g/dL and only 10% of patients developing thrombocytopenia. No side effects were reported with honey treatment (Zidan et al 2006).

DOSAGE RANGE

Honey is applied topically (see 'Tips on how best to use honey in practice' below).

TOXICITY

Not applicable — mostly used externally.

A rare type of food poisoning caused by the presence of grayanotoxin has been reported, particularly in the Black Sea region of Turkey. Described as 'mad honey', the dose-dependent effects include mild symptoms such as hypersalivation, vomiting, dizziness and weakness, whilst severe intoxication can lead to potentially serious cardiac complications. No fatal cases have been reported (Koca & Koca 2007).

ADVERSE REACTIONS

A mild transient stinging may occur when applied to open wounds. If this is too uncomfortable, honey can be washed away with warm water.

Allergic reactions have also been reported, but these are considered rare.

SIGNIFICANT INTERACTIONS

None known.

Oral intake may induce CYP3A4 enzyme activity, according to a small clinical study (Tushar et al 2007).

CONTRAINDICATIONS AND PRECAUTIONS

Diabetics

Honey contains a large concentration of glucose. If applied to large open wounds, it may theoretically elevate blood sugar levels — monitor blood sugar levels.

PREGNANCY USE

Safety has not been scientifically established, but historical use suggests that it is safe.

PATIENTS' FAQs

What will honey do for me?

If you apply a honey preparation that has tested positive for antibacterial activity, it will enhance wound healing, reduce pain and inflammation, and reduce the risk of wound infection.

When will it start to work?

Studies have found that by the seventh day of use, most wounds show considerable improvement and healing.

Are there any safety issues?

Using sterile honey preparations is recommended.

PRACTICE POINTS/PATIENT COUNSELLING

- Topical application of honey has been used to enhance wound healing and infection control.
- Honey has a deodorising and debriding effect on wounds, accelerates epithelialisation and reduces inflammation and pain.
- Effects are generally seen within 7 days of use.
- Not all honeys have significant antibacterial properties; however, research has identified the New Zealand *Leptospermum* (manuka honey) and Australian jelly bush honey as having potent activity.
- The honey to be used as a topical wound-healing agent or dermatological treatment should ideally be sterile and tested for clinical activity.

TIPS ON HOW BEST TO USE HONEY IN PRACTICE*

- Ensure that there is an even coverage of the wound surface.
- Larger cavities may be filled by pouring in slightly warmed honey.
- Spreading honey on a dressing pad or gauze rather than on the wound directly will be more comfortable for the patient.
- The amount of honey needed depends on the amount of fluid leaking from the wound — if honey becomes diluted, it will be less effective; typically, 20 mL of honey is used on a 10 × 10 cm dressing.
- Cover with absorbent secondary dressings to prevent honey oozing out from the dressing. Change the dressings more frequently if the honey is being diluted — otherwise change every day or two.

Hops

HISTORICAL NOTE Although hops is most famous for producing the bitter flavour in beer, this plant has been used since ancient times to treat digestive complaints and for its slight narcotic and sedative actions. Native Americans used it as a hypnotic. It is related botanically, though not pharmacologically, to cannabis. The climbing nature of the herb influenced its common name, as this is derived from the Anglo-Saxon *hoppan*, which means 'to climb'.

COMMON NAME
Hops

OTHER NAMES
Common hops, European hops, hop strobile, hopfen, houblon, humulus, lupulus, lupulin

BOTANICAL NAME/FAMILY
Humulus lupulus (family Cannabaceae)

PLANT PART USED
Dried strobiles

CHEMICAL COMPONENTS
Resinous bitter principles (mostly alpha-bitter and beta-bitter acids) and their oxidative degradation products, polyphenolic condensed tannins, volatile oil, polysaccharides, mainly monoterpenes and sesquiterpenes, flavonoids (xanthohumol, isoxanthohumol, kaempferol, quercetin and rutin), phenolic acids and amino acids (Blumenthal et al 2000). The volatile oil and bitter acids are the most significant components of hops, the latter providing its valuable quality in the brewing of beer. The prenylated flavonoids, particularly xanthohumol, have oestrogenic activity.

MAIN ACTIONS
Traditionally, hops is viewed as a bitter tonic with antispasmodic, relaxant and sedative actions.

Sedative
A long history of use within well-established systems of traditional medicine, together with scientific testing, have suggested that hops has significant sedative activity (Blumenthal et al 2000), probably through activation of melatonin receptors. A recent in vivo study found that both the extract of hops and a fraction containing alpha-bitter acids had significant sedative properties in mice (Zanoli et al 2005). Both extracts were also found to have an antidepressant action. The sedative activity is still under investigation in order to recognise the active principles responsible for the neuropharmacological effects observed in laboratory animals, and their mechanism of action.

Oestrogenic effects
In 1953, two German scientists followed up on a folk legend that women regularly began to menstruate 2 days after beginning to pick hops. Since then, there has been much research on the oestrogenic effects of hops. Hops showed significant competitive binding to alpha- and beta-oestrogen receptors and upregulation of progesterone receptors in vitro (Liu et al 2001). The oestrogenic activity is due to the constituent 8-prenylnaringenin (Milligan et al 1999, 2000), which is converted by intestinal microflora from isoxanthohumol (Possemiers et al 2005), and mimics the action of 17b-oestradiol,

albeit with a 17-fold lesser potency in alpha-receptor sites (in the breast, liver, CNS and uterus), and a 20,000-fold lesser potency in the beta-receptor sites (mainly in the intestine, prostate, ovaries, testes and urogenital tract). A small, randomised, double-blind, placebo-controlled study using standardised doses of 8-prenylnaringenin demonstrated systemic endocrine effects, including a decrease in LH serum concentrations, in postmenopausal women. In vitro studies also show that hop extracts exert oestrogen-like activities on bone metabolism, although later in vivo studies on rats contradict this finding (Figard et al 2007)

Moderate beer consumption can provide enough 8-prenylnaringenin to ensure some biological activity in humans, with unknown consequences to health (Possemiers et al 2006).

Possible chemopreventative effects

Angiogenesis is necessary for solid tumour growth and dissemination. In addition to angiogenesis, it has become increasingly clear that inflammation is a key component in cancer insurgence that can promote tumour angiogenesis. The hops-derived chalcone, xanthohumol, prevents angiogenesis in vivo and induces detoxification enzymes, in particular quinone reductase, which may contribute to its chemoprotective effects (Dietz et al 2005).

Xanthohumol is a very promising, potential protective agent against genotoxicity of foodborne carcinogens and has been shown to inhibit the growth of the highly angiogenic Kaposi's sarcoma tumour cells in vivo. It also demonstrates antitumour activity on B-chronic lymphocytic leukaemia cells in vitro. The prenylflavonoids are able to modulate aromatase activity, thus decreasing oestrogen synthesis, and it is hypothesised that this may have relevance for the prevention and treatment of oestrogen-dependent disorders such as breast cancer.

Antimicrobial

Hops extract and hops oil have activity against the gram-positive bacteria (*Bacillus subtilis* and *Staphylococcus aureus*) and the fungus *Trichophyton mentagrophytes* var. *interdigitale*, but almost no activity against the gram-negative bacterium *Escherichia coli* and the yeast *Candida albicans* (Langezaal et al 1992). Lupulone, in particular, has been found to have some action against gram-positive bacteria, and certain gram-negative bacteria but not against others such as *E. coli*. A review of the antimicrobial properties concluded that hops was also effective against the parasite *Plasmodium falciparum* and a range of viruses, including HSV types 1 and 2, cytomegalovirus and HIV (Gerhauser 2005). The mechanism of anti-HIV activity is not fully understood, but it is thought that the flavonoid, xanthohumol, may inhibit transcription (Wang et al 2004).

OTHER ACTIONS

Cytochrome P450 induction

Colupulone, a beta-bitter acid, was reported to induce the cytochrome P450 system and increase mRNA levels of cytochrome 2B and 3A in rats (Shipp et al 1994). Another study found that the flavonoids from hops inhibit the cytochrome P450 system in humans, in particular, cytochromes 1A1, 1B1, 1A2, but not 2E1 or 3A4 (Henderson et al 2000). A recent review concluded that hops inhibits phase 1 detoxification and enhances phase 2 by inducing quinone reductase (Gerhauser et al 2002, Stevens & Page 2004). The clinical significance of these findings is unknown.

Anti-inflammatory

In clinical trials, hops has demonstrable anti-inflammatory action. A double-blind, randomised ex vivo study comparing hops extracts with ibuprofen, demonstrates equivalence in cyclo-pxygenase (COX)-2 inhibitory action but with significant COX-1 sparing activity relative to ibuprofen. Thus hops has demonstrable anti-inflammatory action without the risk of gastrointestinal side effects found with other COX enzyme inhibitors, such as ibuprofen. The chalcones from hops, including xanthohumol, significantly reduced NO by suppressing iNOS in mouse macrophage cells (Zhao et al 2003, 2005). Xanthohumol has also been reported to inhibit the production of prostaglandin E2 (PGE2). Animal studies suggest that hops could be a useful agent for intervention strategies targeting inflammatory disorders and/or inflammatory pain in arthritis (Hougee et al 2006) but with low potential for gastrointestinal and cardiovascular toxicity. In fact, mouse studies indicate that hops extract may be useful for the prevention of gastric ulcer and inflammation, as it inhibits one of the important virulence factors responsible for *H. pylori*-induced gastritis and ulceration.

Anti-allergy

Hop extracts inhibit histamine release from rat mast cells and may be effective in the relief of symptoms of allergic rhinitis or in preventing and alleviating atopic dermatitis-like skin disease.

Clinical use

In practice, the herb is prescribed in combination with other herbal medicines, such as valerian and passionflower. As is representative of clinical practice, most studies have investigated the effects of hops in combination with other herbs.

Restlessness and anxiety

Based on the herb's sedative activity, it is likely to have some effect in the treatment of restlessness and anxiety, but careful dosing would be required to avoid sedation. This indication has been approved by Commission E and European Scientific Co-Operative on Phytotherapy (ESCOP) (Blumenthal 1998).

Sleep disturbances

Hops has been used as a bath additive for sleep disturbances. A randomised, double-blind study involving 40 patients found that taking three hops baths (4 g hops in a concentrated extract) on successive days significantly improved both objective and subjective sleep quality (Bone 1996).

Commission E and ESCOP support the use of hops for sleep disturbances, such as difficulty falling asleep and insomnia (Blumenthal et al 2000).

Studies on mice confirm that hops has a central sedating effect that can be attributed to the bitter acids and hop oil. Although there have been no human in vivo studies to support oral doses of hops as a stand-alone sedative agent, several studies have demonstrated that formulas combining hops with other sedative herbs are effective for insomnia.

A number of randomised, double-blind studies have investigated the effects of an oral preparation of hops and valerian in sleep disorders. One study observed equivalent efficacy and tolerability of a hops–valerian preparation comparable to benzodiazepine treatment, with withdrawal symptoms only reported for benzodiazepine use (Schmitz & Jackel 1998). Improvement in subjective perceptions of sleep quality was confirmed in another study, which also reported that a hops–valerian combination was well tolerated compared with flunitrazepam (Gerhard et al 1996). A pilot study (Fussel et al 2000) tested a preparation containing a fixed combination of valerian extract (500 mg) and hops extract (120 mg), known as Ze 91019, in 30 subjects with mild-to-moderate, non-organic insomnia. The treatment was used at bedtime and found to reduce sleep latency and wake time as diagnosed by polysomnographic examination. This was followed up by a randomised, double-blind, placebo-controlled, prospective clinical study which proved that the same fixed extract combination was significantly superior to the placebo in reducing the sleep latency, whilst the single valerian extract failed to be superior to the placebo. The result underlined the usefulness of hops extract for patients suffering from insomnia. In another multicentre, randomised, placebo-controlled, parallel-group study, the valerian–hops combination showed only a modest hypnotic effect relative to placebo. The same was true of the control medication, diphenhydramine. A further double-blind, randomised, placebo-controlled sleep-electroecephalogram (EEG) study showed, however, that both sleep quality and quantity significantly improved with a single dose of tincture combining valerian and hops. These findings are confusing overall, and perhaps reflect the difficulty in assessing which specific herbal treatment may be most useful in treating. A valerian–hops combination may be helpful in some situations.

Menopause

A review of the scientific literature on complementary and alternative therapies for menopausal symptoms (1966–2006) suggests that as a source of phyto-oestrogens, hops may help to alleviate menopausal symptoms and has potential for the prevention of osteoporosis and cardiovascular diseases.

A randomised, double-blind, placebo-controlled trial of a standardised extract of hops (100 μg and 250 μg 8-prenylnaringenin) demonstrated a significant reduction in menopausal discomfort, in particular hot flushes, after 12 weeks of treatment in 67 women (Heyerick et al 2005). Interestingly, no dose–response relationship could be made, as the lower standardised dose was shown to be more effective.

An open, non-controlled clinical trial in 100 postmenopausal women was performed over 12 weeks to investigate the effects of vaginal application of a gel containing phyto-oestrogens from hops extract, hyaluronic acid, liposomes and vitamin E, with the aim of testing its safety and efficacy in postmenopausal women with urogenital atrophy. The results showed a statistically significant reduction in the vaginal dryness, without any adverse effects.

Indigestion

Due to the herb's bitter nature, it is used to stimulate digestion and in the treatment of common digestive complaints such as dyspepsia and indigestion. Animal studies on rats show that hops increases gastric juice volume.

OTHER USES

Traditionally, hops is also used to treat neuralgia, depression and pain and to wean patients off pharmaceutical sedative medicines. Topically it is used to treat leg ulcers and oedema.

Cancer prevention

Xanthohumol and its oxidation product may be potentially useful as a chemopreventive agent during prostate hyperplasia and prostate carcinogenesis, acting via induction of apoptosis and down-regulation of NF[kappa]B activation in BPH-1 cells. Clinical studies are required to confirm significance.

Diabetes

Isohumulones, the bitter compounds in hops, have been shown to improve insulin resistance and hyperlipidaemia in several animal models and may prevent the progression of renal injury caused by hypertension via an antioxidative effect. Clinical studies are required to confirm significance.

Periodontitis

In vitro studies suggest that the hop-derived polyphenols are potent inhibitors of prostaglandin E2 production by gingival epithelial cells stimulated with periodontal pathogen and may be useful for the prevention and treatment of periodontitis. The clinical significance of this finding is unknown and remains to be tested.

DOSAGE RANGE

- Infusion or decoction: 0.5 g in 150 mL water.
- Fluid extract (1:1) (g/mL): 0.5 mL/day; 0.5–1 mL three times daily.
- Tincture (1:5) (g/mL): 1–2.5 mL/day.
- Also used as a bath additive (4 g hops in a concentrated extract) and in pillows.

TOXICITY

Not known

ADVERSE REACTIONS

Drowsiness is theoretically possible at excessive doses. Contact with the herb or oil has resulted in reports of systemic urticaria, allergic dermatitis,

respiratory allergy and anaphylaxis (Pradalier et al 2002).

SIGNIFICANT INTERACTIONS

Interactions reported here are theoretical and yet to be tested clinically for significance.

Pharmaceutical sedatives

Additive effects are theoretically possible — observe the patient (this interaction may be beneficial).

Drugs metabolised chiefly with CYP2B or CYP3A

Altered drug effect — cytochrome (CYP) induction and inhibition have been demonstrated. However, it is unknown whether these effects are clinically significant — observe the patient for signs of altered drug effectiveness.

Anti-oestrogenic drugs

Hops may alter the efficacy of these medicines; use with caution in patients taking antioestrogenic drugs.

CONTRAINDICATIONS AND PRECAUTIONS

According to one source, hops should be used with caution in depression (Ernst 2001). Due to the herb's oestrogenic activity, disruption to the menstrual cycle is considered possible. Use is contraindicated in patients with oestrogen-dependent tumours.

PREGNANCY USE

Caution in pregnancy because of the possible hormonal effects.

PRACTICE POINTS/PATIENT COUNSELLING

- Hops is often used as a mild sedative in combination with other herbs such as valerian and passionflower.
- Several randomised trials have found that the combination of hops and valerian improve sleep quality, without next-day drowsiness; however, further investigation is required to determine the role of hops in achieving this effect.
- Although generally taken orally, it has also been successfully used as a bath additive and in aromatherapy pillows to induce sleep.
- It is traditionally used to treat anxiety, restlessness, pain, neuralgia and indigestion.
- It should not be used in patients with oestrogen-dependent tumours, and should be used with caution in pregnancy.

PATIENTS' FAQs

What will this herb do for me?

Hops may be a useful treatment for anxiety and restlessness, and when combined with other sedative herbs, such as valerian or passionflower, improves sleep quality without inducing next-day hangover effects.

When will it start to work?

Several doses may be required; however, effects are generally seen within 2 weeks.

Are there any safety issues?

Constituents in the herb appear to have some oestrogenic activity; therefore, people with oestrogen-dependent tumours should avoid its use.

Horse chestnut

HISTORICAL NOTE The horse chestnut tree is commonly found in ornamental gardens throughout Europe, growing up to 35 metres tall. The seeds are not edible due to the presence of alkaloid saponins, but both the dried seeds and bark of the horse chestnut tree have been used medicinally since the 16th century. The seeds are also used for the children's game 'conkers' and were used to produce acetone during World Wars I and II. In modern times, a dry extract referred to as horse chestnut seed extract (HCSE) is standardised to contain 16–21% triterpene glycosides (anhydrous escin). HCSE has been extensively researched for its beneficial effects and is commonly used by general practitioners in Germany for the treatment of chronic venous insufficiency. Homoeopathic preparations of both the leaf and seed are also used for treating haemorrhoids, lower back pain and varicose veins, and the buds and flower are used to make the Bach flower remedies chestnut bud and white chestnut. The active component escin is also used intravenously and topically in cosmetics (Bombardelli et al 1996, Herbalgram 2000, PDRHealth 2006).

OTHER NAMES

Aescule, buckeye, chestnut, Castaño de Indias, graine de marronier d'inde, escine, eschilo, hestekastanje, hippocastani semen, marron europeen, marronnier, roßkastaniensamen, Spanish chestnut

BOTANICAL NAME/FAMILY

Aesculus hippocastanum (family [Sapindaceae] Hippocastanaceae).

It should be differentiated from *A. chinensis*, *A. turbinata*, *A. indica*, *A. californica* and *A. glabra*.

PLANT PARTS USED

Seed. Less commonly bark, flower and leaf.

CHEMICAL COMPONENTS

Horse chestnut seed contains 3–6% escin (aescin), a complex mixture of triterpene saponins (including the triterpene oligoglycosides escins Ia, Ib, IIa, IIb and IIIa) (Yoshikawa et al 1996), the acylated polyhydroxyoleanene triterpene oligoglycosides escins IIIb, IV, V and VI and isoescins Ia, Ib and V (Yoshikawa et al 1998), and the sapogenols hippocaesculin and barringtogenol-C (Konoshima & Lee 1986), flavonoids (including flavonol oligosides of quercetin and kaempferol) (Hubner et al 1999), condensed tannins, quinines, sterols (including stigmasterol, alpha-spinasterol, and beta-sitosterol) (Senatore et al 1989), sugars (including glucose, xylose and rhamnose) (Hubner et al 1999), and fatty acids (including linolenic, palmitic and stearic acids) (Herbalgram 2000). It also contains the toxic glycoside esculin (aesculin), a hydroxycoumarin that may increase bleeding time due to antithrombin activity (NMCD 2006).

Horse chestnut bark and flowers also contain the sterols stigmasterol, alpha-spinasterol and beta-sitosterol (NMCD 2006).

Although the majority of trials in the scientific literature have focused on the benefits of the HCSE extract, some authors suggest that the flavonoids contained in *A. hippocastanum* may provide additional benefits (Mills & Bone 2000).

MAIN ACTIONS

The major benefits of *A. hippocastanum* are related to its ability to prevent the degradation of vascular walls, maintaining vascular integrity and in turn preventing vascular hyperpermeability and the resulting oedema.

Vasoprotective/normalises vascular permeability

Horse chestnut appears to prevent the activation of leukocytes and therefore inhibit the activity of lysosomal enzymes (hyaluronidase and possibly elastase) involved in the degradation of proteoglycan (the main component of the extravascular matrix), thus reducing the breakdown of mucopolysaccharides in vascular walls (Pittler & Ernst 2004). Escin is the major constituent thought to be responsible for the inhibitory effects on hyaluronidase. Interestingly, ruscogenins found in *Ruscus aculeatus* L. (butcher's broom), while ineffective on hyaluronidase activity, exhibit significant anti-elastase activity (Facino et al 1995), which may explain the practice by many herbalists of combining the two herbs.

By reducing degradation, the synthesis of proteoglycans is able to occur, which reduces capillary hyperpermeability, preventing the leakage of fluid into intercellular spaces that results in oedema. The anti-exudative activity appears to be mediated by PGF_{2alpha} (Berti et al 1977). In animal studies the escins Ia, Ib, IIa and IIb have been shown to reduce capillary hyperpermeability induced by histamine, ascetic acid, carrageenan and serotonin (Guillaume & Padioleau 1994, Matsuda et al 1997). In experimental rat aortic-ring models, escin has been shown to increase endothelial cell permeability to calcium, which enhances the production of nitric oxide

(NO) (due to the effect of endothelial NO synthase, a calcium-dependent enzyme), and results in enhanced endothelium-dependent relaxation. This is thought to contribute to escin's beneficial effect in the treatment of venous insufficiency (Carrasco & Vidrio 2007).

A. hippocastanum promotes the proliferation behaviour of human endothelial cells in vitro in a dose-dependent manner (Fallier-Becker et al 2002) and may therefore also play a role in maintaining as well as protecting vascular walls.

By improving vascular tone, horse chestnut standardised extract (HCSE) may improve the flow of blood back to the heart, as demonstrated in animal studies in which it significantly increased, within normal arterial parameters, femoral venous pressure and flow, as well as thoracic lymphatic flow (Guillaume & Padioleau 1994).

Anti-oedema

By inhibiting the degradation of vascular walls, horse chestnut prevents the excessive exudation of fluid through the walls of the capillaries that would result in oedema. In animal experiments HCSE reduces oedema of both inflammatory and lymphatic origin (Guillaume & Padioleau 1994). Escin also appears to possess a weak diuretic activity (Mills & Bone 2000, NMCD 2006), which may support its anti-oedematous action.

Anti-inflammatory

Under experimental conditions, escin pre-treatment may reduce IL-6 release from vascular endothelium (Montopoli et al 2007). In animal studies the escins Ia, Ib, IIa and IIb have been shown to reduce capillary hyperpermeability induced by histamine, ascetic acid, carrageenan and serotonin (Guillaume & Padioleau 1994, Matsuda et al 1997). A sterol extract of horse chestnut bark was shown to have anti-inflammatory effects comparable to calcium phenylbutazone in a study of rats with carrageenan-induced paw oedema (Senatore et al 1989).

Antioxidant

HCSE dose-dependently inhibits both enzymatic and non-enzymatic lipid peroxidation in vitro (Guillaume & Padioleau 1994).

Chemopreventive, anti-angiogenic and anti-proliferative

Beta-escin has been shown to be a potent inhibitor of cell proliferation and inducer of apoptosis in HL-60 acute myeloid leukaemia cells (Niu et al 2008b) and human chronic myeloid leukaemia K562 cells (Niu et al 2008a); and inhibits the growth of colon cancer cells in rats (Patlolla et al 2006). Beta-escin sodium (40 micrograms/mL) induces endothelial cell apoptosis and inhibits endothelial cell proliferation in a dose-dependent manner (10, 20, 40 micrograms/mL) (Wang et al 2008).

OTHER ACTIONS

Animal studies have demonstrated that isolated escins Ia, Ib, IIa and IIb inhibit gastric emptying time and ethanol absorption, and exert a hypoglycaemic activity in the oral glucose tolerance test in rats (Matsuda et al 1999, Yoshikawa et al 1996).

Anti-ageing

A number of studies by Fujimura and others (2006a, 2006b, 2007) have suggested that horse chestnut extract can generate contraction forces in fibroblasts through stress fibre formation followed by activation of Rho protein and Rho kinase (Fujimura et al 2006b) and thus act as a potent anti-ageing factor. In a controlled trial of 40 women using an eye gel (3% horse chestnut extract) applied around the eyes three times a day for 9 weeks a significant reduction in wrinkle scores around the corners of the eye and lower eyelids was observed after 6 weeks (Fujimura et al 2006a, 2007).

CLINICAL USE

HCSE is chiefly used in chronic pathological conditions of the veins where there is increased activity of lysosomal enzymes resulting in damage to and hyperpermeability of vascular walls (Herbalgram 2000). Numerous pharmacological and clinical trials have confirmed the efficacy of HCSE in stabilising the walls of the venous system and improving conditions such as chronic venous insufficiency (Blekic 1996).

Chronic venous insufficiency

Horse chestnut has been used traditionally for the treatment of chronic venous insufficiency (CVI) and its associated symptoms, such as lower leg swelling. The ability of horse chestnut seed extract (HCSE) to inhibit the catalytic breakdown of capillary wall proteoglycans is thought in part to mediate this effect. Clinical trials in patients with chronic venous insufficiency and varicose veins have demonstrated a reduction in lower leg oedema and the subjective alleviation of leg pain, heaviness and itching (Suter et al 2006).

A recent Cochrane review that assessed 17 RCT of HCSE capsules (standardised to escin) concluded that signs and symptoms of CVI improve with HCSE as compared with placebo (Pittler & Ernst 2006). Six of seven placebo-controlled trials reported a significant reduction in leg pain for HCSE compared with placebo, another study reported a statistically significant improvement compared with baseline and one study reported that HCSE may be as effective as treatment with compression stockings. Pruritus was assessed in eight placebo-controlled trials. Four trials ($n = 407$) showed a statistically significant reduction compared with placebo and two trials showed a statistically significant difference in favour of HCSE compared with baseline, whereas one trial found no significant differences for a score including the symptom pruritus compared with compression. Meta-analysis of six trials ($n = 502$) suggested a reduction in leg volume compared with placebo, as did the studies in which the circumference at calf and ankle was assessed overall. Adverse events were usually mild and infrequent.

An earlier meta-analysis of 13 RCT ($n = 051$) and 3 observational studies ($n = 10,725$) found

that HCSE reduced leg volume by 46.4 mL (95% CI, 11.3–81.4 mL) and increased the likelihood of improvement in leg pain 4.1-fold (95% CI, 0.98–16.8), oedema 1.5-fold (95% CI, 1.2–1.9) and pruritus 1.7-fold (95% CI, 0.01–3.0). Observational studies reported significant improvements in pain, oedema and leg fatigue/heaviness (Siebert et al 2002).

A case observational study involving more than 800 GPs and more than 5,000 patients with CVI taking HCSE reported that symptoms of pain, tiredness, tension and swelling in the leg, as well as pruritus and tendency to oedema, all improved markedly or disappeared completely, with the additional advantage of better compliance than compression therapy (Greeske & Pohlmann 1996). In an open study carried out to assess the safety and tolerability of *A. hippocastanum*, 91 subjects received a tablet (equivalent to 50 mg escin) twice daily for 8 consecutive weeks. At the end of the study the majority of patients rated horse chestnut to be good or very good for Widmer stage I and II CVI (Dickson et al 2004).

In patients suffering from CVI, oedema can give rise to trophic skin changes, inflammatory lesions, and an increase in blood coagulability with the associated risk of thrombosis development. Therapy should therefore be aimed at providing protection against oedema at the earliest possible stage of venous disease (Widmer CVI stages I or II) to prevent complications (Pohlmann et al 2000). As HCSE therapy appears to provide more significant benefits in the earlier stages (less so with the advancement of the condition) (Ottillinger & Greeske 2001) it would appear prudent to initiate HCSE therapy early in order to prevent or delay the need for compression therapy, which is associated with discomfort and poor patient compliance. In the later stages combined treatment with compression stockings and HCSE may provide added benefit (Blaschek 2004, Pittler & Ernst 2004).

Although the standard dose used in clinical trials appears to be equivalent to 50 mg escin twice daily, one study observed that reducing the dose to 50 mg escin once daily at 8 weeks appeared to maintain similar benefits to the twice daily routine at the end of the 16-week observation period (Pohlmann et al 2000).

Venous leg ulceration

Chronic venous leg ulceration (VLU) is a common recurrent problem in the elderly population and may result in immobility, with 45% of patients being housebound (Baker & Stacey 1994). As a result, individuals with VLU frequently experience depression, anxiety, social isolation, sleeplessness and reduced working capacity (Leach 2004). CVI, which is characterised by an increase in capillary permeability, inflammatory reactions, decreased lymphatic reabsorption, oedema and malnutrition of tissues, is a precursor to VLU. As HCSE increases venous tone while reducing venous fragility and capillary permeability, and possesses anti-oedematous and anti-inflammatory properties, it has been speculated that by improving microcirculation, ulceration may be delayed or prevented (Blaschek 2004).

In a prospective triple-blind randomised placebo-controlled trial, 54 patients with venous leg ulcers received HCSE ($n = 27$) or placebo ($n = 27$) for 12 weeks. At weeks 4, 8 and 12 the difference between groups in the number of healed leg ulcers and change in wound surface area, depth, volume, pain and exudate was not statistically significant. There was however a significant effect on the percentage of wound slough over time ($P = 0.045$) and on the number of dressing changes at week 12 ($P = 0.009$) (Leach et al 2006a). As a result, after taking into account the cost of HCSE, dressing materials, travel, staff salaries and infrastructure for each patient, this study determined a cost benefit for the addition of HCSE to conventional therapy of AU$95 in organisational costs, and AU$10 in dressing materials per patient (Leach et al 2006b). Further large scale trials are required to fully elucidate the potential use in practice.

Haemorrhoids

Horse chestnut is also used both orally and topically for the treatment of haemorrhoids. Although it has not been investigated for this indication, escin has been shown to significantly improve signs and symptoms according to a placebo-controlled double-blind study of 72 volunteers with haemorrhoids. Symptom relief was experienced by 82% of subjects compared with 32% for placebo, and swelling improved in 87% compared with 38% for placebo (Sirtori 2001). Symptom improvement required at least 6 days of treatment to become established and the dose used was 40 mg escin three times daily.

OTHER USES

Traditionally the seeds are used to treat conditions affecting the veins, including haemorrhoids, phlebitis and varicose veins; bruising, diarrhoea, fever, enlarged prostate, eczema, menstrual pain, painful injuries, sprains, swelling and spinal problems. The leaf is used for soft tissue swelling from bone fracture and sprains, complaints after concussion, cough, arthritis and rheumatism, and the bark for malaria and dysentery, and topically for SLE and skin ulcers (NMCD 2006, PDRHealth 2006).

There is some evidence to support its use for preventing post-operative oedema (Sirtori 2001) and the antioxidant, vascular toning and anti-inflammatory effects of *A. hippocastanum*, as well as the presence of flavonoids and other active constituents, may support some of the other traditional uses (Wilkinson & Brown 1999).

Bell's palsy

Sodium beta-escin has been proposed as a potential agent for treating oedema complicated by Bell's palsy due to its ability to relieve tissue oedema, recover vasopermeability and eliminate pressure caused by oedema (Liu et al 2008).

DOSAGE RANGE

- Chronic venous insufficiency: HCSE standardised to 50–100 mg escin twice daily. The dose may be reduced to a maintenance dose of 50 mg escin once daily after 8 weeks (Pohlmann et al 2000).
- Australian manufacturers recommend 2–5 mL/day of 1:2 liquid extract.
- 1–2 g dried seed daily (Mills & Bone 2005).

ADVERSE REACTIONS

According to clinical trials *A. hippocastanum* and HCSE appear to be well tolerated with only mild, infrequent reports of adverse reactions including gastric irritation, skin irritation, dizziness, nausea, headache and pruritus. Postmarketing surveillance reports adverse effects of 0.7% (Micromedex 2003, NMCD 2006, PDRHealth 2006, Pittler & Ernst 2004, Siebert et al 2002).

Horse chestnut contains a toxic glycoside esculin (aesculin), a hydroxycoumarin that may increase bleeding time because of its antithrombin activity and may be lethal when the raw seeds, bark, flower or leaves are used orally. Poisoning has been reported from children drinking tea made with twigs and leaves (NMCD 2006).

Symptoms of overdose include diarrhoea, vomiting, reddening of the face, severe thirst, muscle twitching, weakness, loss of coordination, visual disturbances, enlarged pupils, depression, paralysis, stupor and loss of consciousness (NMCD 2006, PDRHealth 2006).

Horse chestnut can also cause hypersensitivity reactions, which occur more commonly in people who are allergic to latex (Diaz-Perales et al 1999).

Isolated cases of kidney and liver toxicity have occurred after intravenous and intramuscular administration (Micromedex 2003, Mills & Bone 2005, NMCD 2006).

SIGNIFICANT INTERACTIONS

In vitro studies have revealed that horse chestnut may inhibit CYP3A4 mediated metabolism and P-glycoprotein efflux transport activity (Hellum & Nilsen 2008). The clinical significance of these findings remains to be tested.

Antiplatelet/ anticoagulant medications

Properly prepared HCSE should not contain esculin and should not carry the risk of antithrombin activity — observe. Clinical significance unclear.

Hypoglycaemic agents

Due to possible hypoglycaemic activity, blood glucose levels should be monitored when horse chestnut or HCSE and hypoglycaemic agents are used concurrently (Yoshikawa et al 1996) — observe. Clinical significance unclear.

CONTRAINDICATIONS AND PRECAUTIONS

As saponins may cause irritation to the gastric mucosa and skin, *A. hippocastanum* should be taken with food, should not be applied topically to broken or ulcerated skin and should be avoided by people with infectious or inflammatory conditions of the gastrointestinal tract, including coeliac disease and malabsorption disorders.

PRACTICE POINTS/PATIENT COUNSELLING

- Horse chestnut extract has been extensively researched for its beneficial effects and is commonly used by GPs in Germany for the treatment of CVI. There is strong evidence to support its use for this indication.
- In practice, a dry extract is used (HCSE standardised to contain 16–21% triterpene glycosides (anhydrous escin)).
- HCSE is also used for venous leg ulceration because it increases venous tone while reducing venous fragility and capillary permeability, and possesses anti-oedematous and anti-inflammatory properties.
- HCSE is also used in the treatment of haemorrhoids. Although it has not been investigated for this indication, escin has been shown to significantly improve signs and symptoms under double-blind study conditions.
- HCSE is well tolerated with only mild, infrequent reports of adverse reactions including gastric irritation, skin irritation, dizziness, nausea, headache and pruritus.
- Horse chestnut can cause hypersensitivity reactions, which occur more commonly in people who are allergic to latex.

Horse chestnut flower, raw seed, branch bark or leaf may be toxic and are not recommended (Tiffany et al 2002).

Avoid use in the presence of hepatic or renal impairment (Micromedex 2003, NMCD 2006, PDRHealth 2006).

In toxicity studies in rats, escin decreased white blood cells, increased the number of red blood cells and platelets, and haemoglobin content; and reduced prothrombin time and thrombin time (5, 10, 15 mg/kg) (Li et al 2006).

PREGNANCY USE

Safety in pregnancy and lactation has not been well established.

PATIENTS' FAQs

What will this herb do for me?

Horse chestnut standardised extract (HCSE) will relieve signs and symptoms of chronic venous insufficiency such as pain, pruritus and oedema. It may also be of benefit in alleviating signs and symptoms in people with haemorrhoids and has been used in venous leg ulceration.

When will it start to work?

Beneficial effects in chronic venous insufficiency have been reported within 3–6 weeks; however, 12 weeks may be required in some cases. Escin provided symptom relief in haemorrhoids after 6 days of treatment.

Are there any safety issues?

HCSE is well tolerated with only mild, infrequent reports of adverse reactions including gastric irritation, skin irritation, dizziness, nausea, headache and pruritus. It can cause hypersensitivity reactions, which occur more commonly in people who are allergic to latex.

Horseradish

HISTORICAL NOTE Horseradish is a commonly used spice with a long history of use in traditional medicine. The leaves are used in cooking and as a salad green. Horseradish is one of the 'five bitter herbs' of the biblical Passover.

COMMON NAME
Horseradish

OTHER NAMES
Amoraciae rusticanae radix, great mountain root, great raifort, mountain radish, pepperrot, red cole

BOTANICAL NAME/FAMILY
Armoracia rusticana, synonym *Armoracia lopathifolia*; *Cochlearia armoracia*, *Nasturtium armoracia*, *Roripa armoracia* (family Brassicaceae [Cruciferae])

PLANT PARTS USED
Fresh or dried roots and leaves

CHEMICAL COMPONENTS
Horseradish root contains volatile oils: glucosinolates (mustard oil glycosides); gluconasturtiin and sinigrin (S-glucosides); coumarins (aesculetin, scopoletin); phenolic acids, including caffeic acid derivatives and hydroxycinnamic acid derivatives, ascorbic acid; asparagin; resin; and peroxidase enzymes. Horseradish is one of the richest plant sources of peroxidase enzymes, which are commonly used as oxidising agents in commercial chemical tests.

MAIN ACTIONS
Horseradish is widely known for its pungent burning flavour. The pungency of horseradish is due to the release of allyl isothiocyanate and butyl thiocyanate upon crushing (Yu et al 2001). These mustard oil glycosides may irritate the mucous membranes upon contact or inhalation and may act as circulatory and digestive stimulants; however, the mechanism of action has not been fully elucidated (Blumenthal et al 2000, Jordt et al 2004). It has been found that topical application of allyl isothiocyanate to the skin activates sensory nerve endings producing pain, inflammation and hypersensitivity to thermal and mechanical stimuli due to depolarising the same sensory neurons that are activated by capsaicin and tetrahydrocannabinol (THC) (Jordt et al 2004). Allyl isothiocynate is known to have antimicrobial and antitumour properties (Pengelly 1996).

Circulatory stimulant
The mustard oils released when horseradish is crushed may be responsible for this activity.

Digestive stimulant
Again, it is suspected that the mustard oils may be responsible as these act as irritants. Large doses may cause emesis (Pengelly 1996).

OTHER ACTIONS
Isothiocyanates may inhibit thyroxine formation and be goitrogenic (Langer 1965), although this has not been demonstrated clinically.

The peroxidase enzymes assist in wound healing, whereas the sulfur-containing compounds may decrease the thickness of mucus by altering the structure of its mucopolysaccharide constituents (Mills & Bone 2000). Antispasmodic and antimicrobial effects have also been reported (Blumenthal et al 2000, Newell et al 1996). Horseradish has been found to lower plasma cholesterol and faecal bile acid excretion in mice fed with a cholesterol-enriched diet possibly due to interference with exogenous cholesterol absorption (Balasinska et al 2005).

Horseradish has also been found to contain compounds that inhibit tumour cell growth and COX-1 enzymes (Weil et al 2005). In vivo trials testing a combination of herbs, including horseradish, has been found to protect against viral transmission of avian influenza (Oxford et al 2007).

CLINICAL USE
The therapeutic effectiveness of horseradish has not been significantly investigated.

Nasal congestion and sinusitis
Horseradish is widely used in combination with other ingredients such as garlic in herbal decongestant formulations. Anecdotal evidence suggests that a mild, transient decongestant effect occurs. It is reputed to eliminate excessive catarrh from the respiratory tract (Drew 2002, Tancred 2006), although clinical research is not available to confirm its efficacy.

OTHER USES
It has been used traditionally to treat both bronchial and urinary infections, joint and tissue inflammations, as well as treating gall bladder disorders, reducing oedema and as an abortifacient (Skidmore-Roth 2001).

An in vivo study in mice demonstrated that allyl isothiocyanate markedly inhibited the formation of gastric lesions (Matsuda et al 2007).

DOSAGE RANGE
- The typical dose of horseradish is 2–20 g/day of the root or equivalent preparations.
- Topical preparations with a maximum of 2% mustard oil content are commonly used (Blumenthal et al 2000).

ADVERSE REACTIONS
Despite the potential for severe irritation, horseradish is generally recognised as safe for human consumption in quantities used as food. Consuming large amounts of horseradish can cause gastrointestinal upset, vomiting and diarrhoea, and

irritation of mucous membranes. Skin contact with fresh horseradish can cause irritation and blistering or allergic reactions. If used topically it should be diluted 50% with water and not applied for prolonged periods. Application to a small test area before wider application is recommended for people with sensitive skin.

SIGNIFICANT INTERACTIONS

None known.

CONTRAINDICATIONS AND PRECAUTIONS

Internal use should be avoided in people with stomach and intestinal ulcers and kidney disorders, as well as in children under the age of 4 years (Blumenthal et al 2000).

Traditionally, horseradish is considered a warming herb that will exacerbate any 'hot' condition and is specifically indicated for 'cold' conditions.

PREGNANCY USE

The mustard oils released upon crushing are potentially toxic, therefore doses exceeding dietary intakes are contraindicated (Newell et al 1996).

PRACTICE POINTS/PATIENT COUNSELLING

- Horseradish has been used as a vegetable, condiment, diuretic and treatment for bronchial and urinary infections, joint and tissue inflammation and swelling.
- It is widely used together with other herbal ingredients such as garlic, as a decongestant in the treatment of colds and sinusitis.
- No scientific investigation has been undertaken to support its use, although anecdotal evidence suggests that it may be useful.
- Horseradish is generally safe when the root is ingested in usual dietary amounts, although excessive intake may cause irritation to the stomach, respiratory tract and kidneys.

PATIENTS' FAQs

What will this herb do for me?

Anecdotal evidence suggests that it may have decongestant effects and is a very popular treatment when combined with other herbs such as garlic, to relieve the symptoms of colds and sinusitis.

When will it start to work?

It may relieve symptoms within the first few doses, but scientific tests are not available to confirm this.

Are there any safety issues?

Horseradish can be quite irritating for some people due to its bitter and pungent characteristics.

Iodine

BACKGROUND AND RELEVANT PHARMACOKINETICS

Iodine is an essential trace element required for proper functioning of the thyroid gland. It is mainly consumed as iodide salts obtained from sea salt, shellfish and seawater fish and vegetables, which are more bioavailable than the organic forms. The iodine content of soil is considered to be one of the most variable of all minerals, influenced by local geography and the type and quantity of fertiliser used in agriculture (Groff et al 2009). There is evidence of iodine-deficient soils in many regions of Australia. Dietary iodine content is also significantly influenced by agricultural iodine-containing compounds, used in irrigation products, fertilisers and livestock feeds (Zimmermann et al 2008).

Iodide is rapidly absorbed from the stomach to the small intestine and distributed via the blood to a range of tissues, most notably the thyroid, which traps iodide through an ATP-dependent iodide pump called the sodium iodide symporter. The thyroid contains 80% of the body's iodine pool, which is approximately 15 mg in adults. Also found in high concentrations in the salivary, gastric and mammary glands (exclusively during pregnancy and lactation in the latter), iodine's uptake is regulated by thyroid-stimulating hormone (TSH) (Groff et al 2009, Kohlmeier 2003).

Excreted via the kidneys when the needs of the thyroid have been met and an excess remains (Kohlmeier 2003), urine concentrations reflect plasma levels and have been used since the middle

of the 20th century to assess iodine status. Interestingly, there is no renal conservation mechanism for this mineral and the only evidence of iodine preservation comes from the scavenging and recycling of thyroid hormones by the selenium-dependent deiodinase DII (Kohlmeier 2003). Of the total amount excreted, 20% occurs via faeces and additional losses can occur through sweat, which, although a minor eliminatory pathway under normal circumstances, can be a significant contributor for people living in hot climates with low dietary consumption (Groff et al 2009).

FOOD SOURCES

Iodine can occur in foods as either an inorganic or organic salt, or as thyroxine in animal sources. Unlike many other essential nutrients, the organic form of iodine found in animal products has poor bioavailability, whereas the iodide salts found in the sea are almost completely absorbed (Jones 2002).

However, irrespective of whether it is animal or plant derived, food from the land has enormous variability in terms of iodine content, from 1 to 10 microgram/kg (Geissler & Powers 2005), due to iodine's high solubility and therefore susceptibility to leaching (Wahlqvist 2002).

Additionally, chemicals known as goitrogens are naturally found in some foods (e.g. brassica [cabbage] family) and these interfere with iodine utilisation and thyroid hormone production.

Best sources

Due to the high saltwater levels of bioavailable iodide, all sea-dwelling creatures, animal or plant, are considered as superior dietary sources.

- Seawater fish
- Shellfish
- Sea vegetables such as seaweeds
- Iodised salt (fortified form of table salt) — providing 20–40 microgram/g
- Commercially manufactured breads due to the iodate dough oxidisers
- Dairy milk (variable)

In Australia, milk no longer supplies a significant amount of iodine, whereas in the United Kingdom it is still an important dietary source because of the use of both supplemented feeds and iodine-based antiseptics in the dairy industry (Geissler & Powers 2005).

DEFICIENCY SIGNS AND SYMPTOMS

Primary deficiency

Iodine deficiency results when iodide intake is < 20 microgram/day (Kasper et al 2005). In situations of moderate deficiency, TSH induces thyroid hypertrophy in order to concentrate iodide, resulting in goitre. Most of these cases remain euthyroid, but in cases of severe iodine deficiency, myxoedema may result in adults and cretinism in infants, both of which are serious conditions.

Myxoedema is characterised by swelling of the hands, face, feet and peri-orbital tissues and can lead to coma and death if sufficiently severe and left untreated. Endemic cretinism is divided into two forms, neurologic or myxoedematous, depending on the interplay of genetics and iodine deficiency. Usually, children with neurologic cretinism are mentally deficient and often deaf mute but of normal height and strength and may have goitre. Myxoedematous cretinism is characterised by dwarfism, mental deficiency, dry skin, large tongue, umbilical hernia, muscular incoordination and puffy facial features. Concomitant selenium deficiency may be a contributing factor in myxoedematous cretinism. Early treatment with thyroid hormone supplementation can promote normal physical growth; however, intellectual disability may not be prevented and in very severe cases death may ensue.

The term 'iodine deficiency disorders' (IDD) has been coined to refer to the collection of health problems that result from iodine deficiency, ranging from the mild and common (e.g. goitre) to severe and life threatening (e.g. cretinism and myxoedema) (Groff et al 2009).

Although severe iodine deficiency is rare in Australia and New Zealand, many parts of the world have notoriously low iodine levels. Countries where iodine deficiency is a primary concern include China, Latin America, Southeast Asia and the eastern Mediterranean (Wahlqvist 2002). A report conducted by the World Health Organization in 2005 found that while many countries had succeeded in reaching optimal iodine nutrition through enhanced monitoring and fortification programs over the past decade, an estimated 285 million school-age children and close to 2 million adults worldwide still suffer from IDD (Andersson et al 2005).

Fetal deficiency

The fetus depends solely on maternal thyroid hormones during the first trimester of pregnancy (Soldin et al 2002) and iodine deficiency uncorrected prior to mid-gestation results in irreversible brain damage (de Escobar et al 2007). To accommodate for this, increasing plasma volume, renal clearance and the increased thyroid hormone degradation secondary to hyperactivity of the uterine–placental deiodinases, healthy pregnant women exhibit a surge in T_4 production, partly under the stimulation of human chorionic gonadotropin (HCG). From week 11 of gestation, fetal thyroid hormone synthesis usually begins, still dependent on maternal provision of iodine and at term a residual 20–40% of T_4 found in cord blood is of maternal origin (de Escobar et al 2008, Delange 2007, Glinoer 2007, Zimmermannn 2008). These demands necessitate a ≈ 100% increase (e.g. 250–300 microgram/day) (de Escobar et al 2008, Delange 2007) in iodine intake from conception. Should such needs go unmet, the mother will adapt by preferentially producing T_3 to stave off both clinical and biochemical hypothyroidism. The fetus, however, yet to develop rapid adaptations to circulating iodine levels, will exhibit reductions of all thyroid hormones and develop hypothyroidism in spite of the mother's euthyroid state (de Escobar et al 2008).

Adequate iodine and healthy functioning of both the maternal and the fetal thyroid glands play a critical role in fetal neuropsycho-intellectual development, due to its role in neuronal migration and myelination, with brain damage risk secondary to a deficiency, peaking in the second trimester and the early neonatal period. Studies have also confirmed that 'mild but measurable' psychomotor deficits in early childhood can result from subclinical hypothyroidism and hypothyroxaemia caused by mild-to-moderate iodine deficiency in pregnancy (Glinoer 2007, Soldin et al 2002). Finally, severe iodine deficiency during pregnancy also increases risk of stillbirths, miscarriage, perinatal mortality and congenital abnormalities (Zimmermann 2008).

Because of the severe neurological consequences of untreated congenital hypothyroidism, neonatal screening programs have been established in some developed countries; however, early or pre-pregnancy detection of subclinical iodine deficiency would be most effective (Ares et al 2008).

Premature infant deficiency

Premature infants face a significantly elevated risk of iodine deficiency secondary to a collusion of factors: interruption of maternal supply (small amounts of breast milk provide substantially smaller quantities of iodine than placental transfer), immaturity of the hypothalamic pituitary thyroid axis and the deiodinase systems, maternal antibodies and postnatal exposure to drugs (e.g. dopamine, heparin, corticosteroids) (Ares et al 2008). Research suggests that 75% of premature neonates demonstrate a negative iodine balance at 5 days post-partum prior to intentional repletion.

Secondary deficiency

High consumption of goitrogens can induce a secondary deficiency state. Goitrogens are substances that inhibit iodine metabolism and include thiocyanates found in the cabbage family (e.g. cabbage, kale, cauliflower, broccoli, turnips and Brussels sprouts) and in linseed, cassava, millet, soybean and competing entities, such as other members of the halogen family (e.g. bromine, fluorine and lithium, as well as arsenic) (Groff et al 2009). Most researchers agree, however, that moderate intake of goitrogens in the diet is not an issue, except when accompanied by low iodine consumption (Groff et al 2009, Kohlmeier 2003). A very rare cause of secondary iodine deficiency and hypothyroidism is TSH deficiency.

Low selenium intake

Low dietary intake of selenium is a factor that exacerbates the effects of iodine deficiency. Selenium is found in the thyroid gland in high concentrations, and while iodine is required for thyroid hormone synthesis, selenium-dependent enzymes are required for the peripheral conversion of thyroxine (T_4) to its biologically active form triiodothyronine (T_3) (Higdon 2003), as well as the general recycling of iodine. Selenium deficiency results in decreased T_4 catabolism, which leads to increased production of peroxide and thyroid cell destruction, fibrosis and functional failure.

SIGNS AND SYMPTOMS

Overall, in addition to highly visible goitre, moderate-to-severe iodine deficiency produces subtle but widespread effects secondary to hypothyroidism, including reduced educability, apathy and impaired productivity, culminating ultimately in poor social and economic development (Zimmermann 2008).

Mild hypothyroidism

This refers to biochemical evidence of thyroid hormone deficiency in patients who have few or no apparent clinical features of hypothyroidism.

Congenital hypothyroidism

The majority of infants appear normal at birth and < 10% are diagnosed with hypothyroidism based on the following clinical features:

- prolonged jaundice
- feeding problems
- hypotonia
- enlarged tongue
- delayed bone maturation
- umbilical hernia.

Importantly, permanent neurologic damage results if treatment is delayed.

Adult hypothyroidism

According to Beers (2005), the clinical signs of hypothyroidism in adults are as follows:

- weakness, tiredness and sleepiness
- dry skin
- cold intolerance
- hair loss and diffuse alopecia
- poor memory and difficulty concentrating
- constipation
- reduced appetite and weight gain
- dyspnoea
- hoarse voice
- increased susceptibility to infectious diseases
- increased susceptibility to cardiovascular diseases
- paraesthesia
- puffy hands, feet and face and peripheral oedema
- impaired hearing
- menorrhagia (later amenorrhoea)
- carpal tunnel and other entrapment syndromes are common, as is impairment of muscle function with stiffness, cramps and pain
- reduced myocardial contractility and pulse rate, leading to a reduced stroke volume and bradycardia.

In adults, mild–moderate iodine deficiency also results in higher rates of more aggressive subtypes of thyroid cancer and an increased risk of (non) toxic goitre (Zimmermann 2008).

MAIN ACTIONS

Thyroid hormone production

Iodine is essential for the manufacture of T_4 and T_3, which are hormones that influence growth, maturation, thermogenesis, oxidation, myelination of the CNS and the metabolism of all tissues (Jones

2002). The thyroid hormones, especially T_3, exert their effects by binding to nuclear receptors on cell surfaces, which in turn trigger binding of the zinc fingers of the receptor protein to the DNA (Groff et al 2009).

OTHER ACTIONS

Due to the concentration of appreciable iodine levels in a range of other tissues, including salivary, gastric and lactating mammary glands, and the ovaries, questions remain about potential additional actions of iodine. One hypothesis postulates iodine as an indirect antioxidant, via its capacity to reduce elevated TSH, a trigger of increased peroxide levels in the body (Smyth 2003).

CLINICAL USE

Increased iodine intake can be achieved through dietary modification and supplementation with tablets. Dietary modification usually refers to increased intake of iodised salt, but may also refer to use of iodised water, iodised vegetable oil or seafood.

Treatment and prevention of deficiency

Iodine deficiency is accepted as the most common cause of brain damage worldwide, with IDD affecting 740 million people (Higdon 2003). Although it is well accepted that severe deficiency is responsible, evidence is now emerging that mild deficiency during pregnancy is also important and can have subtle effects on brain development, lowering intellectual functioning and inducing psychomotor deficits in early childhood (Glinoer 2007). Preliminary data are also emerging to suggest an association between iodine deficiency hypothyroidism of pregnancy and the incidence of attention-deficit/hyperactivity disorder (ADHD) in the offspring; however, this still requires confirmation in larger studies (Soldin et al 2002, Vermiglio et al 2004).

Pregnancy

Severe iodine deficiency is uncommon in Western countries, such as Australia and New Zealand, but several local surveys have identified that mild-to-moderate deficiency is more prevalent than once thought. A research group at Monash Medical Centre in Melbourne screened 802 pregnant women and found that 48.4% of Caucasian women had urinary iodine excretion (UIE) concentrations below 50 microgram/L compared to 38.4% of Vietnamese women and 40.8% of Indian/Sri Lankan women (Hamrosi et al 2005). These figures are disturbing when the WHO defines healthy UIE levels as greater than 100 microgram/L, mild deficiency is diagnosed at 51–100 microgram/L and moderate-to-severe deficiency at < 50 microgram/L (Gunton et al 1999). A study conducted at a Sydney hospital involving 81 women attending a 'high' risk clinic found moderate-to-severe iodine deficiency in 18.8% of subjects and mild iodine deficiency in another 29.6% (Gunton et al 1999), the former clearly too close to the WHO maximum acceptable level of 20%. This study also revealed that almost 5% of the sample had UIE < 25 microgram/L. Based on such results, it may well be expected that endemic cretinism could emerge, with an overt manifestation possibly delayed due to low-to-moderate intake of goitrogens and adequate selenium levels in this population.

Aside from fortification programs in populations affected by severe iodine deficiency, there have been several RCTs of iodine supplementation in mild-to-moderately deficient pregnant women (Zimmerman 2008). While treatment effects include reductions in maternal and newborn thyroid size and, in some, reduced maternal TSH, none of the studies have demonstrated a positive effect on T_4 and T_3 of mother or child, or measured longer term clinical outcomes. Future research needs to address these issues.

Infants

An investigation of infant TSH levels within 72 h of birth at the Royal North Shore Hospital in Sydney suggests that endemic IDD may be emerging (McElduff 2002). Currently, the WHO recommends that less than 3% of newborns should have TSH levels greater than 5 mIU/L and of the 1773 infants enrolled in the study, 5–10% had a TSH reading > 5 mIU/L.

Children and adolescents

Evidence of iodine deficiency is not limited to pregnant women and newborns and has also been demonstrated in Australian schoolchildren (Li et al 2006). Iodine status in schoolchildren is based on median UIE values and is categorised as normal (UIE ≥ 100 microgram/L) or as mild (UIE 50–99 microgram/L), moderate (UIE 20–49 microgram/L) and severe deficiency (UIE < 20 microgram/L). The UIE is considered in combination with the child's sex, year of school and presence of goitre.

A study of Melbourne schoolchildren aged 11–18 years found that 76% (439/577) had abnormal UIE values, with 27% (156/577) possessing values consistent with moderate-to-severe iodine deficiency (McDonnell et al 2003). The median UIE value in girls was lower than that in boys (64 microgram/L vs 82 microgram/L), and girls had significantly lower UIE values overall ($P < 0.002$). A study of 324 schoolchildren aged 5–13 years from the Central Coast of New South Wales produced similar results and there was a median UIE concentration of 82 microgram/L, with 14% of children having levels below 50 microgram/L (Guttikonda et al 2003).

These findings were confirmed in the Australian National Iodine Nutrition Study, which identified inadequate iodine intake in the Australian population and called for the urgent implementation of mandatory iodisation of all edible salt in Australia (Li et al 2006). The study consisted of a survey of 1709 schoolchildren aged 8–10 years in the five mainland Australian States and was conducted between July 2003 and December 2004. It found that, overall, children in mainland Australia are borderline iodine deficient, with a national median UIE of 104 microgram/L. On a state basis, children in Victoria and New South T Wales are mildly iodine deficient,

Clinical note — Why is iodine deficiency on the rise?

In spite of increased rates of household iodised salt use globally since 1990, iodine intakes in Australia are falling (Zimmermann 2008). The emergence or re-emergence of iodine deficiency, however, is not limited to Australia; median UIE had declined by more than 50% between 1971 and 1994 in the United States (Gunton et al 1999, Zimmerman 2008).

Three reasons have been proposed to explain the emergence of iodine deficiency in developed countries. First, milk was traditionally viewed as a good dietary source of iodine; however, since the 1990s its iodine content has reduced significantly because iodine-containing sanitisers have been gradually replaced with chlorine-containing substitutes. The significance of this change within the dairy industry was recently shown by Li et al (2006) who compared the iodine content of Australian milk products from 1975 and 2004. They identified mean iodine concentrations of 593.5 microgram/L and 583 microgram/L from samples taken from Victoria and New South Wales (NSW), respectively in 1975 compared to a median concentration of 195 microgram/L in 2004 (250 mL providing 50–60 microgram iodine). Interestingly, the same researchers demonstrated that dairy products and water in northern and central Queensland contain higher iodine levels, which may explain the lower incidence of iodine deficiency in these areas (Li et al 2006). In spite of this, a survey of dietary habits of Tasmanian schoolchildren has revealed that consumption of dairy products is associated with improved iodine status (Hynes et al 2004), a case of some being better than none.

A second reason may relate to public health campaigns that have resulted in increased awareness of the potential adverse effects of salt and reduced its consumption, but failed to highlight the potential benefits of a moderate intake of iodised salt. In addition, few food manufacturers use iodised salt in their products, further reducing exposure to iodine (Gunton et al 1999).

Lastly, the mineral depletion of soils is another possible contributing factor, in particular, the depletion of selenium. Considering its role in iodine utilisation, selenium deficiency would potentiate the effects of iodine deficiency. Other theoretical considerations include increased environmental exposure to halogens, such as fluorine and chlorine, and increased consumption of goitrogens, such as soy, in the diet.

Although identifying the key factors responsible for the growth of iodine deficiency is important (Thomson 2004), many authors argue that implementation of national iodine monitoring and surveillance of the iodine content in foods are the most immediate concern (Li et al 2006, McDonnell et al 2003). Lessons learnt from Tasmania's iodine supplementation program, where statewide bread fortification failed to reduce the prevalence of iodine deficiency in children, indicate that greater efforts are required to create significant improvements in iodine status.

with median UIE levels of 89 microgram/L and 73.5 microgram/L, respectively, South Australian children are borderline iodine deficient, with a median UIE of 101 microgram/L, whereas both Queensland and Western Australian children are iodine sufficient, with median UIE levels of 136.5 microgram/L and 142.5 microgram/L, respectively. Researchers attributed the decline in iodine intake to changes within the dairy industry, with chlorine-containing sanitisers now replacing iodine-containing sanitisers and decreased intake of iodised salt.

In 2001, an iodine supplementation program was initiated in Tasmania because it was identified as an area of endemic goitre by the Department of Health Services. The program involves the use of iodised salt in 80% of Tasmania's bread production and aims to reduce the incidence of iodine deficiency. Despite encouraging preliminary data (Doyle & Seal 2003), iodine levels are still inadequate according to the WHO standards. There have been conflicting opinions about the success of this program, with the largest study demonstrating evidence of ongoing iodine deficiency (Seal et al 2003, Guttikonda et al 2002).

Iodine deficiency in children and adolescents is associated with poorer school performance, reduced achievement motivation and a higher incidence of learning disabilities (Tiwari et al 1996, Zimmermann 2008). A meta-analysis of 18 studies from eight countries of people aged between 2 and 30 years showed that iodine deficiency alone reduced mean IQ scores by 13.5 points in children (Bleichrodt et al 1996). Iodine repletion studies in children have yielded improved somatic growth, partial reversal of cognitive impairment and normalisation of age of onset of puberty; however, the strength of the evidence is hampered by methodological issues (Markou et al 2008, Zimmermann et al 2006, Zimmermann 2008).

Adults

A study of non-pregnant adults in 1999 demonstrated iodine deficiency in 26.3% of 'healthy' subjects and 34.1% of diabetic subjects (Gunton et al 1999).

Non-toxic goitre thyroidectomy

One 12-month study involving 139 patients who had undergone thyroidectomy for non-toxic goitre identified that supplementing L-thyroxine therapy with iodised salt produced significant improvements in thyroid function compared with stand alone L-thyroxine therapy (Carella et al 2002).

OTHER USES

Prevention of attention-deficit hyperactivity disorder

Emerging data from research conducted over the past 15 years suggest a possible link between low maternal iodine status and increased risk of

ADHD in the offspring. According to a report published in 2004, 11 of 16 children born to women living in a moderately iodine-deficient region in Italy developed ADHD compared to no offspring from the 11 control mothers living in a marginally iodine-deficient region (Vermiglio et al 2004).

On the other hand, another group of researchers investigated whether T_4 levels at birth could represent a biomarker for later development of ADHD and found that all newborns in the sample had T_4 within the normal range and no correlation between values and risk could be demonstrated (Soldin 2002, Soldin et al 2003). This evidence invalidated TSH levels as a biomarker of risk, but does not disprove a link between iodine and ADHD, as earlier studies found that those newborns who later developed ADHD were all euthyroid at birth (Vermiglio et al 2004).

Although further investigation is required to clarify these observations, they have provided a new avenue for ADHD research.

Fibrocystic breast disease and cyclic mastalgia

A 1993 review that focused on three clinical studies suggests that iodine supplementation may improve objective and subjective outcomes, including pain and fibrosis, for women with fibrocystic breast disease and cyclic mastalgia (Ghent et al 1993). Together the trials involved 1000 women and used a variety of different forms, the most successful being molecular iodine at a dose of 0.08 mg/kg (approximately equivalent to 500 microgram/day in a 60 kg woman) (Ghent et al 1993).

Recently, a placebo-controlled trial conducted with 11 euthyroid women with cyclic mastalgia tested different doses of molecular iodine ranging from 1.5 to 6 mg/day and showed that after 3 months of treatment, 50% of patients consuming 3 or 6 mg/day experienced a significant decrease in pain (Kessler 2004). Although no dose-related adverse events were detected, further investigation is required to confirm both efficacy and safety.

Breast cancer

There is suggestive evidence of a preventive role for iodine in breast cancer. As far back as 1896, research has suggested a link between iodine deficiency, thyroid disease and breast cancer (Gago-Dominguez & Castelao 2008, Smyth 2003, Stoddard et al 2008). Epidemiological data have demonstrated a correlation between increased incidence of breast cancer and a range of thyroid conditions, most notably hypothyroidism, with both conditions demonstrating peak incidence in postmenopausal women (Gago-Dominguez & Castelao 2008, Smyth 2003). A prospective study of peri- and postmenopausal women revealed that low free T_4 was an independent risk for the development of breast cancer (OR 2.3). Another study found that the premenopausal women treated for differentiated thyroid cancer with radioactive iodine were at an increased risk of developing breast cancer over the following 5–20 years (Gago-Dominguez & Castelao 2008). In addition, the observed low rates of breast cancer in Japanese women consuming a traditional diet are speculated to be partly due to a high dietary iodine intake, further suggesting a protective effect (Patrick 2008). Notably, this protection disappears when Japanese women consume a 'Western diet'.

It is noteworthy that both the thyroid and the breast share the capacity to concentrate iodide, which exerts both an oxidant effect, triggering and facilitating apoptosis and antioxidant effect, protecting cells from peroxidative damage (Gago-Dominguez & Castelao 2008, Venturi 2001) and converts it to iodine. The thyroid retains this capacity throughout life, whereas the healthy breast can only concentrate iodide during pregnancy and lactation, states associated with a reduced risk of breast cancer. Curiously, ≈ 80% of breast cancers also demonstrate iodide uptake (Stoddard et al 2008). It has been theorised that with iodine insufficiency during pregnancy and lactation, the protective effect of iodide may be compromised, concomitant with diminished oxidant and antioxidant activities. Researchers speculate that this scenario may be compounded by co-existing selenium deficiency (Turken et al 2003).

Besides the diminished antioxidant effect, studies with animal models show that iodine deficiency results in changes in the mammary gland that makes it more sensitive to the effects of oestradiol (Stoddard et al 2008, Strum 1979). Iodine has been implicated in the synthesis of alpha-oestrogen receptors, down-regulation of several oestrogen-responsive genes and increased expression of the cytochrome P450 genes responsible for its phase I detoxification (Stoddard et al 2008). Together with other sources of evidence, it is clear that the potential protective effect of iodine against breast cancer is independent of its thyroid role (Stoddard et al 2008).

At present, the only interventional evidence comes from rat studies, demonstrating that administration of Lugol's iodine or iodine-rich Wakame seaweed suppressed the development of induced mammary tumours (Funahashi et al 2001) and in vitro evidence confirming that molecular iodine induces apoptosis in breast cancer cell lines (Shrivastava et al 2006). In light of ongoing evidence of a superior effect of molecular iodine rather than iodide in relation to breast pathology in both animals and humans, rigorous human studies using this form are required (Patrick 2008, Stoddard et al 2008).

Water purification

Iodine-releasing tablets and iodine tincture have been used for many years to decontaminate water and have been used by the United States Army since World War II. A weak aqueous solution of 3–5 ppm of elemental iodine can destroy a wide range of enteroviruses, ameobae and their cysts, bacteria and their spores, as well as algae. Under temperate conditions of 25°C the disinfection process takes 15 minutes, longer in colder conditions. Adding to the versatility of iodine as a water decontamination agent is its ability to act over a wide range of pH and still be effective in the presence of

ammonia and amino ions from nitrogenous wastes that may be also present in the water (Kahn & Visscher 1975).

Antiseptic

Iodine solution is widely used as a topical antiseptic in the treatment of superficial wounds. It is a highly effective method of decontaminating intact skin and minor wounds and has a low toxicity profile. Povidone–iodine preparations have replaced older iodine solutions and are now the most widely used form.

Although the treatment is considered safe, a number of reports of iodine toxicity in newborns receiving ongoing treatment with topical iodine-based solutions suggest that it should be used with caution as an ongoing treatment in this group and TSH monitoring considered where appropriate.

DOSAGE RANGE

Australian recommended daily intake (RDI)

- Infants
  - 0–6 months: 90 microgram/day.
  - 7–12 months: 110 microgram/day.
- Children
  - 1–3 years: 90 microgram/day.
  - 4–8 years: 90 microgram/day.
  - 9–14 years: 120 microgram/day.
  - >14 years: 150 microgram/day.
- Adults: 150 microgram/day.
- Pregnancy: 220 microgram/day.
- Lactation: 270 microgram/day.
- Upper level of intake
  - 1–3 years: 200 microgram/day.
  - 4–8 years: 300 microgram/day.
  - 9–13 years: 600 microgram/day.
  - 14–18 years (including pregnancy, lactation): 900 microgram/day.
  - Adults >18 years (including pregnancy, lactation): 1100 microgram/day.

These are the newly revised Australian RDIs, which are more closely aligned with the WHO recommendations than previously.

According to clinical studies

- ADHD prevention: adequate intake to prevent maternal deficiency (approximately 250 microgram/day).
- Fibrocystic breast disease and cyclic mastalgia: 500 microgram–6 mg molecular iodine/day.
- Breast cancer prevention: dose is unknown; however, it is suggested that women meet RDI to prevent deficiency.
- Water disinfectant: 3–5 ppm in water or eight drops of 2% tincture to approximately 1 L of water.

TOXICITY

Chronic iodine toxicity results when iodide intake is approximately 2 mg daily or greater (Beers 2005). Overconsumption of iodine can cause gastrointestinal irritation, abdominal pain, nausea, vomiting and diarrhoea, cardiovascular symptoms and can induce both hypo- and hyperthyroidism, depending on the patient's preexisting susceptibility (Wahlqvist 2002, Zimmermann 2008). Excess iodine during pregnancy has also been associated with increased risk of postpartum thyroiditis (Guan et al 2005). Alternatively, there are many cases in which excesses have been tolerated without any overt consequences, particularly in individuals with healthy thyroid function (Geissler & Powers 2005, Groff et al 2009, Zimmermann 2008). Chronic ingestion of ≥ 500 microgram/day by children has resulted in increased thyroid size (Zimmermann 2008). Intake of very high doses can lead to a brassy taste in the mouth, increased salivation, gastric irritation and acneiform skin lesions.

SIGNIFICANT INTERACTIONS

Goitrogens

These are substances that interfere with iodine utilisation or thyroid hormone production and include thiocyanates found in the cabbage family (e.g. cabbage, kale, cauliflower, broccoli, turnips and Brussels sprouts) and in linseed, cassava, millet and soybean — separate intake of iodine and goitrogens where possible. Smoking has also been shown to increase thiocyanate levels and reduce iodine content in the breastmilk of smoking mothers (Zimmermann et al 2008). Other chemical goitrogens include perchlorate and disulphides, the latter from coal processes and there is accumulating evidence of thyroid endocrine disruptors in the form of ingredients used in cosmetics, as pesticides or plasticisers. Major targets are the sodium–iodide symporter (NIS), the hemoprotein thyroperoxidase (TPO), the T_4 distributor protein transthyretin (TTR) and the deiodinases (Köhrle 2008).

Soy

The actions of this particular goitrogen are two-fold: ingestion of soy appears to inhibit iodine absorption to some extent (particularly when presented in its thyroxine form in the gut) and also high levels of the isoflavones, genistein and daidzein, can inhibit T_3 and T_4 production — separate intake of iodine and goitrogens where possible. Particular attention should be paid to minimising soy consumption in individuals taking thyroid hormone supplementation, as it has been shown that soy consumption can increase dosage requirements.

Selenium

Selenium is intrinsic to the metabolism and activity of the thyroid hormones, facilitating the conversion of T_4 to T_3 and is also responsible for the only iodine recycling pathway of the body through the action of the deiodinases on excess or unnecessary thyroid hormones to release the iodine — beneficial interaction.

CONTRAINDICATIONS AND PRECAUTIONS

Thyroid conditions

Due to the complex and diverse causes of thyroid conditions, it is advised that iodine supplementation should be avoided unless under the supervision of a medical practitioner.

PRACTICE POINTS/PATIENT COUNSELLING

- Iodine is an essential trace element required for healthy functioning of the thyroid gland and for normal growth and development.
- It is mainly consumed as iodide salts from sea salt, shellfish, seawater fish and vegetables.
- Iodine is essential for the manufacture of thyroxine (T_4) and liothyronine (T_3), which are hormones that influence growth, maturation, thermogenesis, oxidation, myelination of the CNS and the metabolism of all tissues (Jones 2002).
- Iodine supplementation is commonly used to prevent and treat deficiency. There is also some evidence that it may reduce pain in fibrocystic breast disease and cyclic mastalgia and suggestive evidence of a protective role against breast cancer; however, rigorous research is required to confirm these observations.
- Current evidence points to widespread mild-to-moderate iodine deficiency in Australia, suggesting that dietary intake is inadequate and supplementation or fortification of foods with additional iodine may be required.

PREGNANCY USE

Up until 2006, the Australian recommended daily intake of iodine was 150 microgram for pregnant women and 170 microgram for lactating women; however, reflecting new research, the Australian RDI levels for pregnancy have been revised and increased. Care should be taken to avoid ingestion of excessive amounts during pregnancy due to suspected links with increased rates of postpartum thyroiditis and other disorders of thyroid function (Guan et al 2005).

PATIENTS' FAQs

What will this supplement do for me?

Adequate intake of iodine is critical for healthy thyroid function and normal growth and development. Ensuring adequate intake becomes critical during pregnancy and breastfeeding when the infant is solely dependent on the mother's intake for normal growth and brain development. Currently, there is some suggestive evidence that adequate iodine particularly during the female reproductive years may be protective against breast cancer and supplementation may relieve symptoms of breast pain in fibrocystic breast disease and cyclic mastalgia.

When will it start to work?

The time frames depend on the indication it is being used to treat and the level of deficiency. In the case of breast pain, studies suggest that 3 months of treatment are required to attain significant symptom relief.

Are there any safety issues?

People with preexisting thyroid conditions should only increase iodine intake under professional supervision. Doses in excess of the RDI should be avoided unless under the supervision of a medical practitioner.

Iron

BACKGROUND AND RELEVANT PHARMACOKINETICS

Iron is an essential mineral found in the body in haem or non-haem form. The average human body contains 2–4 g of iron. Although the metal exists in several oxidation states in nature, only the ferrous (Fe^{2+}) and ferric (Fe^{3+}) forms are stable in the aqueous environment of the body (Groff & Gropper 2000).

Iron is found in the body in: haemoglobin (65%); myoglobin (10%); enzymes (1–5%); the transport form, transferrin (0.05%); and the storage forms ferritin (4–9%) and haemosiderin (1–4%).

The haem form of iron is more soluble than the non-haem form and is absorbed 2–3 times more readily. It is absorbed via mucosal cells in the small intestine. Non-haem iron is bound to other substances in food, and must first be liberated by gastric secretions such as hydrochloric acid and pepsin. As such, absorption is best in the acidic environment of the stomach (Groff & Gropper 2000).

Here is a brief summary of the main influences on iron absorption.

Solubility enhancers of non-haem iron

- Acids (including ascorbic acid) aid solubility of non-haem iron, thus improving absorption; the addition of 20 mg ascorbic acid has been shown to increase non-haem iron absorption by 39% (Hallberg et al 2003).
- Sugars (e.g. fructose) aid absorption.
- Meat stimulates digestive secretions, and breakdown products such as cysteine-containing peptides aid absorption (Hurrell et al 1988). The addition of red meat increases non-haem iron absorption by 85% (Hallberg et al 2003). This appears to be dose-dependent, as a recent study found that the addition of 60 g Danish pork meat three times daily improved the absorption of non-haem iron from 5.3% to 7.9% (Bach-Kristensen et al 2005) although the addition of smaller amounts were not as effective (Baech et al 2003).
- The addition of fish to a high-phytate bean meal has also been shown to increase iron absorption (Navas-Carretero et al 2008).
- Alcohol appears to improve iron uptake. The consumption of up to two alcoholic drinks per day is associated with reduced risk of iron deficiency and more than two can increase the risk of iron overload (Ioannou et al 2004).

Solubility inhibitors of non-haem iron

- Polyphenols, including tannin derivatives of gallic acid (tea has been reported to reduce iron absorption by 60%, coffee by 40%) (Kaltwasser et al 1998, Morck et al 1983). A number of studies have shown that tea catechins can inhibit intestinal non-haem iron absorption (Ullmann et al 2005); however, polyphenols do not have chelating effects on cooked haem iron (Breet et al 2005).

> ***Clinical note — Factors affecting the absorption of iron***
> If the dietary intake of iron is adequate, it is often assumed that a patient's iron levels will be within the normal range. In practice, this is not always the case as absorption is significantly affected by a number of factors, thereby increasing or decreasing the amount of ingested dietary iron that reaches the systemic circulation.

Recent studies suggest that impaired absorption is unlikely to be significant in people with normal iron stores (Breet et al 2005, Ullmann et al 2005). The addition of milk to tea may reduce the chelating effects.
- Phytic acid (whole grains).
- Oxalic acid (spinach, chard, chocolate, berries).
- Calcium — single-meal studies have established that calcium (including calcium phosphate and foods such as milk) reduces iron absorption by up to 70% (Hallberg et al 1991); however, the effect may not be as pronounced when calcium is served as part of a whole diet. For instance, the consumption of a glass of milk or the equivalent amount of calcium from fortified food does not appear to decrease non-haem iron absorption (Grinder-Pedersen et al 2004). Although it remains to be shown in iron-deficient persons, long-term iron status does not seem to be compromised by high calcium intake (Molgaard et al 2005).
- Zinc competes with iron for absorption (Solomons 1983) — inorganic zinc supplements may reduce iron absorption by 66–80% (Crofton et al 1989), and supplements containing both iron and zinc may not be as efficacious as the same doses given in isolation (Fischer Walker et al 2005, Lind et al 2003), but nutrients consumed in a meal may not be as affected (Whittaker 1998).
- Manganese may reduce absorption by 22–40% (Rossander-Hulten 1991).
- Rapid intestinal transit time.
- Malabsorption syndromes.
- *Helicobacter pylori* infection (Ciacci et al 2004).
- Gastrointestinal blood loss (Higgins & Rockey 2003).
- Insufficient digestive secretions (including achlorhydria).
- Antacids and proton pump inhibitor drugs.

CHEMICAL COMPONENTS

Ferrous sulfate is the most widely studied form. Other ferrous forms include ascorbate, carbonate, citrate, fumarate, gluconate, lactate, succinate and tartrate (non-haem iron). Iron from ferrous sulfate has a significantly greater bioavailability than ferrous glycine chelate or ferric EDTA (Ferreira da Silva et al 2004). Other ferric forms include ammonium citrate, chloride, citrate, pyrophosphate and sulfate. Amino acid chelates, such as iron glycine, are also available. Dietary ferritin is as equally well absorbed as ferrous sulfate and therefore food sources are likely to be effective (Davila-Hicks et al 2004). Cooking in iron pots may also improve iron status (Geerligs et al 2003).

FOOD SOURCES

The average Western diet is estimated to contain 5–7 mg iron/1000 kcal.

Haem iron

About 50–60% of the iron in animal sources is in the haem form. Sources include liver, lean red meat, poultry, fish, oysters, clams, shellfish, kidney and heart.

Non-haem iron

This is found in plant and dairy products in the form of iron salts and makes up about 85% of the average intake. Sources include nuts, legumes, fruit, dried fruit, vegetables including beetroot, grains and tofu. Dairy is a relatively poor source of iron.

A number of iron-fortified foods are also available and include egg yolks, dried fruit, dark molasses, wholegrain and enriched bread, pasta, cereal, soy sauce, Thai fish sauce, milk, orange juice and wines.

Considering that minerals such as calcium may reduce iron absorption, fortification of some foods may be relatively ineffectual unless absorption enhancers such as vitamin C are also included (Davidsson et al 1998).

DEFICIENCY SIGNS AND SYMPTOMS

Iron deficiency anaemia is considered to be the most common micronutrient deficiency in the world, affecting approximately 1.2 billion people including up to 46% of schoolchildren in developing countries (Sejas et al 2008). Iron deficiency may occur with or without anaemia (Gillespie et al 1991).

Iron deficiency anaemia, also known as hypochromic microcytic anaemia, results in reduced work capacity in adults and a reduced ability to learn in children. Signs and symptoms include:
- fatigue and lethargy
- decreased resistance to infection
- cardiovascular and respiratory changes, which can progress to cardiac failure if left untreated
- increased lead absorption, which in turn inhibits haem synthesis
- decreased selenium and glutathione peroxidase levels
- pale inside lower eyelid or mouth
- pale-coloured nail bed
- pale lines on stretched palm (palmar creases)
- ridged, spoon-shaped, thin flat nails
- brittle hair
- impaired cognitive and motor function
- adverse pregnancy outcomes and increased perinatal maternal mortality (NMCD 2005)
- reduced thyroid function and ability to make thyroid hormones (Beard et al 1990)
- difficulty maintaining body temperature in a cold environment.

Primary deficiency

Primary deficiency is most common in vegetarians, the elderly, those with protein-calorie malnutrition, and during periods of increased iron requirement due to expanded blood volume in infancy, adolescence and pregnancy.

Secondary deficiency

Underlying causes of iron-deficiency anaemia include blood loss, inefficient absorption due to gastrointestinal disturbances and increased destruction of red blood cells.
- Blood loss (menstruation, menorrhagia, bleeding haemorrhoids, parasites, bleeding peptic ulcer, malignancy, *H. pylori* infection, gastrointestinal bleeding due to medication such as NSAIDs).

- Inefficient absorption (chronic gastrointestinal disturbances, malabsorption syndromes, coeliac disease) (Annibale et al 2001).
- Increased destruction of red blood cells (malaria, high-intensity exercise).

Note: The majority of iron utilised in erythropoiesis is provided by recovered iron from old erythrocytes (Handelman & Levin 2008), thus a failure in this system will also impact on iron status.

MAIN ACTIONS

Iron plays a central role in many biochemical processes in the body.

Oxygen transport and storage

The key function of iron is to facilitate oxygen transport by haemoglobin, the oxygen-carrying pigment of erythrocytes. It is also involved in oxygen storage by myoglobin, an iron-containing protein that transports and stores oxygen within muscle and releases it to meet increased metabolic demands during muscle contraction.

Immunity

Iron is vital for the proliferation of all cells including those of the immune system. In vitro and in vivo studies have indicated a link between iron deficiency and impaired T lymphocyte proliferation. In anaemic children in Bolivia who received iron treatment for three months, the proportion of circulating immature T lymphocytes decreased from 18.3% to 9.2% (Sejas et al 2008).

Iron deficiency causes several defects in both humoral and cellular immunity (Bowlus 2003), including a reduction in peripheral T cells secondary to atrophy of the thymus and inhibition of thymocyte proliferation (Bowlus 2003) and a reduction in IL-2 production (Bergman et al 2004). Reduced IL-2 production may partly explain the increased susceptibility to infections and cancer in patients with iron deficiency anaemia (Bergman et al 2004). Supplementation of ferrous sulfate (60 mg Fe) once daily for 8 weeks has been shown to reduce the incidence and duration of upper-respiratory tract infections in children (De-Silva et al 2003).

However, there is also preliminary evidence that iron may be implicated in the pathogenesis of auto-immune disorders, including SLE, scleroderma, type 1 diabetes, Goodpasture syndrome, multiple sclerosis and RA (Bowlus 2003). Current evidence suggests that moderately elevated iron stores may be associated with an overall increased risk for cancer, especially colorectal cancer (McCarty 2003). Additionally, it has been proposed that iron may increase HIV replication and the rate of progression of HIV infection, although doses of 60 mg of elemental iron twice weekly for 4 months did not appear to affect HIV-1 viral load in clinical studies (Olsen et al 2004). Although maintaining adequate iron status may be important for immunity, the benefits of routine supplementation in the absence of deficiency cannot be justified.

Enzyme systems

Both haem and non-haem iron are a part of many enzymes that are involved in:

- cellular respiration
- amino acid metabolism (e.g. carnitine)
- detoxification (as part of cytochrome P450 enzymes in the liver)
- protection against free radical damage
- synthesis of nutrients such as vitamin A
- synthesis of hormones and neurotransmitters (serotonin and noradrenaline)
- synthesis of collagen and elastin.

CLINICAL USE

Iron supplementation is administered using various routes (e.g. by injection or orally). This review will only focus on oral supplementation as this is the form generally used by the public and available OTC.

Iron deficiency

Iron supplementation is used to rectify deficiency states resulting from inadequate intake, increased requirements such as pregnancy, increased losses such as menstruation, and where absorption is affected due to gastric bypass or chronic gastrointestinal disturbances. Currently, researchers are attempting to clarify the best forms, administration routes and dosage regimens to use in different iron deficiency situations.

Iron deficiency anaemia

Previous evidence suggested that weekly administration of iron was an effective strategy for the treatment and prevention of iron deficiency and iron deficiency anaemia in most population groups including pregnant women and children (Agarwal et al 2003, Mukhopadhyay et al 2004, Siddiqui et al 2004, Sungthong et al 2004, Yang et al 2004). Although this is associated with lower cost, fewer side-effects and improved compliance (Haidar et al 2003), this notion has been recently challenged when twice-weekly doses of iron (ferrous dextran containing 60 mg elemental iron) for 12 months failed to improve haemoglobin or serum ferritin (iron stores) in children or adults (Olsen et al 2006). It has since been suggested that weekly doses may assist in maintenance but may not improve iron status (Wijaya-Erhardt et al 2007). Higher doses or

Clinical note — Testing for iron deficiency

In iron deficiency anaemia, storage iron declines until the delivery of iron to bone marrow is insufficient for erythropoiesis to occur. In the early stages, blood tests will reveal low plasma ferritin, followed by decreased plasma iron and transferrin saturation, and ultimately low haemoglobin in red blood cells (Handelman & Levin 2008). As isolated haemoglobin has both low specificity and low sensitivity for determining iron status, the optimal diagnostic approach is to measure the serum ferritin as an index of iron stores and the serum transferrin receptor as an index of tissue iron deficiency (Cook 2005, Flesland et al 2004, Mei et al 2005).

addressing concomitant deficiencies of other micronutrients may be required to obtain the benefits of less frequent dosing regimens.

Children

A recent systematic review revealed that iron supplementation significantly but modestly increased haemoglobin levels in children. The effects appeared to be greater in those who were anaemic at the start of treatment and lower for those in hyper-endemic malarial areas or consuming iron-fortified foods (Gera et al 2007).

In a 2004 study, 60 children (age 5–10 years) with iron deficiency anaemia were given ferrous sulfate (200 mg) daily or weekly for 2 months with similar efficacy and fewer side-effects in the once weekly group (Siddiqui et al 2004). In another study, children receiving weekly doses of ferrous sulfate (300 mg) had similar improvements in haemoglobin, but a significantly higher increase in IQ, compared to those taking the same dose of iron 5 days per week (Sungthong et al 2004). The doses used in these trials may be higher than those actually required to correct deficiency.

Elderly

Patients, such as the elderly, who are particularly vulnerable to the dose-dependent adverse effects of iron supplementation, should be given the lowest effective dose. A randomised trial of 90 hospitalised elderly patients demonstrated that 15 mg of liquid ferrous gluconate produced similar improvements in haemoglobin and ferritin over 60 days to 150 mg of ferrous calcium citrate tablets without the negative side-effects (Rimon et al 2005).

In all cases the lowest safe and effective dose at the lowest frequency of dosing should be used to correct iron deficiency with or without anaemia.

Pregnancy

A recent Cochrane review determined that while severe anaemia can have very serious consequences for mothers and babies, there is a paucity of good quality trials assessing iron supplementation on maternal and neonatal clinical effects. The treatment of mild to moderate anaemia in pregnancy by oral or parenteral (intramuscular and intravenous) administration remains controversial (Reveiz et al 2007). A 2007 study showed that the iron status of children at 6 months and 4 years born to women who were randomly allocated to receive 20 mg of iron daily in the second half of pregnancy did not differ from children of mothers in the control group (Zhou et al 2007a). Another study found that prenatal iron supplementation used to reduce the incidence of iron deficiency anaemia from 11% to 1% had no effect on the IQ of the offspring at 4 years of age (Zhou et al 2006). Due to the possibility of uncontrolled lipid peroxidation, predictive of adverse effects for mother and fetus, iron supplementation should be prescribed on the basis of biological criteria, not on the assumption of anaemia alone (Lachili et al 2001) and the minimum dose possible should be used. Low-dose iron supplements (20 mg elemental iron) have demonstrated efficacy in treating anaemia in pregnancy with less gastrointestinal side effects (Zhou et al 2007b).

According to trials, a supplement of 40 mg ferrous iron/day from 18 weeks gestation appears adequate to prevent iron deficiency in 90% of women and iron deficiency anaemia in at least 95% of women during pregnancy and postpartum (Milman et al 2004). A single weekly dose of 200 mg elemental iron, however, may be sufficient as this has been shown to be comparable with 100 mg elemental iron daily on erythrocyte indices (Mukhopadhyay et al 2004). In recent trials, low doses of sodium feredetate (33 mg and 66 mg of elemental iron given twice daily) produced comparable results to ferrous fumarate (100 mg elemental iron given twice daily) with no reports of adverse effects; however, larger scale trials are required to confirm these effects (Sarkate et al 2007).

Although iron supplementation is often used as stand-alone treatment in pregnant iron-deficient women, one RCT indicated that a combination of iron and folate therapy (80 mg iron protein succinylate, with 0.370 mg folinic acid daily) for 60 days produces a better therapeutic response than iron-only supplementation (Juarez-Vazquez et al 2002).

Postpartum anaemia

Postpartum anaemia is associated with breathlessness, tiredness, palpitations, maternal infections and impaired mood and cognition. A 2004 Cochrane review suggested that further high-quality trials were required before the benefits of iron supplementation or iron-rich diets in the treatment of postpartum anaemia could be established (Dodd et al 2004). Since then a randomised placebo-controlled study of iron sulfate (80 mg daily) for 12 weeks starting 24–48 hours after delivery demonstrated an improvement in haemoglobin levels and iron stores (Krafft et al 2005) and supplementation of ferrous sulfate (125 mg) with folate (10 μg) and vitamin C (25 mg) demonstrated improvements in cognitive function, as well as depression and stress compared with folate and vitamin C alone (Beard et al 2005). However, further studies are still warranted.

Unexplained fatigue without anaemia

Iron supplementation is sometimes used in women who are not anaemic (haemoglobin >117 g/L) yet complain of fatigue. A recent, double-blind, randomised placebo-controlled trial designed to determine the subjective response to iron therapy in non-anaemic women (haemoglobin >117 g/L) with unexplained fatigue found that supplementation with oral ferrous sulfate (80 mg/day elemental iron) for 4 weeks reduced the level of fatigue in the iron group by 29% compared with 13% in the placebo group. Subgroup analysis showed that only women with ferritin concentrations <50 μg/L improved with oral supplementation. This was common in 85% of subjects and 51% of subjects had ferritin concentrations <20 μg/L (Verdon et al 2003). This study suggests that iron deficiency anaemia may be present despite haemoglobin and

ferritin levels being within the 'normal' range and that the lower reference levels for women may need to be revised.

Improving athletic performance in marginally deficient people

Sports anaemia is a common finding among professional and non-professional athletes engaging in strenuous physical activity. Possible mechanisms include: dilutional pseudoanaemia, which is caused by plasma volume expansion greater than that of the red blood cell mass, but does not reflect actual blood loss and will generally normalise within 3–5 days of ceasing training; intravascular haemolysis due to mechanical trauma such as 'foot strike haemolysis', which can result in urinary loss of iron; or transient ischaemia resulting from vasoconstriction of the splanchnic and renal vessels, which can also result in blood loss from the gastrointestinal and urinary tracts (Merkel et al 2005).

In a placebo-controlled trial, iron supplementation (50 mg ferrous sulfate twice daily) for 6 weeks significantly improved iron status and maximal oxygen uptake ($\dot{V}O_{2max}$) after 4 weeks' concurrent aerobic training in previously marginally deficient and untrained women (Brownlie et al 2002). In a later randomised double-blind placebo-controlled study of 41 untrained iron-deficient women without anaemia, ferrous sulfate (100 mg) for 6 weeks improved endurance capacity after aerobic training (Brownlie et al 2004). However, a recent review concluded that the current evidence does not justify the use of supplementation solely for the purpose of performance enhancement (Rodenberg & Gustafson 2007).

Due to the potential side-effects of inappropriate iron supplementation and the possibility of masking more serious underlying complaints, athletes should only be supplemented if iron deficiency is established on the basis of biological criteria (Zoller & Vogel 2004). Supplementing antioxidants (vitamin E 500 mg/day, vitamin C 1 g/day, beta-carotene 30 mg/day) may assist in preventing exercise-induced decreases in iron status and antioxidant defences (Aguilo et al 2004) and may be a safer option in iron-replete athletes.

Anaemia of inflammation/chronic disease

In this form of anaemia storage iron is often abundant but not available for erythropoiesis. Thus, elevated markers of inflammation should be used for diagnosis. Treatment is difficult but often involves intravenous iron and erythropoietin (EPO) supplements (Handelman & Levin 2008).

Perioperative care

Iron is sometimes given before surgery to reduce postoperative decreases in haemoglobin (Andrews et al 1997). However, this use is contentious and numerous studies have failed to report benefits for preoperative autologous blood collection (Cid et al 2005) or for correcting anaemia associated with cardiac surgery (Madi-Jebara et al 2004) or orthopaedic surgery, such as hip or knee arthroplasty (Mundy et al 2005, Weatherall & Maling 2004). In a more recent randomised placebo-controlled trial in patients undergoing colorectal surgery, oral ferrous sulfate (200 mg TDS) for 2 weeks pre-operatively resulted in increased mean haemoglobin and ferritin concentrations, and reduced the need for operative blood transfusion (mean 0 units transfused [range, 0–4 units] versus 2 units transfused [range, 0–11 units]; $P = 0.031$; 95% CI 0.13–2.59) (Lidder et al 2007).

Gastric bypass patients

Iron deficiency may develop after gastric bypass due to red meat intolerance, diminished gastric acid secretion and exclusion of the duodenum from the gastrointestinal tract. Patients require lifelong follow-up of hematological and iron parameters since iron deficiency and anaemia may develop years after surgery and, once developed, may prove refractory to oral treatment, resulting in the need for parenteral iron, blood transfusions or surgical interventions (Love & Billett 2008).

Cognitive function

Iron supplementation has been shown to improve cognitive function and depression in postpartum anaemic women (Beard et al 2005); however, the majority of trials in this area focus on childhood development. An association between iron-deficiency anaemia and poor cognitive and motor development with behavioural problems has been observed, and attention deficit may be substantially improved with iron supplementation (elemental iron 5 mg/kg/day) for up to 3 months (Otero et al 2004). Two-month supplementation of 15 mg iron (and multivitamin) versus multivitamin alone in preschoolers with iron-deficiency anaemia resulted in improvements in discrimination (specifically selective attention), accuracy and efficiency (Metallinos-Katsaras et al 2004).

Recently however, a systematic review reported no effects on motor development scores and only modest improvements in mental development scores, although these were more prevalent in those who were initially anaemic or iron deficient (Sachdev et al 2005). Preventing iron deficiency appears to be a rapid and effective means of improving infant lead levels, even in non-anaemic infants (Wolf et al 2003) and this may also contribute to benefits in some children.

Improving cognition in children and postpartum women appears to be the result of correcting iron deficiency and it cannot be inferred that iron supplementation will benefit cognitive function in iron-replete individuals.

Attention deficit hyperactivity disorder (ADHD) in children

Preliminary evidence suggests that iron deficiency might contribute to ADHD (as well as restless leg syndrome and Tourette's) via its impact on the metabolism of dopamine and other catecholamines (Cortese et al 2008). As a result, children with ADHD and a positive family history of restless leg syndrome appear to be at increased risk for severe ADHD symptoms (Konofal et al 2007). Iron

supplementation (80 mg/day) for 12 weeks appeared to significantly improve ADHD symptoms in children with low serum ferritin levels but without anaemia. The mean Clinical Global Impression-Severity ($P < 0.01$) and ADHD Rating Scale (–11.0 ± 13.9; $P < 0.008$) were improved in a manner comparable to stimulants (Konofal et al 2008).

Blood donors

Iron supplementation (150 mg ferrous sulfate TDS) for 1 week following blood donation reduced the decline in haemoglobin concentration and maintained haematocrit, serum iron, serum ferritin and percent saturation (Maghsudlu et al 2008). Normalisation of low haemoglobin, and thus blood donor retention, may be further enhanced by a standardised protocol offering iron supplementation and simple oral and written advice based on plasma ferritin measurements (Magnussen et al 2008).

OTHER USES

Breath-holding spells

Iron supplementation may significantly reduce the incidence of breath holding spells, especially in iron-deficient children as shown in an RCT (Daoud et al 1997).

Haemodialysis

Intravenous iron is frequently, but contentiously, prescribed for the aggressive management of anaemia associated with dialysis (Agarwal et al 2004, Gillespie & Wolf 2004, Ruiz-Jaramillo et al 2004). CYP3A4 activity is reduced in haemodialysis patients, which may be related to functional iron deficiency. However, with the exception of a subset of haemodialysis patients with low baseline CYP3A4 activity, IV iron does not appear to have a significant effect on hepatic CYP3A4 (Pai et al 2007). It has been suggested that strategies to improve vitamin C status and to decrease inflammation would lead to better utilisation of iron in these patients (Handelman 2007).

DOSAGE RANGE

- Therapeutic dose: 2–5 mg/kg/day; however, in many cases the equivalent of this dose may be given weekly.
- In cases of deficiency, initial effects on haemoglobin and erythrocyte concentrations take about 2 weeks but it may take 6–12 months to build iron stores (Groff & Gropper 2000).
- The Australian Iron Status Advisory Panel advocates dietary intervention as the first treatment option for mild iron deficiency (serum ferritin 10–15 μg/L) (Patterson et al 2001). Trials have shown a significant increase in serum ferritin levels (26%) using dietary intervention alone (Heath et al 2001).

In Table 1, the RDI of iron is expressed as a range to allow for differences in bioavailability of iron from different Australian foods.

Studies have shown that there can be a significant sex difference in haemoglobin and other indicators of iron status during infancy. Some of these may be genetically determined, whereas others seem to reflect an increased incidence of true iron deficiency in boys (Domellof et al 2002).

TOXICITY

Iron toxicity causes severe organ damage and death. The most pronounced effects are haemorrhagic necrosis of the gastrointestinal tract, which manifests as vomiting, bloody diarrhoea and hepatotoxicity.

Conditions that increase risk of toxicity include:

- Haemochromatosis (iron overload) — excess storage of iron in the body, which can cause organ and tissue damage (especially liver and heart) and an increased risk for hepatic carcinoma. It may be caused by an excessive oral intake, a genetic defect that causes the body to absorb more iron than normal, or repeated blood transfusions.
- Haemosiderosis — iron overload without tissue damage.
- Iron-loading anaemias — thalassaemia and sidero blastic anaemia.

ADVERSE REACTIONS

Oral supplements may cause gastrointestinal disturbances such as nausea, diarrhoea, constipation, heartburn and upper gastric discomfort.

Taking supplements with food appears to reduce the possibility of gastrointestinal side-effects. Liquid iron preparations can discolour teeth — brush teeth after use.

In the absence of appropriate storage or chelation, excess free-iron can readily participate in the formation of toxic free-radicals, inducing oxidative stress and apoptosis (Whitnall & Richardson 2006). Iron depletion leads to decreased availability of redox-active iron in vivo and appears to reduce atherosclerotic lesion size and increase plaque stability (Sullivan & Mascitelli 2007). Iron toxicity and subsequent organ damage can develop from long-term excessive intake.

There is preliminary evidence that iron may be implicated in the pathogenesis of auto-immune disorders (Bowlus 2003) and neurodegenerative diseases (Whitnall & Richardson 2006); and that moderately elevated iron stores may be associated with an overall increased risk for cancer, especially

TABLE 1 Australian Recommended Daily Intake by age and sex

Age	Australian RDI (mg/day)
Infants (0–6 months; breastfed)	0.2
Infants (7–12 months)	11
Children (1–13 years)	8–10
Girls (14–18 years)	15
Boys (14–18 years)	11
Men (>19 years)	8
Women (19 to menopause)	18
After menopause	8
Pregnancy	27
Lactation	9

TABLE 2 Summary of Iron Interactions

Drug/ therapeutic substance	Mechanism	Possible outcome	Action required
ACE inhibitors	Reduced absorption of ACE inhibitors. A small clinical trial found that concomitant iron administration reduced area-under-the-curve plasma levels of unconjugated captopril by 37% (Lee et al 2001, Schaefer et al 1998).	Reduced drug effect	Separate doses by at least 2 hours.
Antacids and products containing aluminium, calcium or magnesium	Reduces iron absorption (O'Neil-Cutting & Crosby 1986).	Reduced effect of iron	Separate doses by at least 2 hours.
Ascorbic acid	Increases iron absorption.	Increased effects of iron	Beneficial interaction is possible — caution in haemochromatosis.
Cholestyramine and colestipol	In vitro investigations have shown that cholestyramine and colestipol both bind iron citrate (Leonard et al 1979).	Reduced drug and iron effect	Monitor for iron efficacy if cholestyramine is being used concurrently. Separate doses by 4 hours. Increased iron intake may be required with long-term therapy.
Cimetidine	Iron can bind cimetidine in the gastrointestinal tract and reduce its absorption (Campbell et al 1993).	Reduced drug and iron effect	Separate doses by at least 2 hours.
Dairy products and eggs	May reduce iron absorption.	Reduced effect of iron	Monitor for iron efficacy.
Erythropoietin	Pharmacodynamic interaction (Carnielli et al 1998). In patients with chemotherapy-related anaemia without iron deficiency, the addition of IV iron supplementation may improve the success of darbepoetin (92.5% versus 70% for darbepoetin alone; $P = 0.0033$) without increasing toxicity (Pedrazzoli et al 2008).	Additive pharmaco-logical effect possible	Beneficial interaction is possible.
H_2-receptor antagonists (antiulcer drugs)	Iron absorption is dependent upon gastric pH; therefore, medications that affect gastric pH may interfere with absorption of iron (Aymard et al 1988).	Reduced effect of iron	Monitor for iron efficacy if these drugs are being used concurrently.
Haloperidol	May cause decreased blood levels of iron (Leenders et al 1994, Threlkeld 1998).	Reduced effect of iron	Monitor for iron efficacy if these drugs are being used concurrently. Increased iron intake may be required with long-term therapy.
L-Dopa and carbidopa	May reduce bioavailability of carbidopa and L-dopa (van Woert 1977).	Reduced drug effect	Separate doses by 2 hours.
Omeprazole and other proton-pump inhibitors	Reduced iron absorption due to changes in gastric pH	Reduced effect of iron	Monitor for iron efficacy if omeprazole is being used concurrently.

TABLE 2 Summary of Iron Interactions (*continued*)

Drug/ therapeutic substance	Mechanism	Possible outcome	Action required
Penicillamine	Reduced drug and iron absorption	Reduced drug and iron effect	Separate doses by at least 2 hours. Sudden withdrawal of iron during penicillamine use has been associated with penicillamine toxicity and kidney damage (Harkness & Blake 1982) — caution.
Quinolone antibiotics (e.g. norfloxacin)	Reduced drug absorption (Brouwers 1992)	Reduced drug effect	Take drug 2 hours before or 4–6 hours after iron dosing. Monitor patient for continued antibiotic efficacy.
Sulfasalazine	May bind together, decreasing the absorption of both (Dukes & Duncan 1995).	Reduced drug and iron effect	Separate doses by at least 2 hours.
Tannins — herbs with significant tannin content (e.g. green tea, bilberry, raspberry leaf)	Tannin can bind to iron and reduce its absorption.	Reduced effect of iron	Monitor for iron efficacy if these herbs are being used concurrently. Separate doses by 2 hours.
Tetracycline antibiotics (e.g. minocycline, doxycycline)	While early studies suggested reduced drug and iron absorption (Neuvonen 1976), recent human data found no effect on erythrocyte iron uptake when in patients taking 100 mg iron orally and oral tetracycline (Potgieter et al 2007).	Reduced drug effect	Monitor for iron efficacy if tetracyclines are being used long term. Separate doses by 4 hours.
L-Thyroxine	Decreased drug absorption possible. Iron supplements may decrease absorption of thyroid medication; however, iron deficiency may impair the body's ability to make thyroid hormones.	Reduced drug effect	Thyroid function should be monitored and L-thyroxine dose may need alteration during treatment with iron. Separate doses by at least 2–4 hours (Shakir et al 1997).
Vitamin A	Iron supplementation may cause a redistribution of retinol inducing vitamin A deficiency in infants with marginal vitamin A status (Wieringa et al 2003).	Redistribution of retinol	Iron supplementation in infants should be accompanied by measures to improve vitamin A status.

colorectal cancer (McCarty 2003). In younger people iron depletion is associated with a reduced risk of all-cause mortality (Sullivan & Mascitelli 2007), although numerous confounding factors cannot be ignored. While haem-iron intake from red meat may present a risk for increased blood pressure, non-haem dietary intake may slightly reduce systolic blood pressure (Tzoulaki et al 2008). For the time being, supplementation without demonstrated biological need cannot be justified as the potential risks may outweigh any short-term benefits.

SIGNIFICANT INTERACTIONS

Iron interacts with a variety of foods, herbs and drugs through several different mechanisms. Most commonly, the formation of insoluble complexes occurs whereby both iron and drug absorption is hindered. Separation of doses by several hours will often reduce the severity of this type of interaction. Additionally, substances that alter gastric pH have the theoretical ability to reduce iron absorption. A summary of interactions is presented in Table 2 for easy reference.

CONTRAINDICATIONS AND PRECAUTIONS

Iron poisoning can occur due to accidental ingestion of excess iron supplements. As such, iron supplements should be kept in childproof bottles and out of the reach of children.

Caution should be exercised when supplementing iron to infants or children with apparently normal growth when the iron status of the child is unknown. A double-blind placebo-controlled trial showed that while iron therapy produced a significant improvement of mean monthly weight gain and linear growth in iron-deficient children, it significantly decreased the weight gain and linear growth of iron-replete children (Majumdar et al 2003). This study confirms the results of earlier studies (Dewey et al 2002).

- Iron supplements should not be used in haemochromatosis, haemosiderosis, or iron-loading anaemias (thalassaemia, sideroblastic anaemia).
- Daily oral iron supplementation providing 50 mg elemental iron for 8 weeks did not result in increased oxidative damage in the plasma of college-aged women (Gropper et al 2003). However, more recently 100 mg doses of iron daily for 8 weeks were shown to increase lipid peroxidation. As iron status and duration of supplementation increased so too did indicators of lipid peroxidation (King et al 2008). As the use of iron supplements may potentially result in oxidative damage, risk should always be assessed against benefit before prescribing iron supplements.
- Elevated levels of serum ferritin have been implicated in the pathogenesis of vascular (and other) diseases, although this remains controversial (McCarty 2003, Zacharski et al 2004).

PRACTICE POINTS/PATIENT COUNSELLING

- Iron is an essential mineral that facilitates oxygen transport and storage in the body and is part of many enzyme systems.
- Haem iron, found in animal products, is absorbed 2–3-fold better than non-haem forms found in vegetable sources. However, iron absorption is influenced by many factors, such as other foods ingested, medicines and gastric activity.
- Iron deficiency is the most common nutritional deficiency in the world and may occur with or without anaemia. Excessive blood loss during menstruation is the most common cause.
- Supplements are generally used to treat or prevent deficiency. Excess iron can be dangerous and can lead to organ damage and death.
- As inappropriate iron supplementation can inhibit growth in non-deficient children and adversely affect pregnancy outcomes, iron status should be tested before administration.
- Correction of iron deficiency with or without anaemia may be achieved with lower doses than those recommended in some trials. In many cases, once weekly dosing of iron is as effective as daily dosing and improves compliance while reducing side-effects and cost.
- Haem-rich flesh foods may need to be limited in people with insulin resistance due to a possible link with increased cancer risk mediated by iron excess in such populations (McCarty 2003).
- Iron supplementation should be prescribed on the basis of biological criteria, not on the assumption of anaemia alone, as unnecessary iron supplementation can result in adverse effects. The lowest safe and effective dose and frequency of dose should be recommended.

PREGNANCY USE

Oral iron preparations are considered safe in pregnancy; however, unnecessary iron supplementation can result in uncontrolled lipid peroxidation (Lachili et al 2001), lowered serum levels of copper and zinc (Ziaei et al 2008), low birth weight and maternal hypertension disorder (Ziaei et al 2007). Routine iron supplementation in non-anaemic women is not justified and may be harmful, so supplementation should be prescribed on the basis of biological criteria, not on the assumption of anaemia alone.

PATIENTS' FAQs

What will this supplement do for me?

Iron is necessary for health and wellbeing. It facilitates oxygen transport and storage in the body and is part of many enzyme systems. Iron deficiency is the most common deficiency in the world.

When will it start to work?

Iron deficiency responds to supplementation within 2 weeks; however, 6–12 months may be required to build up the body's iron stores.

Are there any safety issues?

Excess iron can be dangerous and ultimately can lead to severe organ damage and death.

Kava kava

HISTORICAL NOTE For many centuries, Pacific Islanders have used the kava kava root to prepare a beverage used in welcoming ceremonies for important visitors. Drinking kava kava is not only done to induce pleasant mental states but also to reduce anxiety and promote socialising. It is believed that the first report about kava kava came to the West from Captain James Cook during his voyages through the Pacific region.

COMMON NAME
Kava kava

OTHER NAMES
Kawa, awa, intoxicating pepper, rauschpfeffer, sakau, tonga, yagona

BOTANICAL NAME/FAMILY
Piper methysticum (family Piperaceae)

PLANT PARTS USED
Root and rhizome

CHEMICAL COMPONENTS
The most important constituents responsible for the pharmacological activity of kava rhizome are the fat-soluble kava lactones (kavapyrones), mainly methysticin, dihydromethisticin, kavain, dihydrokavain and desmethoxyangonin and flavonoids (flavokavains).

MAIN ACTIONS

Central nervous system (CNS) effects
The kava lactones reach a large number of targets that influence CNS activity and act centrally and peripherally. They interact with dopaminergic, serotonergic, GABA-ergic and glutamatergic neurotransmission, seem to inhibit monoamine oxidase B and exert multiple effects on ion channels, according to in vitro and in vivo research (Grunze et al 2001). Additionally, animal studies show that kava lactones are chiefly responsible for these effects that give rise to many of the herb's clinical actions (Cairney et al 2002).

Hypnotic
Although the exact mechanism of action is not yet understood, it has been observed that sleep promotion may be due to the preferential activity of D,L-kavain and kava kava extract on the limbic structures and, in particular, the amygdalar complex (Holm et al 1991) in the brain.

In an electroencephalogram (EEG) brain-mapping study it was demonstrated that D,L-kavain could induce a dose-dependent increase in delta-, theta- and alpha-1 power, as well as a decrease in alpha-2 and beta power. These results indicate a sedative effect at the higher dose range (Frey 1991).

Anxiolytic effects
A recent study showed that kava kava extract produces a statistically significant dose-dependent anxiolytic-like behavioural change in rat models of anxiety (Garrett et al 2003). The effect is not mediated through the benzodiazepine binding site on the GABA-A receptor complex, as flumazenil, a competitive benzodiazepine receptor antagonist, did not block this effect. Meta-analyses confirm that the anxiolytic effect is clinically significant and comparable to benzodiazepines.

Analgesic and local anaesthetic
Both the aqueous and lipid-soluble extracts of kava kava exhibit antinociceptive properties in experimental animal models (Jamieson & Duffield 1990). The effect is not mediated by an opiate pathway, as naloxone does not reduce the effects when administered in doses that reverse the effects of morphine. More recently, in vitro research has identified several compounds found in kava kava that have the ability to inhibit COX-1 and to a lesser extent COX-2 enzyme activities (Wu et al 2002).

The local anaesthetic effect of kava kava is well known for topical use and has been described as similar to procaine and cocaine (Mills & Bone 2000).

Antispasmodic activity
Antispasmodic activity for skeletal muscle has been observed in vitro and in vivo for both kava kava extract and kava lactones (Mills & Bone 2000). In vivo research suggests that kavain impairs vascular smooth muscle contraction, likely through inhibition of calcium channels (Martin et al 2002).

OTHER ACTIONS

Cytochrome inhibition
In vitro studies published in 2002 suggested that whole kava kava extract and kava lactones have widespread inhibitory effects on various cytochrome enzymes,

such as CYP3A4 (Unger et al 2002), whereas in vivo tests found no effects on CYP3A4/5, CYP1A2 or CYP2D6, but did demonstrate significant inhibition (approximately 40%) of CYP2E1 (Gurley et al 2005). Clinical tests confirm no significant effect on CYP2D6 (Gurley et al 2008).

Animal studies found that kava kava extract decreased the expression of CYP2D1 (human CYP2D6 homolog) at a dose of 2.0 g/kg in females and increased the expression of CYP1A2, 2B1 and 3A1 in 1.0 and 2.0 g/kg groups of both sexes (Clayton et al 2007). The clinical relevance of these findings is unclear, as the doses used were extremely large and not clinically relevant.

CLINICAL USE

Kava kava extracts are popular in Europe and have been investigated in numerous clinical trials, primarily in European countries. As a result, many research papers have been published in languages other than English. In order to provide a more complete description of the evidence available, secondary sources have been used where necessary. The extract which has been most studied is kava kava extract WS®1490.

Anxiety

Evidence from double-blind clinical studies indicates that kava kava is an effective treatment for anxiety, repeatedly shown to be as effective as benzodiazepines.

A 2000 Cochrane review of the scientific literature assessed the results from seven, double-blind, randomised, placebo-controlled trials and concluded that kava kava extract has significant anxiolytic activity and is superior to placebo for the symptomatic treatment of anxiety (Pittler & Ernst 2000). An update of this review was published in 2003 and analysed results from 12 clinical studies involving 700 subjects (Pittler & Ernst 2003). The results of seven studies that used the Hamilton Anxiety Scale (HAM-A) score were pooled and a significant reduction in anxiety was observed for kava kava treatment compared with placebo. The results of the five studies that were not submitted to meta-analysis largely support these findings. The extract most commonly tested was WS 1490 at a dose of up to 300 mg daily.

According to the authors of the review, none of the trials reported any hepatotoxic events and seven trials measured liver enzyme levels as safety parameters and reported no clinically significant changes.

In 2005, Witte et al published results of another meta-analysis which included data from six placebo-controlled, randomised trials with the kava kava extract WS®1490. The endpoints were the change in HAMA during treatment (continuous and binary). Kava kava significantly improved anxiety with a mean improvement of 5.94 points on the HAMA scale better than placebo. Interestingly, kava kava seemed to be more effective in females and in younger patients. The rigorous meta-analysis found no evidence of publication bias, no remarkable heterogeneity amongst the studies and concluded that trials had high methodological standards. Based on this impressive result, authors concluded that kava kava remains as an effective alternative to benzodiazepines, selective serotonin re-uptake inhibitors (SSRIs) and other antidepressants in the treatment of non-psychotic anxiety disorders.

Generalised anxiety disorder

An 8-week randomised, double-blind, multicentre clinical trial involving 129 outpatients with GAD showed that kava kava LI 150 (400 mg/day) was as effective as buspirone in the acute treatment of GAD, with about 75% of patients responding to treatment (Boerner et al 2003).

Comparative studies

Comparative studies suggest the absence of significant differences between benzodiazepines and kavain or kava kava extract as treatments for anxiety. A 1993 double-blind, comparative study involving 174 subjects over 6 weeks demonstrated that 300 mg/day of a 70% kava lactone extract produced a similar improvement in anxiety level, as measured by HAM-A scores, to 15 mg oxazepam or 9 mg bromazepam taken daily (Woelk et al 1993). D,L-kavain produced equivalent anxiolytic effects to oxazepam in 38 outpatients with neurotic or psychosomatic disturbances, under double-blind study conditions (Lindenberg & Pitule-Schodel 1990).

Benzodiazepine withdrawal

Kava kava may have a role in reducing anxiety and improving subjective wellbeing during benzodiazepine withdrawal, according to a 2001 randomised, double-blind, placebo-controlled study (Malsch & Kieser 2001). During the first 2 weeks of that study, kava kava dose was increased from 50 mg/day to 300 mg/day while benzodiazepine use was tapered off during the same period. Kava kava extract was superior to placebo in reducing anxiety as measured by the HAM-A scale and improved subjects' feelings of wellbeing according to a subjective wellbeing scale (Bf-S total scores).

Lack of tolerance

The results from a randomised, double-blind trial conducted over 25 weeks have found that physical tolerance does not develop to kava kava extract and it is well tolerated (Volz & Kieser 1997). Evidence from a randomised, double-blind study conducted with 84 patients has shown that treatment with kavain (one of the active constituents of kava kava) produces continuous improvements in parameters such as memory function, vigilance, fluency of mental functions and reaction time. Interestingly, these effects were reported over a relatively short period of 3 weeks (Scholing & Clausen 1977). Another randomised, double-blind trial conducted with 52 patients over 28 days not only confirmed anxiolytic activity but also found that kavain promoted subjective vitality-related performance (Lehmann et al 1989).

Commission E approves the use of kava kava in conditions of nervous anxiety and restlessness (Blumenthal et al 2000).

Menopausal and perimenopausal anxiety

A randomised, placebo-controlled study conducted with 40 menopausal women found that using kava kava extract, together with hormone replacement therapy (HRT), led to significant reductions in anxiety, as measured by the HAM-A scale at both 3- and 6-month follow-up (De et al 2000). A 3-month, randomised, open study of 68 perimenopausal women showed that treatment with kava kava (100 mg/day) significantly reduced anxiety ($P < 0.001$) at 1 month and 3 months. This was significantly greater than that spontaneously occurring in controls ($P < 0.009$) (Cagnacci et al 2003).

Insomnia

The hypnotic activity of kava kava extract was confirmed in a RCT in which a single dose of 300 mg kava kava extract was found to improve the quality of sleep significantly (Emser & Bartylla 1991, as reported by Ernst et al 2001). In vivo experiments with D,L-kavain have shown that it reduces active wakefulness and significantly prolongs sleep, compared with placebo (Holm et al 1991).

OTHER USES

Traditionally, the herb has been used to treat urinary tract infections, asthma, conditions associated with pain, gonorrhoea and syphilis, and to assist with weight reduction, muscle relaxation and sleep. Topically, it has been used as a local anaesthetic and to treat pruritus.

DOSAGE RANGE

- Cut rhizome: 1.7–3.4 g/day.
- Dried rhizome: 1.5–3 g/day in divided doses or equivalent to 60–120 mg kavapyrones daily.
- Fluid extract (1:2): 3–8.5 mL/day in divided doses.
- Ideally, ethanolic extracts should contain > 20 mg/mL kava lactones.

According to clinical studies

- Anxiety: generally doses up to 300 mg daily of kava kava extract WS 1490 providing 105–210 mg kavalactones. A kava kava extract LI 150 (400 mg/day) was used successfully in generalised anxiety disorder.
- Insomnia — a single dose of 300 mg kava kava extract.
- Benzodiazepine withdrawal — 300 mg/day of kava kava extract.

ADVERSE REACTIONS

In RCT, the incidence of adverse effects to kava kava has been found to be similar to placebo. Two postmarketing surveillance studies involving more than 6000 patients found adverse effects in 2.3% and 1.5% of patients taking 120–240 mg standardised extract (Ernst 2002). The most common side effects appear to be gastrointestinal upset and headaches when used in recommended doses.

Hepatotoxicity

A systematic review assessing the safety of kava kava which included a total of 7078 patients taking kava kava extract equivalent to 10 mg to 240 mg kava lactones per day for 5–7 weeks identified no cases of hepatotoxicity (Stevinson et al 2002). Considering that case reports of hepatotoxicity exist, they should be considered a very rare event based on the evidence.

In 2008, a quantitative causality assessment of 26 critical cases came to a similar conclusion stating kava kava taken as recommended is associated with rare hepatotoxicity, whereas overdose, prolonged treatment, and co-medication may carry an increased risk (Teschke et al 2008). Importantly, a recent World Health Organization report identified that liver toxicity risk is associated with kava kava acetonic and ethanolic extracts, whereas the traditional kava kava preparation which has been prepared for centuries in water does not have the same risk of liver injury.

To put the risk into perspective, estimates from case reports and the sales figures of kava kava extracts (using data from Germany) show an incidence rate of one potential case in 60–125 million patients for liver toxicity (Sorrentino et al 2006).

Possible mechanisms for kava-kava-induced hepatotoxicity

The exact cause remains elusive; however, several mechanisms have been proposed. Genetic polymorphism of cytochrome enzymes, leading to interindividual variation in drug metabolism, may be one important factor in the marked discrepancy in hepatotoxic response to kava kava (Singh 2005). Other possible mechanisms are inhibition of cytochrome P450 by kava kava, reduction in liver glutathione content and, more remotely, inhibition of cyclooxygenase enzyme activity. The direct toxicity of kava kava extracts is quite small under any analysis; yet, the potential for drug interactions and/or the potentiation of the toxicity of other compounds is larger (Clouatre 2004). Recent animal tests with three different kava kava extracts (a methanolic and an acetonic root and a methanolic leaf extract) indicate that the these kava kava extracts are toxic to mitochondria, leading to inhibition of the respiratory chain, increased reactive oxygen species (ROS) production, a decrease in the mitochondrial membrane potential and eventually to apoptosis of exposed cells. In predisposed patients, mitochondrial toxicity of kava kava extract may provide another explanation for hepatotoxic reactions (Lude et al 2008). It has also been suggested that reactions are immunologically mediated (Schulze et al 2003). Considering that the toxic reactions are limited to methanolic and ethanolic extracts, it is possible that chemicals other than kava lactones, such as alkaloids not bioavailable in water extracts, may be responsible for hepatotoxicity.

Long-term use

Heavy kava kava drinkers acquire a reversible ichthyosiform eruption, known as kanikani in Fijian or 'kava dermopathy' in English-speaking countries. This condition is characterised by yellow discolouration of the skin, hair and nails. This temporary condition reverses once kava kava use is discontinued. A 2003 report found no evidence of brain dysfunction in heavy and long-term kava kava users (Cairney et al 2003).

Clinical note — Commercial kava kava products and links to hepatotoxicity

Conflicting reports abound. On 15 August 2002, the Therapeutic Goods Administration (TGA) initiated a voluntary recall of all products containing kava kava. The response was undertaken due to incoming details from European countries of case reports of hepatotoxicity apparently associated with the use of commercial kava kava products.

The decision to remove kava kava from the market has been viewed as controversial and questioned by many people. Toxicological and clinical studies have shown that kava kava extracts are virtually devoid of toxic effects and, when assessed primarily by the British regulatory authority (MCA) and a German research group, a critical analysis of the suspected cases in Germany reveals that a very probable causal relationship could be established in only one patient (Teschke et al 2003). It is suspected that a rare, immunologically mediated, idiosyncratic mechanism may be responsible (Schulze et al 2003) and the extraction process used to produce kava kava products also had an influence. It now appears that the aqueous method results in extraction of glutathione, in addition to kava lactones, an important factor for protecting the liver from potential damage, whereas the acetone extraction method does not (Whitton et al 2003). As a result, kava kava products made with the acetone extraction process are more toxic than those produced via aqueous extraction methods. This is an important distinction to make, as most European products were made using acetone extraction, whereas Australian products were chiefly made via aqueous extraction.

Interestingly, fulminant hepatic failure has not been documented with traditional use either in Pacific countries or in the Northern Territory, where Aboriginal kava kava drinkers consume kava lactones in doses estimated to be 10–50-fold the recommended levels (Currie & Clough 2003). Several reports published in 2003 have found no evidence of aqueous kava kava extracts inducing irreversible liver toxicity in vivo (Singh & Devkota 2003) or in humans (Clough et al 2003). One study involving long-term users of aqueous kava kava extracts found that although changes to liver function could occur at moderate levels of consumption, they are reversible and begin to return to baseline after 1–2 weeks' abstinence from kava kava. A recent animal study testing large concentrations of kava lactones (7.3 or 73 mg/kg of kava lactones/day) over 3 months and 6 months found no signs of toxicity. In addition, no behavioural or physiological changes were observed on discontinuation of kava lactone feeding after 3 months (Sorrentino et al 2006).

Australia was not alone, and other countries also issued health advisory cautions or banned kava kava-containing products from sale. Although these actions effectively removed kava kava products from the market, the traditional kava kava beverage continued to be consumed in the Pacific Islands and the kava kava-producing countries of the Pacific found the controversy surprising, given the long history of apparent safe use in the Pacific. The impact of European and UK withdrawal of kava kava was devastating to the South Pacific economies. In January 2003, the Kava Evaluation Group was established in Australia to review the accumulating safety data and by August that same year the Complementary Medicine Evaluation Committee recommended to the TGA that certain forms of kava kava could be considered safe. The TGA accepted these recommendations and amended the regulations accordingly. Currently in Australia, there is a maximum limit of 125 mg kava lactones allowable per tablet or capsule, 3 g of dried rhizome per tea bag and all products containing kava kava must not provide more than 250 mg kava lactones in the recommended daily dose.

The World Health Organization published a report in May 2007 entitled *Assessment of the risk of hepatotoxicity with kava products* (WHO 2007). It evaluated data from 93 case reports of which 8 were determined to have a close association between the use of kava kava and liver dysfunction; 53 cases were classified as having a possible relationship, but they could not be fully assessed due to insufficient data or other potential causes of liver damage; 5 cases had a positive rechallenge. Most of the other case reports could not be evaluated due to lack of information. It concluded that there is 'significant concern' for a cause and effect relationship between kava kava products and hepatotoxity, especially for organic extracts. Other risk factors appear to include heavy alcohol intake, preexisting liver disease, genetic polymorphisms of cytochrome P450 enzymes, excessive dosage and co-medication with other potentially hepatotoxic drugs and potentially interacting drugs.

SIGNIFICANT INTERACTIONS

Alcohol

Potentiation of CNS sedative effects has been reported in an animal study; however, one double-blind, placebo-controlled study found no additive effects on CNS depression or safety related performance (Herberg 1993). Alternatively, a study of 10 subjects found that when alcohol and kava kava were combined, kava kava potentiated both the perceived and measured impairment compared to alcohol alone (Foo & Lemon 1997). Caution is advised when taking this combination together.

Barbiturates

Additive effects are theoretically possible. Use with caution and monitor drug dosage. However, interaction may be beneficial under professional supervision.

Benzodiazepines

Additive effects are theoretically possible. Use with caution and monitor drug dosage. However, interaction may be beneficial under professional supervision. The combination has been used successfully to ease symptoms of benzodiazepine withdrawal.

L-Dopa medication
Antagonistic effects are theoretically possible, thereby reducing the effectiveness of L-dopa. Avoid concurrent use unless under professional supervision until safety is confirmed.

Methadone and morphine
Additive effects with increased CNS depression are theoretically possible, so use with caution, although interactions may be beneficial under professional supervision.

Substrates for CYP2E1
Inhibition of CYP2E1 has been demonstrated in vivo — serum levels of CYP2E1 substrates may become elevated — use caution.

CONTRAINDICATIONS AND PRECAUTIONS
Endogenous depression — according to Commission E (Blumenthal et al 2000).

Although clinical studies indicate no adverse effects on vigilance, the herb's CNS effects may slow some individuals' reaction times, thereby affecting ability to drive a car or operate heavy machinery. Additionally, it should not be used by people with preexisting liver disease and long-term continuous use should be avoided unless under medical supervision. It should be used with caution in the elderly and in those with Parkinson's disease.

PREGNANCY USE
Safety is unknown.

PRACTICE POINTS/PATIENT COUNSELLING
- Kava kava is a scientifically proven treatment for the symptoms of anxiety and stress states. Its anxiety-reducing effects are similar to those of 15 mg oxazepam or 9 mg bromazepam; yet, physical tolerance and reduced vigilance have not been observed.
- It also reduces symptoms of anxiety related to menopause when used together with HRT, and reduces withdrawal symptoms associated with benzodiazepine discontinuation.
- It has anxiolytic, sedative, antispasmodic, analgesic and local anaesthetic activities.
- Although the herb is considered to have a low incidence of adverse effects, long-term use should be carefully supervised because of the possibility of developing adverse reactions.
- Rare hepatotoxic effects have been reported for methanolic and ethanolic extracts, whereas traditional aqueous extracts are considerably safer. The mechanism responsible remains elusive.

PATIENTS' FAQs
What will this herb do for me?
Kava kava is an effective herbal relaxant that reduces symptoms of anxiety and restlessness. It is also used to relieve anxiety in menopause, insomnia and symptoms of benzodiazepine withdrawal.

When will it start to work?
Anxiety-relieving effects are usually seen within the first few weeks of use.

Are there any safety issues?
Taking high doses long term has been associated with a number of side effects and should be avoided.

Lavender

HISTORICAL NOTE Lavender, both the whole plant and its essential oils, have a long history of traditional use for a range of medical conditions. Lavender was used as an antiseptic in ancient Arabian, Greek and Roman medicines. Its generic name comes from the Latin *lavare*, to wash, and it was used as a bath additive as well as an antiseptic in the hospitals and sick rooms of ancient Persia, Greece and Rome (Blumenthal et al 2000) and as an antibacterial agent in World War I (Cavanagh & Wilkinson 2005). In the 17th century, Culpeper described lavender as having 'use for pains in the head following cold, cramps, convulsions, palsies and faintings' (Battaglia 1995). Lavender was also used traditionally to scent bed linen and to protect stored clothes from moths. This was such a well-accepted practice that the phrase 'laying up in lavender' was used metaphorically to mean 'putting away in storage' (Kirk-Smith 2003). Lavender is now widely used in perfumes, potpourri, toiletries and cosmetics, to flavour food as well as therapeutically. However, research produces a conflicting evidence base for lavender for a range of reasons, including the facts that the species of lavender is not always identified, that lavender is frequently adulterated, and that little attention has been paid to species other than *Lavandula angustifolia*, which is also known as true lavender. Lavender is commonly adulterated with related species that can vary in their chemical constituents. Spike lavender yields more oil, but is of lower quality than true lavender. Lavandin is a hybrid of spike lavender and true lavender.

COMMON NAME
Lavender

OTHER NAMES
Common lavender, English lavender, French lavender, garden lavender, Spanish lavender, spike lavender, true lavender

BOTANICAL NAME/FAMILY
Lavandula angustifolia (synonyms: *L. officinalis*, *L. vera*, *L. spica*); *L. dentata*; *L. latifolia*; *L. pubescens*; *L. stoechas*, *L multifida* (family Labiatae)

PLANT PARTS USED
Flower

CHEMICAL COMPONENTS
Lavender flowers contain between 1% and 3% essential oil. The oil is a complex mixture of many different compounds, the amounts of which can vary between species. The most abundant compounds include linalyl acetate (30–55%), linalool (20–35%), cineole, camphor, coumarins and tannins (5–10%) (Schulz et al 1998) together with 1,8-cineole, thymol and carvacrol (Aburjai et al 2005). Perillyl alcohol and D-limonene have been shown to exert anticancer effects (see clinical note). More recently, 39 constituents, accounting for 99% of total constituents, were extracted from *Lavandula multifida* (Rhaffari et al 2007). The main constituents were phenols such as thymol (32%), carvacrol

Clinical note — Perillyl alcohol and anticancer effects

Perillyl alcohol and D-limonene are monoterpenes found in lavender (also in cherries, mint and celery seeds) that have shown chemotherapeutic and chemoprotective effects in a wide variety of in vitro and animal models (Shi & Gould 2002) and are currently being examined in human clinical trials (Gould 1997, Kelloff et al 1999). Perillyl alcohol treatment has resulted in 70–99% inhibition of 'aberrant hyperproliferation', a late-occurring event preceding mammary tumorigenesis in vivo (Katdare et al 1997) and, together with limonene, perillyl alcohol has been shown to induce the complete regression of rat mammary carcinomas by what appears to be a cytostatic and differentiation process (Shi & Gould 1995). Perillyl alcohol has also been shown to inhibit human breast cancer cell growth in vitro and in vivo (Yuri et al 2004) and inhibit the expression and function of the androgen receptor in human prostate cancer cells (Chung et al 2006).

A variety of mechanisms has been proposed to explain these effects. The compounds may act via interfering with Ras signal transduction pathways that regulate malignant cell proliferation (Hohl 1996) and have been found to promote apoptosis in pancreatic adenocarcinoma cells (Stayrook et al 1997) and liver tumours in vivo (Mills et al 1995). Perillyl alcohol, together with D-limonene, has been found to preferentially inhibit HMG-CoA reductase in tumour cells (Elson et al 1999), as well as inhibit ubiquinone synthesis and block the conversion of lathosterol to cholesterol, which may add to its antitumour activity (Ren & Gould 1994). Limonene is oxidised by the CYP2C9 and CYP2C19 enzymes in human liver microsomes (Miyazawa et al 2002a) and there are reported sex-related differences in the oxidative metabolism of limonene by liver microsomes in rats (Miyazawa et al 2002b).

Although in vitro and animal studies have demonstrated the ability of perillyl alcohol to inhibit tumorigenesis in the mammary gland, liver and pancreas, the results are not yet conclusive and one animal study testing perillyl alcohol detected a weakly promoting effect early in nitrosamine-induced oesophageal tumorigenesis in rats (Liston et al 2003). In initial phase II clinical trials, perillyl alcohol administered orally, four times daily, at a dose of 1200 mg/m^2 had no clinical antitumour activity on advanced ovarian cancer (Bailey et al 2002) metastatic androgen-independent prostate cancer (Liu et al 2003) or metastatic colorectal cancer (Meadows et al 2002).

(27.77%) and *p*-cymene (15.72%), and *γ*-terpinene (9.54%). Phenols are not commonly found in lavender. These constituents give the oil significant antibacterial activity similar to ampicillin and tetracycline in a dose-dependent manner (Rhaffari et al 2007).

MAIN ACTIONS

The pharmacological actions of lavender and several of its constituents have been demonstrated. However, the true therapeutic benefit is controversial partly because many studies have methodological flaws and often combine lavender with massage and other therapies such as acupressure.

Sedative/anxiolytic

The sedative properties of the essential oil and its main constituents (linalool and linalyl acetate) were shown to have a dose-dependent effect in mice and to reverse caffeine-induced hyperactivity in mice (Buchbauer et al 1991, Lim et al 2005), as well as reduce stress, as indicated by modulation of adrenocorticotrophic hormone (ACTH), catecholamine and gonadotropin levels in experimental menopausal rats (Yamada et al 2005), and reduce cortisol responses in infant Japanese macaques (Kawakami et al 2002). Inhalation of lavender has also been shown to produce a dose-dependent anticonvulsant effect in both rats and mice (Yamada et al 1994).

In human trials, inhalation of lavender has been shown to induce relaxation and sedation (Schulz et al 1998) and to alter EEG responses (Diego et al 1998, Dimpfel et al 2004, Lee et al 1994, Sanders et al 2002, Yagyu 1994), as well as significantly decrease heart rate and increase high-frequency spectral components to produce calm and vigorous mood states in healthy volunteers (Kuroda et al 2005). Transdermal absorption of linalool without inhalation produced a decrease in systolic blood pressure and a smaller decrease of skin temperature with no effects on subjective evaluation of wellbeing in healthy human subjects (Heuberger et al 2004), and another study found that lavender scent was associated with lower fatigue following an anxiety-provoking task (Burnett et al 2004).

These positive studies are contrasted by studies with negative findings. Lavender aromatherapy did not significantly improve scores on the Hospital Anxiety and Depression Scale or the Somatic and Psychological Health Report (SPHERE) in a RCT of 313 patients undergoing radiotherapy (Graham et al 2003) and a study of 169 subjects, including both depressed and non-depressed subjects, showed that lavender increased fatigue, tension, confusion and total mood disturbance, and decreased vigour (Goel & Grasso 2004).

Antimicrobial

Various in vitro data suggest that lavender oil has antibacterial activity (Dadalioglu & Evrendilek 2004, Larrondo et al 1995), including against methicillin-resistant *Staphylococcus aureus* (MRSA) and vancomycin-resistant enterococcus (VRE) (Nelson 1997), antifungal activity (Inouye et al 2001), including against *Aspergillus nidulans* and *Trichophyton megatrophytes* (Daferera et al 2000) and mitocidal activity (Perrucci et al 1996, Refaat et al 2002), with

both lavender and linalool having fungistatic and fungicidal activities against *Candida albicans* strains at high concentrations and inhibiting germ tube formation and hyphal elongation at low concentrations, suggesting that it may be useful for reducing fungal progression and the spread of infection in host tissues (D'Auria et al 2005). Lavender has been shown to be active alone and to work synergistically with tea tree oil against the fungi responsible for tinea and onychomycosis (Cassella et al 2002). However, effective vapour concentrations have not yet been established for aromatherapy use.

The fungistatic properties of linalool have led to the suggestion that it could be used to complement environmental measures in preventing fungal contamination in storage areas of libraries (Rakotonirainy & Lavedrine 2005).

Carminative

Linalool, one of lavender's major components, demonstrated spasmolytic activity when tested on an in vitro preparation of guinea-pig ileum smooth muscle (Lis-Balchin & Hart 1999).

Antineoplastic effects

In vitro and animal studies suggest that perillyl alcohol and D-limonene (see Clinical note) may have useful chemotherapeutic and chemoprotective effects in a range of cancers, including cancers of the colon, liver, lung, breast, pancreas and prostate, as well as in melanoma (Micromedex 2003). These results have not yet been confirmed in human studies.

OTHER ACTIONS

When applied topically, lavender oil has rubefacient properties (Fisher & Painter 1996) and is thought to have analgesic, antihistaminic and anti-inflammatory activities. A small study comparing the effects of a bath containing lavender oil, synthetic lavender oil and distilled water in reducing perineal discomfort after childbirth found lower mean discomfort scores in the lavender group; however, the differences between groups were not significant (Cornwell & Dale 1995).

Traditionally, lavender oil is considered to have a balancing effect on the CNS, acting as an aromatic stimulant or calming agent.

Extracts of *L. multifida* have been found to have topical anti-inflammatory activity in mice, with some extracted compounds having activity comparable to that of indomethacin (Sosa et al 2005). At high concentrations (0.1%), lavender oil has also been found to suppress TNF-alpha-induced neutrophil adherence (Abe et al 2003). Lavender has also demonstrated powerful antioxidant activity (Gulcin et al 2004), as well as antimutagenic activity (Evandri et al 2005) and antiplatelet and antithrombotic properties demonstrated both in vitro and in vivo (Ballabeni et al 2004).

CLINICAL USE

Although few scientific or clinical studies have been conducted with lavender oil, much of the evidence supporting its use is based on the known pharmacological actions of the constituents and a long history of traditional use.

Anxiety, insomnia and mood enhancement

A number of controlled trials and observational studies suggest that inhalation of ambient lavender oil has a relaxing effect and is able to reduce anxiety and improve mood, concentration and sleep.

In a study of 31 healthy volunteers, intermittent exposure to ambient lavender oil over a 30-minute period was found to increase the percentage of deep or slow-wave sleep in men and women with corresponding reports of higher vigour the morning after lavender exposure (Goel et al 2005). That study also reported gender-specific effects with increased stage 2 (light) sleep, as well as decreased rapid-eye movement sleep and decreased amount of time needed to reach wakefulness after first falling asleep in women, and opposite effects in men. In a 4-week randomised, double-blind pilot study, lavender tincture (1:5 in 50% alcohol) 60 drops/day was not as effective as imipramine for treating depression; however, a combination of lavender tincture and imipramine was found to be more effective than imipramine alone with better and earlier improvement (Akhondzadeh et al 2003). In another randomised, placebo-controlled pilot study, using a crossover design, lavender aromatherapy produced a non-significant improvement in insomnia compared with exposure to almond oil (Lewith et al 2005). A case study of four geriatric patients with impaired sleep also found that lavender aromatherapy increased sleep time and was comparable in effectiveness to hypnotics or tranquillisers (Hardy et al 1995). A double-blind study of 140 patients found that an essential oil spray or gargle containing lavender with 14 other essential oils significantly reduced snoring as reported by bed partners (Prichard 2004).

In hospitalised patients, aromatherapy with lavender oil was found to significantly reduce anxiety in a study of 14 female haemodialysis patients (Itai et al 2000). Another controlled trial of 200 subjects found that lavender aromatherapy reduced anxiety and improved mood in patients waiting for dental treatment (Lehrner et al 2005).

A number of studies have examined the use of lavender aromatherapy and massage with lavender oil (see below) for reducing agitation in dementia patients; however, these studies are generally small and results have been mixed. A placebo-controlled study found that lavender aromatherapy effectively reduced agitated behaviour in 15 patients with severe dementia (Holmes et al 2002), but it had no effect on reducing agitation in another controlled trial of seven severely demented patients (Snow et al 2004), nor was there effect on reducing resistive behaviour in 13 people with dementia in a residential aged care facility (Gray & Clair 2002).

In a RCT involving 80 non-depressed women, adding lavender oil to a bath was found to enhance the general mood-enhancing effects of daily bathing and produce a reduction in pessimism (Morris 2002). It has been suggested that the relaxing effects may be useful in the treatment of chronic

pain (Buckle 1999), and this is supported by a study reporting that while lavender did not elicit a direct analgesic effect, it did alter affective appraisal of the pain experience with retrospective impression of pain intensity and pain unpleasantness from experimentally induced heat, pressure and ischaemic pain being reduced after treatment with lavender aromatherapy (Gedney & Glover 2004).

When used in combination with massage

Overall, the evidence supporting the use of lavender oil in massage is encouraging; however, most studies are relatively small and there are mixed reports of its efficacy.

A controlled trial of 122 patients found that massage with lavender oil improved mood and perceived levels of anxiety in 122 intensive care patients (Dunn et al 1995). In a RCT, eight sessions of acupressure using lavender essential oil over 3 weeks was found to be effective in relieving pain, neck stiffness and stress in 32 adults with subacute non-specific neck pain (Yip & Tse 2006). In another controlled trial, a 2-week lavender aromatherapy hand massage program produced significant improvements in emotion and aggressive behaviour in elderly people with Alzheimer's type dementia (Lee 2005). Alternatively, one RCT involving 42 subjects found that the addition of lavender essential oil did not appear to increase the beneficial effects of massage for patients with advanced cancer (Soden et al 2004).

Use in animals

Lavender aromatherapy has also been found to produce increased resting and reduced movement and vocalisation in dogs housed in a rescue shelter (Graham et al 2005). Daily essential oil baths using *L. angustifolia* for 14 days led to lower stress and trait anxiety in both the experimental and the control groups but a larger effect occurred in the lavender group ($n = 37$) (Morris 2008).

Lavender aromatherapy reduced serum cortisol (a marker of stress hormones) and improved coronary flow velocity reserve (CFVR) in healthy men suggesting that lavender aromatherapy has relaxation effects and may have beneficial acute effects on coronary circulation (Shiina et al 2008). CFVR was measured with non-invasive transthoracic Doppler echocardiography (TTDE). CFVR was assessed at baseline and immediately after lavender aromatherapy (four drops of essential oil diluted with 20 mL of hot water and inhaled for 30 minutes). Simultaneously, serum cortisol was measured.

Another study of healthy young women found that lavender aromatic treatment induced not only relaxation but also increased arousal level in these subjects as measured by continuous electrocardiographic (ECG) monitoring before and after (10, 20, 30 minutes) the lavender fragrance stimuli (Duan et al 2007). Increases in the parasympathetic tone were observed after the lavender fragrance stimulus seen as increases in the heart function component and decreases in the low frequency (LF)/high frequency (HF). Additional measurement with positron emission tomography demonstrated the regional metabolic activation in the orbitofrontal, posterior cingulate gyrus, brainstem, thalamus and cerebellum, as well as the reductions in the pre/post-central gyrus and frontal eye field.

Commission E supports the use of oral lavender in mood disturbances such as restlessness and insomnia (Blumenthal et al 2000).

Dementia care

Managing difficult behaviours in aged care facilities is very challenging. A number of researchers have shown reductions in agitated behaviour using lavender in massage, baths, vaporisers and on bedclothes (Bowles et al 2005, Holmes et al 2002, Lin et al 2007, Smallwood et al 2001). These studies generally show positive effects; however, they are difficult to interpret because of the individual nature of behaviour and odour effects on individuals as well as the methodological differences among the studies.

Most recently, a crossover randomised trial of 70 Chinese older adults with dementia demonstrated that lavender inhalation for 3 weeks significantly decreased agitated behaviours (Lin et al 2007). As this patient population is particularly vulnerable to side effects of psychotropic medications, aromatherapy using lavender may offer an attractive alternative option.

Improved concentration

In a RCT, exposure to lavender aromatherapy during breaks resulted in significantly higher concentration levels during the afternoon period when concentration was found to be lowest in a control group (Sakamoto et al 2005). Lavender oil aromatherapy has also been found to reduce mental stress and increase arousal rate (Motomura et al 2001), to elicit a subjective sense of 'happiness' (Vernet-Maury et al 1999) and to produce increased relaxation, less depressed mood and faster and more accurate mathematical computations (Field et al 2005). In a RCT, lavender aromatherapy tended to enhance calculating speed and calculating accuracy in female but not male subjects (Liu et al 2004), but results from another study suggest that lavender reduced working memory and impaired reaction times for both memory and attention-based tasks compared with controls (Moss et al 2003).

A controlled study of dementia patients found that a blend of lavender, sweet marjoram, patchouli and vetiver essential oils in a cream massaged 5 times/day for 4 weeks onto the bodies and limbs of 56 aged care facility residents with moderate-to-severe dementia produced a small but significant improvement in mini mental state examination associated with increased mental alertness and awareness and resistance to nursing care procedures compared with massage with cream alone (Bowles et al 2002).

Dyspepsia and bloating

Although there have been no clinical trials to investigate its use, lavender is commonly recommended for gastrointestinal disorders as a carminative and antiflatulent to soothe indigestion, colic, dyspepsia

and bloating (Blumenthal et al 2000). Based on the antispasmodic actions of a key constituent, linalool, lavender may be useful in these conditions. No controlled clinical studies could be located to determine its effectiveness for these indications.

Alopecia

A RCT of scalp massage using thyme, rosemary, lavender and cedarwood essential oils in 86 patients with alopecia areata found a significant improvement in hair growth after 7 months (Hay et al 1998). Although the efficacy of lavender as a standalone treatment was not clarified with this trial, it is known that the herb has some antibacterial and antifungal activity that may play a role. In a single case study, topical application of lavender, together with other essential oils, was reported to assist in treating scalp eczema (De Valois 2004).

Perineal discomfort following childbirth

A RCT in 635 women following childbirth found that using lavender oil in bath water was safe and pleasant to use and that there was a tendency towards lower discomfort scores between the third and fifth day (Dale & Cornwell 1994). In that study, six drops of pure lavender oil was added to the bath.

Dysmenorrhoea

Aromatherapy applied topically in the form of an abdominal massage using two drops of lavender (*Lavandula officinalis*), one drop of clary sage (*Salvia sclarea*), and one drop of rose (*Rosa centifolia*) in 5 cc of almond oil significantly decreased the severity of menstrual cramps, according to a randomised, placebo-controlled study (Han et al 2006). The study involved 67 female college students who rated their menstrual cramps to be greater than 6 on a 10-point visual analogue scale, who had no systemic or reproductive diseases, and who did not use contraceptive drugs.

Insect bites

In vitro and animal studies suggest that lavender oil inhibits immediate-type allergic reactions by inhibition of mast cell degranulation (Kim & Cho 1999).

OTHER USES

Lavender has a long history of use as a sedative, an antidepressant, an antimicrobial agent, a carminative (smooth muscle relaxant), a topical analgesic agent for burns and insect bites (Cavanagh & Wilkinson 2002) and an insect repellent. Lavender has also been used to treat migraines and neuralgia, as an astringent to treat minor cuts and bruises, and is used externally for strained muscles, as well as acne, eczema and varicose ulcers (Fisher & Painter 1996). It is also used in a gargle for loss of voice.

A recent study in Hong Kong using eight sessions of acupoint stimulation followed by acupressure with lavender oil over 3 weeks compared with a placebo demonstrated effective short-term relief of neck pain (Yip & Tse 2005). Pain, stress, neck stiffness, tension and mobility all improved.

In Australia, lavender essential oil is the most popular aromatherapy oil, out-selling the second most popular (orange) oil by more than seven times (F Kheery (In Essence) pers. commun. 2002). It is often combined with bergamot and cedarwood oils for relieving anxiety and stress and combined with marjoram to induce sleep. There is a lack of definitive evidence for the effects of lavender on sleep. However, small comparative studies using lavender oil and placebo and case studies suggest a trend towards improved sleep quality and duration (Diego et al 1998, Hardy et al 1995).

Lavender oil has also been studied for veterinary applications. The ambient odour of lavender reduced travel-induced excitement in dogs, according to a study involving 32 dogs with a history of travel-induced excitement in owners' cars (Wells 2006). Dogs exposed to lavender spent significantly more time resting and sitting and less time moving and vocalising during the experimental condition.

DOSAGE RANGE

Probably no other herb is available in as many forms as lavender.

- Infusion (tea): 1.5 g dried flowers in 150 mL water, which is 1–2 teaspoons lavender flowers or leaves in one cup of boiling water steeped for 5–10 minutes and strained before drinking.
- Internal: 1–4 drops (20–80 mg) on a sugar cube.
- Liquid extract (1:2): 2–4.5 mL/day.
- External use: mix 20 drops of oil with 20 mL of carrier oil such as almond oil. May be applied undiluted to insect bites or stings.
- As a bath additive: 20–100 g lavender flowers are commonly steeped in 2 L boiling water, strained, and then added to the bathwater.
- Aromatherapy: use 2–4 drops of lavender oil in a suitable oil diffuser or on a pillow case to assist sleep.

Lavender oil is quickly absorbed by the skin and constituents linalool and linalyl acetate have been detected in the blood 5 minutes after administration. Blood levels peak after 19 minutes and are negligible by 90 minutes.

TOXICITY

McGuffin (1997) lists lavender as a Class I herb, a classification which represents herbs that can be 'safely consumed when used appropriately'. The acute oral toxicity dose (LD_{50}) in rats for lavender and linalool are 5 g/kg and 2.8 g/kg, respectively and the acute dermal toxicity in rabbits is 5 g/kg and 5.6 g/kg, respectively (Kiefer 2007). These doses would translate to approximately 350 g lavender oil or 1.5 cups.

Although there are no specific reports of toxicity, it is suggested that no more than two drops be taken internally. There is a potential for irritant or allergenic skin reactions with the topical use of lavender oil, as it has been found to be cytotoxic to human skin cells in vitro (endothelial cells and fibroblasts) at a concentration of 0.25% v/v, possibly due to membrane damage. The activity

of linalool was found to reflect the cytotoxicity of the whole oil, whereas the cytotoxicity of linalyl acetate was found to be higher than that of the oil, suggesting suppression of its activity by an unknown factor in the oil (Prashar et al 2004). Three case reports have been published of gynaecomastia developing in boys aged four, seven and ten following regular topical use of lavender-containing products (soap, shampoo and lotions) (Henley et al 2007). Henley et al postulated that lavender has oestrogenic and antiandrogenic effects on several different cell lines. The implications for clinical practice and aromatherapy are unknown.

Skin sensitivity to lavender might develop with increased exposure and prolonged use (Sugiura et al 2000).

SIGNIFICANT INTERACTIONS

Controlled studies are not available; therefore, interactions are based on evidence of activity and are largely theoretical and speculative.

Pharmaceutical sedatives

Theoretically, lavender can potentiate the effects of sedatives, so observe patients taking this combination closely — beneficial interaction possible under professional supervision.

Antidepressants

Lavender tincture may have additive effects when used with these medicines — beneficial interaction possible.

PREGNANCY USE

No restrictions known for external use.

Safety of internal use has not been scientifically established.

PRACTICE POINTS/PATIENT COUNSELLING

- The active part of lavender is the volatile oil, which has relaxing, sedative, antispasmodic and antiseptic activity.
- Lavender can be taken as a tincture or tea, or the oil can be applied topically, used in baths or inhaled from a diffuser.
- It is advised that topical preparations be tested on a small area of skin before widespread application.
- Lavender has traditionally been used for sleep disorders, anxiety and nervous stomach, as well as to treat minor cuts, burns, bruises and insect bites and is commonly found in cosmetics and toiletries.
- Lavender contains substances that are currently being studied for cancer prevention.
  - Ambient lavender induces a relaxation response in healthy people, the elderly with dementia and agitation and also dogs with travel-induced excitement.
  - Abdominal massage with lavender oil (in combination with several others) has been shown to reduce menstrual cramps to a better degree than a non-aromatherapy oil.

PATIENTS' FAQs

What will this herb do for me?

Lavender oil is used to assist in relaxation, digestive problems and as first aid for minor skin conditions. Ambient lavender induces a relaxation response in healthy people and the elderly with dementia and agitation and also calms dogs during travel. Used as part of an aromatherapy massage, it also has antispasmodic activity.

When will it start to work?

As a relaxant, effects may be felt on the first day of use, but this will depend on the dose and form used.

Are there any safety issues?

Although lavender has not been scientifically studied as extensively as some other herbal medicines, historical use suggests that it is generally safe.

Lemon balm

HISTORICAL NOTE Lemon balm was used in ancient Greece and Rome as a topical treatment for wounds. In the Middle Ages it was used internally as a sedative and by the 17th century, English herbalist Culpeper claimed it could improve mood and stimulate clear thinking. Nowadays, it is still used to induce a sense of calm and help with anxiety, but is also added to cosmetics, insect repellants, furniture polish and food.

COMMON NAME
Lemon balm

OTHER NAMES
Balm mint, bee balm, blue balm, common balm, cure-all, dropsy plant, garden balm, sweet balm

BOTANICAL NAME/FAMILY
Melissa officinalis (family Lamiaceae)

PLANT PART USED
Aerial parts

CHEMICAL COMPONENTS
Flavonoids, phenolic acids, tannins, triterpenes, essential oil and sesquiterpenes. Of note, the herb contains citronellal, caffeic acid, eugenol, rosmarinic acid and choline (Wake et al 2000). Growing and harvesting methods have a major influence on

the amount of volatile oil present in the leaves. It has been found that the oil content in the herb is highest in the top third and lowest in the bottom two-thirds (Mrlianova et al 2002).

MAIN ACTIONS

Anxiolytic and sedative

Over the years, a number of studies involving rodents have suggested specific anxiolytic or sedative effects (Kennedy et al 2002, Soulimani et al 1991, Abuhamdah et al 2008). A number of possible active components of the dried leaf and essential oil of the herb may be responsible for these effects, such as eugenol and citronellol, which bind to GABA-A receptors and increase the affinity of GABA to receptors (Aoshima & Hamamoto 1999). Rosmarinic acid has also been shown to possess anti-anxiety properties in vivo (Pereira et al 2005)

Antiviral

A lemon balm extract was found to have significant virucidal effects against HSV-1 within 3 and 6 hours of treatment in vitro and in animal tests (Dimitrova et al 1993). The volatile oils from *M. officinalis* have also been shown to inhibit the replication of HSV-2 in vitro (Allahverdiyer et al 2004).

Two more recent studies have demonstrated the antiviral effects of lemon balm against HSV in plaque reduction assays. One study used an essential oil preparation, whilst the other used an aqueous extract (Schnitzler et al 2008, Nolkemper et al 2006). Both studies demonstrated > 90% inhibition of plaque formation for HSV-1 and HSV-2, and in one study an acyclovir-resistant strain of HSV-1 was reduced by 85% (Nolkemper et al 2006). Both studies also found that lemon balm affected HSV before adsorption, but had no effect on viral replication.

Lemon balm has demonstrated a virucidal effect against HIV-1 in T-cell lines and macrophages in vitro (Geuenich et al 2008). Inhibitory activity against HIV-1 reverse transcriptase has also been shown (Yamasaki et al 1998).

Antibacterial and antifungal

One in vitro study found that lemon balm extract exhibited activity against bacteria, filamentous fungi and yeasts (Larrondo et al 1995). It is likely that the constituent eugenol is chiefly responsible, as it has well established antibacterial activity against such organisms as *Escherichia coli* and *Staphylococcus aureus* (Walsh et al 2003).

Cholinergic

Lemon balm exhibits CNS acetylcholine receptor activity, with both nicotinic and muscarinic binding properties (Wake et al 2000). In vitro data has demonstrated that lemon balm is a weak inhibitor of acetylcholinesterase and has a moderate affinity to the GABA-A benzodiazepine receptor site (Salah & Jager 2005). This indicates that lemon balm may have a role to play in the treatment of Alzheimer's disease and epilepsy. However, a 2003 randomised, double-blind, placebo-controlled, crossover trial demonstrated that lemon balm did not inhibit cholinesterase. The trial demonstrated improved cognitive function and mood and concluded that for these reasons it was a valuable adjunct to Alzheimer's therapy (Kennedy et al 2003).

> ***Clinical note***
> Long before the current biologically based theory of cholinergic abnormalities in Alzheimer's dementia emerged, Western European medicine systems have traditionally used several herbs that are now known to exert cholinergic activity (such as sage and lemon balm) for their dementia-treating properties.

Anti-inflammatory, analgesic and antispasmodic

The plant extract exerts analgesic activity at high doses in vivo (Soulimani et al 1991). Two constituents in lemon balm have documented anti-inflammatory activity, achieved through different mechanisms of action. Rosmarinic acid, a naturally occurring constituent found in *M. officinalis*, inhibits several complement-dependent inflammatory processes (Englberger et al 1988, Peake et al 1991). Eugenol, another important component, inhibits COX-1 and -2 activities in vitro (Huss et al 2002, Kelm et al 2000).

Both the whole volatile oil and its main component citral have demonstrated antispasmodic ability on isolated rat ileum (Sadraei et al 2003). Similarly, both the aqueous extract and rosmarinic acid component demonstrated vasorelaxant properties on isolated rat aorta (Ersoy et al 2008). An in vivo study has shown both an extract of lemon balm and the herbal formulation ColiMil® (chamomile, fennel and lemon balm) may delay gastric emptying (Capasso et al 2007). The group treated with lemon balm exhibited 36% inhibition, chamomile 28% and fennel 9% as compared to 45% for the ColiMil® group, suggesting a synergistic action.

Antioxidant

Lemon balm has shown antioxidant activity in several studies (Apak et al 2006, Canadanovic-Brunet et al 2008, Ferreira et al 2006, Hohmann et al 1999, Lopez et al 2007). According to a 2003 study, concentrations of antioxidants within lemon balm are >75 mmol/100 g (Dragland et al 2003).

Cardiovascular effects

Aqueous extracts of lemon balm have been shown to slow cardiac rate but not alter the force of contraction in isolated rat hearts (Gazola et al 2004). An extract of lemon balm reduced blood cholesterol and lipid levels in rats fed a high fat and alcohol diet (Bolkent et al 2005). Interestingly, the extract also increased glutathione levels and reduced lipid peroxidation in the liver, demonstrating a hepatoprotective effect.

OTHER ACTIONS

Lemon balm inhibits the binding of TSH to thyroid plasma membranes in vitro and the extrathyroidal enzymic T4-5'-deiodination to T3 (Auf'mkolk

et al 1984a). Antitumour activity has also been demonstrated (Chlabicz & Galasinski 1986, Dudai et al 2005, Galasinski 1996, Galasinski et al 1996).

CLINICAL USE

In clinical practice, lemon balm is often prescribed in combination with other herbal medicines. As a reflection of this, many clinical studies have investigated the effects of lemon balm as an ingredient of a herbal combination, making it difficult to determine the efficacy of this herb individually.

Anxiety

In 2005 a small double-blind, placebo-controlled, randomised, crossover trial involving 18 healthy volunteers investigated the effects of a whole extract of lemon balm in two different doses (300 and 600 mg) and found a significant reduction in stress in the volunteers taking the larger dose (Kennedy et al 2004).

The essential oil of lemon balm has also been investigated under double-blind placebo-controlled conditions and found to be a safe and effective treatment for clinically significant agitation in people with severe dementia (Ballard et al 2002). The trial, which involved 71 subjects, found that after 1 month's treatment, patients were less agitated, less socially withdrawn and spent more time in constructive activities than those in the placebo group.

Commission E approves the use of lemon balm in the treatment of anxiety and restlessness (Blumenthal et al 2000).

In combination

A combination of lemon balm and valerian (*Valeriana officinalis*) was examined for acute effects on anxiety in a double-blind, placebo-controlled, randomised, crossover experiment of 24 individuals (Kennedy et al 2006). Three separate concentrations of the standardised product (600 mg, 1200 mg, 1800 mg) were given on separate days after a 7-day wash-out period. Any changes to mood and anxiety were assessed pre-dose and at 1, 3 and 6 hour intervals. Interestingly, the lower dose (600 mg) was shown to decrease anxiety levels whereas the highest dose (1800 mg) increased anxiety. The exact effect of lemon balm in this preparation is hard to determine.

Cognitive function

Lemon balm has been used for centuries to improve cognitive function and encouraging results from a 2002 clinical study confirm that it can influence memory.

The randomised, double-blind crossover study involving 20 healthy young volunteers found that single doses of lemon balm were able to modulate both mood and cognitive performance in a dose- and time-dependent manner (Kennedy et al 2002). In this study, treatment with the lowest dose (300 mg) increased self-rated 'calmness' within 1 hour whereas the 600 mg and 900 mg doses produced significant effects on memory task performance, observable at both 2.5 hours and 4 hours after administration. The highest tested dose (900 mg) was found to significantly reduce alertness within 1 hour, suggesting a dose–response effect.

Alzheimer's disease

A randomised, double-blind, placebo-controlled trial demonstrated the efficacy and safety of *M. officinalis* in 42 patients aged 65–80 with mild to moderate Alzheimer's disease who were given 60 drops/day for 4 months (Akhondzadeh et al 2003). Outcome measures included significantly better cognition and reduced agitation.

Insomnia

In clinical practice, lemon balm is often prescribed in combination with other herbs such as valerian in the treatment of insomnia. As a reflection of this, a randomised, double-blind multicentre study investigated the effects of a commercial valerian and lemon balm herbal combination (Songha Night) in 98 healthy subjects (Cerny & Schmid 1999). Treatment was administered over a 30-day period and consisted of 3 tablets taken half an hour before bedtime, providing a total dose of 1–6 g valerian and 1–2 g lemon balm. Herbal treatment was found to significantly improve sleep quality and was well tolerated.

Another randomised, double-blind crossover study found that the same combination of valerian and lemon balm taken over 9 nights was as effective as triazolam in the treatment of insomnia (Dressing et al 1992). The dose used was equivalent to 1.4 g dried valerian and 0.9 g dried lemon balm.

As with all herbal combination studies, it is difficult to determine the contribution each individual herb made to the end result. As such, these studies are encouraging but the role of lemon balm as a stand-alone treatment for insomnia remains unclear.

Commission E approves the use of lemon balm in the treatment of insomnia (Blumenthal et al 2000).

Gastrointestinal conditions associated with spasm and nervousness

To date, only studies using lemon balm in combination with other herbs are available.

A pilot study investigated the effects of Carmint, containing lemon balm, spearmint and coriander, in 32 patients with irritable bowel syndrome (Vejdani et al 2006). Patients were randomly assigned Carmint or placebo, plus Loperamide or psyllium (based on their IBS subtype) for 8 weeks. The severity and frequency of abdominal pain and bloating were significantly lower in the Carmint group as compared to placebo at the end of the 8 weeks. A larger follow-up trial is needed to confirm these results.

A 15-day open study involving 24 subjects with chronic non-specific colitis investigated whether a combination of lemon balm, St John's wort, dandelion, marigold and fennel could provide symptom relief (Chakurski et al 1981). Excellent results were obtained by the end of the study, with

herbal treatment resulting in the disappearance of spontaneous and palpable pains along the large intestine in 95.83% of patients. A double-blind study using a herbal tea prepared from chamomile, lemon balm, vervain, licorice and fennel in infantile colic has also been conducted. A dose of 150 mL offered up to three times daily was found to eliminate symptoms of colic in 57% of infants, whereas placebo was helpful in only 26% after 7 days' treatment (Weizman et al 1993).

A randomised, double-blind, placebo-controlled trial was conducted to examine the effectiveness of ColiMil (lemon balm, chamomile and fennel) in 93 breast fed infants with colic (Savino et al 2005). The infants were randomised into two groups to receive either ColiMil or placebo both twice a day at 5pm and 8pm before feeding (2 mL/kg/day) for 7 days. A reduction in crying time was observed in 85.4% subjects in the active treatment group as compared to 48.9% for placebo ($P < 0.005$). This is a significant result, especially considering the treatment period was only seven days. No side effects were reported. Commission E supports the use of lemon balm for functional gastrointestinal conditions (Blumenthal et al 2000).

Herpes simplex type I — external use

The topical use of lemon balm preparations for HSV infection is very popular in Europe. Results from a randomised double-blind study in 66 subjects with a history of recurrent herpes labialis (> 3 episodes/year) found that standardised lemon balm ointment (700 mg crude herb per gram) applied four times daily for 5 days significantly shortened healing time, prevented infection spread and produced rapid symptom relief (Koytchev et al 1999). Decreased symptoms and increased rate of healing were also observed in another double-blind study of lemon balm cream in 116 subjects (Woelbling & Leonhardt 1994).

OTHER USES

Animal studies have identified dose-dependent anti-ulcerogenic activity for lemon balm extract, which has been histologically confirmed. This activity is associated with a reduced acid output and an increased mucin secretion, an increase in PGE_2 release and a decrease in leukotrienes (Khayyal et al 2001).

DOSAGE RANGE

- Fresh herb: 1.5–4.5 g two–three times daily.
- Infusion: 1.5–4.5 g in 150 mL water.
- Fluid extract (1:1) (g/mL): 6–12 mL/day.
- Ointment: 700 mg/g ointment applied four times daily for herpes simplex infection.

TOXICITY

Not known.

ADVERSE REACTIONS

Lemon balm is well tolerated according to one double-blind, randomised crossover study (Kennedy et al 2002).

SIGNIFICANT INTERACTIONS

Controlled clinical studies are not available, so interactions are speculative and based on evidence of activity.

Barbiturates

Increased sedative effects: one animal study (Soulimani et al 1991) found that concomitant administration of lemon balm extract with pentobarbital produced an increased sedative effect — observe patients taking this combination.

Cholinergic drugs

Additive effects are theoretically possible and may be beneficial — observe patients taking this combination.

CONTRAINDICATIONS AND PRECAUTIONS

Hypothyroidism — one in vitro study found that an extract of *M. officinalis* inhibited both the extrathyroidal enzymic T4-5'-deiodination to T3 and the T4-5'-deiodination (Auf'mkolk et al 1984b). Whether this has any clinical significance has yet to be determined.

PREGNANCY USE

Safety has not been scientifically established and is unknown.

PATIENTS' FAQs

What will this herb do for me?

Lemon balm has several different actions and is used for a number of different conditions. Taking the herb internally may help reduce anxiety and improve mood and mental concentration. When taken together with valerian, it can relieve insomnia. It may also relieve stomach spasms associated with nervousness, or in chronic, non-specific colitis when taken as part of a specific herbal combination. Melissa cream applied four times daily to herpes simplex infections can reduce symptoms, accelerate healing and reduce the chance of the infection spreading.

PRACTICE POINTS/PATIENT COUNSELLING

- Lemon balm has been used traditionally to treat insomnia, irritability, restlessness, anxiety and dementia. It is also used to relieve gastrointestinal symptoms associated with spasms and nervousness.
- Used topically as a cold sore treatment, it significantly reduces symptoms, shortens the healing period and prevents infection spread. It may be suitable both as an active treatment and as a preventative agent in cases of chronic recurrent herpes simplex infections.
- Lemon balm may have some anti-inflammatory and antispasmodic activity.
- The essential oil is used in aromatherapy to relieve anxiety and promote calm and a sense of wellbeing, which has been confirmed in one clinical study.
- One clinical study has found that it can modulate both mood and cognitive performance in a dose- and time-dependent manner.

When will it start to work?

Approximately one month's treatment with the essential oil is required for calming effects on agitation in dementia to be seen. Taken internally with valerian, effects on sleep may be seen after 9 days' use. Improved memory occurred within 2.5 hours according to one study; however, it is not known if and when effects are seen in dementia. Melissa cream has been shown to significantly reduce symptoms of herpes simplex within 2 days, when applied four times daily.

Are there any safety issues?

One study using lemon balm in tablet form found that it was well tolerated. Drug interactions are theoretically possible and this herb should be used cautiously in people with hypothyroidism.

Licorice

HISTORICAL NOTE Licorice root has been used in Europe since prehistoric times, and its medicinal use is well documented (Fiore et al 2005). References to licorice date back to approximately 2500 BC on Assyrian clay tablets and Egyptian papyri. It has been used as both a food and a medicine since ancient times. The genus name, meaning 'sweet root', is attributed to the first century Greek physician Dioscorides. The herb is also popular in traditional Chinese and Ayurvedic medicines (Blumenthal et al 2000).

OTHER NAMES

Liquorice, licorice root, Chinese licorice, sweet root, gan cao, kanzo, kanzoh, radix glycyrrhizae, yashimadhu, yasti-madhu, alcacuz.

BOTANICAL NAME/FAMILY

Glycyrrhiza glabra L. (family Leguminosae)

There are around 30 species of *Glycyrrhiza* spp. so *G. glabra* should be differentiated from other medicinally used herbs such as: *G. uralensis* (synonyms: Chinese licorice, gan cao, licorice root, sweet root), *G. inflata* (synonyms: gan cao, zhigancao), *G. pallidiflora*, *G. glandulifera*, *G. pallida*, *G. typica* and *G. violacea*, although some studies do not always clearly state which form is used. In addition, there are three varieties of *G. glabra*: var. *violacea* (Persia, Turkey), var. *gladulifera* (Russia) and var. *typical* (Spain, Italy) (Asl & Hosseinzadeh 2008).

PLANT PARTS USED

Root and stolon

CHEMICAL COMPONENTS

Licorice contains several triterpenoid saponins (4–20%), the most studied of which is glycyrrhizin (GL, also known as glycyrrhizic acid or glycyrrhizinic acid), which is a mixture of potassium and calcium salts of glycyrrhetinic acid (GA). Other triterpenes include: liquiritic acid, glycyrretol, glabrolide and isoglabrolide (Asl & Hosseinzadeh 2008).

Other important constituents include: flavonoids (isoflavonoids, liquiritin, isoliquiritin, liquiritigenin, formononetin, glabridin, rhamnoliquiritin, neoliquiritin and the chalcones [isoliquiritigenin, licochalcone A and B]); sterols (beta-sitosterol, dihydrostigmasterol); polysaccharides (arabinogalactans); coumarins (liqcoumarin, glabrocoumarone A and B, herniarin, umbelliferone, glycerin, glycocoumarin, licofuranocoumarin, licopyranocoumarin and glabrocoumarin); phenols, fatty acids, glabrol; amines; glucose, sucrose; resin; and volatile oil. 5,8-Dihydroxy-flavone-7-*O*-beta-D-glucuronide, glychionide A, 5-hydroxy-8-methoxyl-flavone-7-*O*-beta-D-glucuronide, glychionide B, hispaglabridin A, hispaglabridin B, 4′-*O*-methylglabridin and 3′-hydroxy-4′-*O*-methylglabridin, glabroisoflavanone A and B and glabroisoflavanone B have also been isolated (Asl & Hosseinzadeh 2008, Blumenthal et al 2000).

Glycyrrhiza glabra should be differentiated from other species such as *G. inflata* and *G. uralensis*. While the constituent properties of *G. glabra* resemble that of *G. inflata*, they are not similar to *G. uralensis*. Furthermore, there are species-specific typical constituents including glabridin (*G. glabra*), licochalcone A (*G. inflata*) and glycycoumarin (*G. uralensis*) that may influence the pharmacological effects (Kondo et al 2007). Additionally, among different samples of *G. glabra* there may be significant differences in the content of active constituents and biological activity (Statti et al 2004). The lack of

Clinical note — GL, GA and side effects

GL is mainly absorbed after presystemic hydrolysis to GA (18-beta-glycyrrhetinic acid (glycyrrhetic acid; the aglycone of GL)). On excretion via the bile it may be reconjugated to GA by commensal bowel flora and then reabsorbed (Gunnarsdottir & Johannesson 1997, Hattori et al 1983, Ploeger et al 2001). GL and GA are associated with the side effects encountered with high-dose or long-term licorice use, such as elevated blood pressure and fluid retention. In people with prolonged gastrointestinal transit time, GA can accumulate after repeated intake. As GA is 200- to 1000-fold more powerful in inhibiting 11-beta-hydroxysteroid dehydrogenase (11HSD) than GL, this may lead to more significant mineralocorticoid effects (Ploeger et al 2001). In order to minimise the risk of side effects, practitioners often use a deglycyrrhizinised form of licorice (DGL).

While *G. glabra*, *G. uralensis* and *G. inflata* are often seen as similar remedies, there are some differences in the constituents, such as the phenolic contents (Mills & Bone 2000).

standardisation of herbs such as licorice provides a challenge for demonstrating reproducible efficacy in clinical settings.

MAIN ACTIONS

Mineralocorticoid effect

The GA constituent in licorice (and its metabolite 3-monoglucuronyl-glycyrrhetinic acid) inhibits the enzyme 11HSD (Kato et al 1995), which catalyses the conversion of cortisol into its inactive metabolite, cortisone. This results in delayed excretion and prolonged activity of cortisol. Additionally, GL and GA bind to mineralocorticoid and glucocorticoid receptors and may displace cortisol from its carrier molecule, transcortin (Nissen 2003).

Pseudohyperaldosteronism

As cortisol levels rise, they stimulate mineralocorticoid receptors in the distal renal tubule (Walker et al 1992). This creates pseudohyperaldosteronism, which has the same clinical features as primary aldosteronism, including sodium retention, fluid retention and oedema, hypertension, hypokalaemia and metabolic alkalosis (Armanini et al 1996, Heldal & Midtvedt 2002, Kato et al 1995, vanUum et al 1998, Walker & Edwards 1994).

A case report suggests that the symptoms occur despite low plasma levels of aldosterone (Nobata et al 2001). Decreased plasma renin activity (Bernardi et al 1994, Epstein et al 1977) and increased cortisol levels result in vasoconstriction of vascular smooth muscle (Dobbins & Saul 2000, Walker et al 1992), which may further exacerbate the hypertensive effects. This may be of particular significance in patients with prolonged intestinal transit time where GA levels can accumulate (Ploeger et al 2001).

Anti-inflammatory

The anti-inflammatory action of beta-glycyrrhetinic acid (GA), a major metabolite of GL, is largely mediated by cortisol, an endogenous hormone with anti-inflammatory action (Teelucksingh et al 1990). It inhibits glucocorticoid metabolism and therefore potentiates its effects.

Several studies have found that GA inhibits the activity of 11HSD and hepatic delta-4-5-beta-steroid reductase, preventing the conversion of cortisol to its inactive metabolite, cortisone (Kageyama et al 1997, MacKenzie et al 1990, Soma et al 1994, Whorwood et al 1993). As such, cortisol activity is prolonged and levels may rise, thereby increasing its anti-inflammatory effects. It may also inhibit classical complement pathway activation (Asl & Hosseinzadeh 2008). For these reasons, licorice has also been investigated for its ability to potentiate the effects of steroid medications (Teelucksingh et al 1990).

This mechanism alone does not fully account for the anti-inflammatory effects of licorice as oral doses of GL also appear to exert an effect in adrenalectomised rats (Gujral et al 2000). GL (10 mg/kg i.p. 5 min prior to carrageenan) exerts potent anti-inflammatory effects in mice by preventing the activation of nuclear factor (NF)-kappaB and STAT-3 (Menegazzi et al 2008). The DGL also exerts anti-inflammatory effects and steroid-like activity has also been attributed to the liquiritin constituent (Bradley 1992).

Anti-allergic

The anti-allergic effects of licorice are mainly due to GL, 18-beta-glycyrrhetinic acid and liquiritigenin, which can relieve IgE-induced allergic reactions, inhibit passive cutaneous anaphylactic reactions and scratching behaviour in mice (Shin et al 2007). A mouse model of asthma GL (5 mg/kg) markedly inhibited airway constriction and hyperreactivity, lung inflammation and infiltration of eosinophils in the peribronchial and perivascular areas. It decreased interleukin (IL)-4, IL-5 and ovalbumin-specific IgE levels (Ram et al 2006). These effects may prove beneficial for the treatment of allergic conditions such as asthma and dermatitis; however, further research is required.

Mucoprotective

Early investigation into the mucoprotective qualities of licorice led to the development of the anti-inflammatory and anti-ulcer medications, carbenoxolone (a hemisuccinate derivative of GA), and enoxolone (an analogue of carbenoxolone) used to treat gastric and oesophageal ulcer disease. Researchers have suggested that it may exert its mucoprotective effects by increasing mucosal blood flow as well as mucus production, and by interfering with gastric prostanoid synthesis (Guslandi 1985). Animal studies indicate that licorice preparations such as DGL improve the environment in the stomach by increasing mucus production, thereby allowing for proliferation of tissue and healing to occur. DGL increases mucus production by increasing the number of fundus glands and the number of mucus-secreting cells on each gland (van Marle et al 1981).

The increase in mucus production seen with carbenoxolone and licorice appears to occur in a number of epithelial tissues other than the digestive tract. It has been reported in the lungs and also bladder, according to in vivo studies (Mooreville & Fritz 1983), and in the trachea, accounting for its expectorant properties (Bradley 1992).

Anti-ulcer effects

Licorice demonstrates the ability to promote mucosal repair and reduce symptoms of active ulcer (Larkworthy & Holgate 1975).

The anti-ulcer effects of licorice are due to inhibition of 15-hydroxyprostaglandin dehydrogenase (which converts prostaglandin E2 (PGE_2) and F_{2alpha} to their inactive forms) and delta-13-PG reductase. Licorice-derived compounds therefore increase the local concentration of PGs that promote mucus secretion and cell proliferation in the stomach, leading to healing of ulcers (Baker 1994).

Anti-inflammatory activity (as described above) further contributes to the herb's symptom-relieving action.

Antiviral

Both oral and injectable dose forms of licorice have been tested and found to have activity against a range of viruses. In human trials, GL and its derivatives reduce the liver sequelae associated with hepatitis B and C viruses; animal studies demonstrate a reduction in viral activity for herpes simplex virus, encephalitis and influenza A virus pneumonia; and in vitro studies reveal antiviral activity against HIV-1, severe acute respiratory syndrome (SARS) related coronavirus, respiratory syncytial virus, arboviruses, vaccinia virus and vesicular stomatitis virus (Fiore et al 2008). The effects appear to be mediated by the constituents GL and GA (Jeong & Kim 2002). The proposed mechanisms for these antiviral effects include 'reduced transport to the membrane and sialylation of hepatitis B virus surface antigen, reduction of membrane fluidity leading to inhibition of fusion of the viral membrane of HIV-1 with the cell, induction of interferon gamma in T-cells, inhibition of phosphorylating enzymes in vesicular stomatitis virus infection and reduction of viral latency' (Fiore et al 2008). It should be noted that current studies focus largely on GL, which is converted in the gut to GA and may not produce the same results as those demonstrated for GL in vitro.

SARS-associated coronavirus

In vitro studies have shown GL to inhibit SARS-CV (clinical isolates FFM-1 and FFM-2) replication by inhibiting adsorption and penetration of the virus in the early steps of the replicative cycle. GL was most effective when given both during and after the adsorption period. High concentrations of GL (4000 mg/L) were found to completely block replication of the virus (Cinatl et al 2003). The ability of GL to reduce platelet accumulation in the lungs (Yu et al 2005) may also support this use and provide a possible therapeutic option for further investigation.

HIV

Preliminary evidence indicates that intravenous administration of GL may reduce replication of HIV. High-dose GL (1600 mg/day) was most effective in reducing HIV type 1 p24 antigen and increasing lymphocytes (Hattori et al 1989). In vitro, GL has the potential to inhibit viral replication in cultures of peripheral blood mononuclear cells from HIV-infected patients infected with a non-syncytium-inducing variant of HIV (Sasaki et al 2002–03).

Influenza

Animal studies have shown that GL offers protection against influenza virus in mice through stimulation of interferon-gamma production by T-cells (Utsunomiya et al 1997).

Epstein–Barr virus

In vitro studies suggest that GL may interfere with an early step of the Epstein Barr Virus replication cycle (possibly penetration) (Lin 2003).

Herpes simplex virus 1

In Kaposi sarcoma-associated herpes virus (KSHV), GL reduced the synthesis of a viral latency protein and induced apoptosis of infected cells (Cohen 2005) terminating KSHV latent infection of B-lymphocytes (Bradbury 2005). Early in vitro studies found that GL inactivated Herpes Simplex Virus irreversibly (Pompei et al 1979). Animal studies show that intraperitoneal administration of GL reduces HSV-1 viral replication and improves survival from herpetic encephalitis in mice (Sekizawa et al 2001). Whether GL may act against other latent herpes viruses or be suitable for clinical use against KSHV requires further elucidation (Bradbury 2005).

Antibacterial

A number of constituents in licorice, including phenolic compounds (glicophenone and glicoisoflavanone), licochalcone A and isoflavones, were found to have antibacterial effects on Methicillin-Resistant *Staphylococcus aureus* and Methicillin-Sensitive *Staphylococcus aureus* in vitro (Hatano et al 2000). Glabridin has been identified as a potentially active agent against *Mycobacterium tuberculosis* (H(37)Ra and H(37)Rv strains), gram-positive and gram-negative bacteria (Gupta et al 2008). Additionally ether–water extracts of licorice have been found to have antibacterial activity against *E. coli*, *B. subtilis*, *E. aerogenes*, *K. pneumoniae* and *S. aureus* (Onkarappa et al 2005).

Expectorant

Expectorant effects may be attributed to the ability of licorice to stimulate tracheal mucus secretion, facilitating the elimination of mucus from the respiratory tract (Bradley 1992).

Antitussive

In animal studies licorice produces a persistent antitussive effect, which is mediated by liquiritin apioside in the earlier phase and liquiritin and liquiritigenin (a metabolite of liquiritin apioside) in the later phase (Kamei et al 2005). Isoliquiritigenin has also been shown to induce tracheal relaxation in guinea pig models (Liu et al 2008).

Antioxidant

In vitro research has identified seven antioxidant compounds from an acetone extract of licorice: four isoflavans (hispaglabridin A, hispaglabridin B, glabridin and 4′-*O*-methylglabridin), two chalcones (isoprenylchalcone derivative and isoliquiritigenin) and an isoflavone (formononetin) (Vaya et al 1997). Isoflavones from licorice were also shown to be effective in protecting mitochondrial function against oxidative stresses (Haraguchi 2000).

Reduces lipid peroxidation

Macrophage-mediated oxidation of LDL cholesterol plays a major role in early atherogenesis. In animal models, glabridin accumulates in macrophages and inhibits macrophage-mediated oxidation of LDL by up to 80% (Aviram 2004). DGL (100 mg/day for 2 weeks) was found to reduce lipid peroxidation of

LDL cholesterol after 1 week's use according to a placebo-controlled trial (Fuhrman et al 1997).

Lipid lowering

Administration of licorice root powder (5 and 10 g in diet) to hypercholesterolaemic male albino rats for 4 weeks resulted in a 'significant reduction in plasma, hepatic total lipids, cholesterol, triglycerides and plasma low-density lipoprotein and VLDL cholesterol accompanied by significant increases in HDL cholesterol levels'. These effects may have been due in part to increases in faecal cholesterol, neutral sterols and bile acid excretion and an increase in hepatic 3-hydroxy-3-methylglutaryl-coenzyme A (HMG-CoA) reductase activity and bile acid production. Additionally, decreased hepatic lipid peroxidation with a concomitant increase in superoxide dismutase (SOD) and catalase activities and total ascorbic acid content were noted. In normocholesterolaemic rats, the higher dose also led to a significant reduction in plasma lipid profiles and an increase in HDL cholesterol content (Visavadiya & Narasimhacharya 2006).

Anticancer effects

Licorice has demonstrated potent anti-angiogenic and antitumour activity in animal studies (Sheela et al 2006). Animal and in vitro studies have shown licorice components to be effective in reducing the occurrence and number of tumour cells in several cancer models (Shibata 1994, Wang & Mukhtar 1994, Wang & Nixon 2001), inducing apoptosis and potentiating the effect of paclitaxel and vinblastine chemotherapy (Rafi et al 2000). In vitro research reveals that chalcone and isoliquiritigenin significantly inhibit the proliferation of prostate cancer cell lines in a dose- and time-dependent manner and that beta-hydroxy-DHP inhibits breast and prostate tumour cells (Kanazawa et al 2003, Maggiolini et al 2002, Rafi et al 2002). Isoliquiritigenin has also been shown to significantly inhibit the proliferation of lung and colon cancer cells, restrain cell cycle progression and induce apoptosis (Chin et al 2007, Ii et al 2004, Takahashi et al 2004).

Although the exact mechanism of action is still being determined, a 2001 review indicates that licorice and its derivatives may protect against carcinogen-induced DNA damage and that GA is an inhibitor of lipo-oxygenase and cyclo-oxygenase, inhibits protein kinase C, and down-regulates the epidermal growth factor receptor (Wang & Nixon 2001).

Cognitive function

Glycyrrhiza glabra has shown promise as a memory-enhancing agent in both exteroceptive and interoceptive behavioural models of memory in mice. The effect is possibly due to facilitation of cholinergic transmission in the mouse brain (Dhingra et al 2004, Parle et al 2004). In animal models, glabridin appears to reduce brain cholinesterase activity in mice (Cui et al 2008). In rats significant spatial memory retention enhancement has also been observed after 4 weeks of licorice administration (aqueous extract equivalent to 5 mg/mL of GL) in drinking water (Sharifzadeh et al 2008).

Neuroprotective

GL has also been shown to reduce the development of inflammation and tissue injury associated with spinal cord trauma in mice resulting in improved recovery of limb function (Genovese et al 2008). Several other constituents have also demonstrated possible neuroprotective effects. Glabridin (25 mg/kg by intraperitoneal injection) was able to modulate the cerebral injuries induced by middle cerebral artery occlusion (MCAO) in rats. The neuroprotective effect appeared to be at least in part associated with the modulation of multiple pathways associated with apoptosis (Yu et al 2008). In addition, pretreatment with isoliquiritigenin (5, 10 and 20 mg/kg, i.g.) significantly reduced cerebral infarct volume and oedema, and produced a significant reduction in neurological deficits due to MCAO-induced focal cerebral ischaemia-reperfusion injury in rats (Zhan & Yang 2006).

Antidepressant (serotonin reuptake inhibition)

Several flavonoid constituents in licorice (glabridin 60%, 4′-*O*-methylglabridin 53% and glabrene 47%) inhibit serotonin reuptake in a dose-dependent manner, according to in vitro research (Ofir et al 2003). However, animal models suggest that the effect may be on noradrenaline and dopamine. In rats licorice extract (150 mg/kg) administered orally for 7 days exerted an antidepressant effect comparable to that of imipramine (15 mg/kg i.p.) and fluoxetine (20 mg/kg i.p.), the effect however appeared to be mediated by an increase of brain noradrenaline and dopamine, not serotonin. It is likely that licorice exerts a monoamine oxidase inhibiting effect (Dhingra & Sharma 2006).

Hepatoprotective effects

Randomised controlled trials have confirmed that GL and its derivatives reduce hepatocellular damage in chronic hepatitis B and C and reduce cirrhosis and hepatocellular carcinoma risk in hepatitis C (Fiore et al 2008). Animal studies demonstrate that licorice protects hepatocytes by inhibiting experimentally induced lipid peroxidation (Rajesh & Latha 2004). GL appears to alleviate carbon tetrachloride-induced liver injury by inducing haem oxygenase-1 and down-regulating pro-inflammatory mediators (tissue necrosis factor (TNF)-alpha, inducible nitric oxide synthase, and cyclo-oxygenase-2 mRNA expression) (Lee et al 2007). In vitro studies have shown hepatoprotective effects of GL against aflatoxin B1-induced cytotoxicity in human hepatoma cells (Chan et al 2003) and animal studies have shown GA exerts hepatoprotective effects against carbon tetrachloride-induced liver injury (Jeong et al 2002).

Several mechanisms appear to be responsible for the hepatoprotective effect. Glycyrrhizic acid enhances the detoxifying activity of the liver enzyme CYP1A1 and glutathione S-transferase and protects against oxidative stress, when induced by aflatoxin (Chan et al 2003).

Animal studies have found that GA inhibits expression of the liver enzyme CYP2E1. Once again, antioxidant mechanisms appear to be involved, as GA prevented glutathione depletion, an increase in ALT, AST activity, and hepatic lipid

peroxidation in a dose-dependent manner when carbon tetrachloride exposure occurred (Jeong et al 2002). In addition, isoliquiritigenin may stimulate the proliferation of human hepatocytes according to in vitro studies (De Bartolo et al 2005).

Antiplatelet effect

Isoliquiritigenin purified from licorice has been shown to inhibit platelet aggregation in vitro and in vivo (Francischetti et al 1997, Kimura et al 1993, Tawata et al 1992). Whether the effect is clinically significant for licorice remains to be determined. Newer data indicate that GL is an effective thrombin inhibitor in vivo (Mendes–Silva et al 2003).

OTHER ACTIONS

Sex hormones

Testosterone

Whether licorice consumption affects testosterone levels is still unknown, as conflicting results have been obtained from clinical studies. Armanini et al have conducted a series of trials investigating the effects of licorice on testosterone levels in males with mixed results (Armanini et al 1999, 2003a).

One study showed that licorice (7 g/day equivalent to 0.5 g GA) was able to reversibly reduce testosterone levels within 7 days, by inhibiting 17,20-lyase (involved in the conversion of 17-hydroxyprogesterone to androstenedione) and 17-beta-hydroxysteroid dehydrogenase (involved in the conversion of androstenedione to testosterone) (Armanini et al 1999). Another study twice attempted to replicate these results, but was unable to detect an effect on testosterone levels in either study; the authors suggest that inappropriate use of statistical tests in the first study may explain the varying results (Josephs et al 2001).

More clinically promising are the results from a small trial of nine healthy women (22–26 years) in the luteal phase of their menstrual cycle. The women received 3.5 g licorice (containing 7.6% w/w of GL) daily for two cycles. Total serum testosterone decreased from 27.8 (±8.2) to 19.0 (±9.4) ng/dL in the first month and to 17 (±6.4) ng/dL in the second month of therapy (Armanini et al 2004). Further larger scale trials are required to confirm these effects in women with conditions of elevated testosterone such as hirsutism and polycystic ovary syndrome (PCOS).

Oestrogen

Licorice contains isoflavones, including licochalcone A, which are also known as 'phyto-oestrogens' because they act as partial oestrogen agonists in the body (Setchell & Cassidy 1999). Additionally, in vitro studies suggest that stimulation of aromatase activity promotes oestradiol synthesis (Takeuchi et al 1991).

Liquiritigenin and isoliquiritigenin have displayed oestrogenic affinity to sex hormone-binding globulin and oestrogen receptors in vitro (Hillerns et al 2005) and glabridin and glabrene have both demonstrated oestrogen-like activities similar to oestradiol-17(beta) in animal studies (Somjen et al 2004a).

In vitro studies also suggest the potential for glabridin to enhance osteoblast function (Choi 2005). As a result glabridin has been proposed as a possible therapeutic aid in the prevention of osteoporosis and inflammatory bone diseases (Choi 2005), as well as cardiovascular diseases and bone disorders, in postmenopausal women (Somjen et al 2004a, 2004b).

Immunomodulation

Although immunostimulating effects have been observed in experimental models (Lin et al 1996), elevated cortisol levels, which are also induced by licorice, may theoretically reduce this effect (Padgett & Glaser 2003).

Inhibition of aldolase reductase

In vitro studies show that licorice may suppress sorbitol accumulation in red blood cells by inhibiting aldolase reductase (Zhou & Zhang 1990). The isoliquiritigenin component appears to be responsible (Aida et al 1990a). This may have positive implications in diabetes.

CLINICAL USE

Peptic ulcer and dyspepsia

The anti-inflammatory, mucoprotective and anti-ulcer activities of licorice make it an attractive treatment for peptic ulcer. While these effects have been attributed to the GL and GA constituents, the DGL, which contains < 3% GL, has also been investigated and appears to produce the most promising results when used long term (Bardhan et al 1978, Larkworthy & Holgate 1975). DGL also promotes differentiation of undifferentiated cells to mucous cells and stimulates mucus production and secretion (van Marle et al 1981).

In an uncontrolled trial of 32 patients with chronic duodenal ulcer, 3800 mg/day of DGL (in five divided doses) produced signs of healing in all cases and total restoration of mucosa in a majority of subjects. Although treatment continued for 24 weeks, considerable improvement was seen in 56% of patients by week 12 and in 78% by week 16 (Larkworthy & Holgate 1975). A shorter 4-week trial of 96 patients with gastric ulcer failed to produce the same positive results (Bardhan et al 1978).

DGL plus antacid (Caved-S; two tablets chewed three times daily between meals) was as effective as cimetidine (200 mg three times daily plus 400 mg at night) after 6 weeks, according to one randomised single-blind trial of 100 volunteers with peptic ulcer. The two treatments continued to produce similar results after 12 weeks and recurrence rates after both medications were reduced were also similar (Morgan et al 1982).

Commission E approves the use of licorice for the treatment of gastric and duodenal ulcers (Blumenthal et al 2000).

Dermatitis

The anti-inflammatory effect induced by GA provides a theoretical basis for its use as a topical anti-inflammatory agent (much like hydrocortisone) in the treatment of dermatitis.

In practice, GA has been used to potentiate the effects of weak steroids (such as hydrocortisone) in order to increase pharmacological effects without the need for stronger corticosteroids (Teelucksingh et al 1990). It is assumed that increasing corticosteroid activity in this way will not attract an increase in adverse effects; however, no studies have yet confirmed this.

An early study comparing the effects of hydrocortisone- and GA-containing ointments in dermatitis found that hydrocortisone was usually superior in acute and infantile eczemas, whereas GA was superior for chronic and subacute conditions (Evans 1958).

It should be noted that GA is many times more powerful inhibitor of 11HSD than GL and therefore should theoretically induce far stronger anti-inflammatory effects. GA is not present in licorice but is produced in the gastrointestinal tract from GL; therefore, it is uncertain whether topical preparations containing pure licorice are likely to produce significant anti-inflammatory effects.

Allergic conditions

The anti-allergic effects of licorice (Ram et al 2006, Shin et al 2007) provide a theoretical basis for the treatment of allergic conditions such as asthma and dermatitis; however, further research is required.

Viral infections

In human trials, GL and its derivatives reduce the liver sequelae associated with hepatitis B and C viruses; animal studies demonstrate a reduction in viral activity for herpes simplex virus, encephalitis and influenza A virus pneumonia; and in vitro studies reveal antiviral activity against HIV-1, SARS related coronavirus, respiratory syncytial virus, arboviruses, vaccinia virus and vesicular stomatitis virus (Fiore et al 2008). However, until controlled studies are available, the clinical effectiveness of this treatment remains unknown.

Respiratory tract infections

Licorice increases mucus production within the respiratory tract and exerts an expectorant (Bradley 1992) and antitussive effect (Kamei et al 2005). When combined with its anti-inflammatory, antiviral and possible immune-enhancing effects, it is a popular treatment for upper and lower respiratory tract infections. In practice, it is often used to treat coughs (especially productive types) and bronchitis (Bradley 1992).

Commission E approves the use of licorice for catarrhs of the upper respiratory tract (Blumenthal et al 2000).

Chronic stress

Traditionally, licorice is viewed as an 'adrenal tonic', most likely due to its ability to slow cortisol breakdown. It may be of benefit in patients experiencing allostatic load due to chronic stress and who are therefore unable to mount a healthy stress response. This is also known as adrenocorticoid insufficiency. Controlled trials are not available to determine its effectiveness in this situation.

Whether this effect is desirable in patients without adrenocorticoid insufficiency and for whom increased cortisol levels may prove problematic is open to conjecture. Chronically high cortisol levels have been associated with desensitisation of the hypothalamic-pituitary-adrenal (HPA) axis, insulin resistance, depression and immunosuppression (Blackburn-Munroe 2001, Jessop 1999, Mitchell & Mitchell 2003). In the initial stages of stress, increased cortisol levels trigger negative feedback mechanisms to keep stress under control and, therefore, short-term use may be warranted but is unlikely to be beneficial unless some adrenocorticoid insufficiency exists.

(For more information see 'Clinical note — Allostasis' in the Siberian ginseng monograph.)

OTHER USES

Licorice has also been used traditionally as a sweetener and aromatic flavouring agent.

Although controlled trials are lacking, licorice is also used for a number of other conditions, largely based on evidence of pharmacological activity.

Chronic fatigue syndrome

The ability of licorice to slow cortisol catabolism may provide a theoretical basis for its use in cases of chronic fatigue syndrome (CFS) accompanied by low cortisol levels. A case report exists of a patient experiencing improved physical and mental stamina and recovery from CFS following use of licorice dissolved in milk (2.5 g/500 mL/day) (Baschetti 1995, 1996).

Polycystic ovary disease

The possibility that licorice may lower testosterone levels in women provides a theoretical basis for its use in PCOS (Armanini et al 2004). While trials using licorice as a stand-alone treatment are lacking, studies of licorice in combination with other herbal medicines such as peony have produced promising results, showing reductions in LH:FSH ratio, ovarian testosterone production and improvements in ovulation (Takahashi & Kitao 1994, Takahashi et al 1988).

Preventing diabetic complications

In diabetic patients with neuropathy, retinopathy or nephropathy, sorbitol:glucose ratios are significantly higher than in those without these complications and ratios increase as complications become more severe (Aida et al 1990b). As licorice and its component isoliquiritigenin have been shown to inhibit aldolase reductase and suppress sorbitol accumulation in red blood cells in vitro (Aida et al 1990b, Zhou & Zhang 1990), a theoretical basis exists for its use in the prevention of diabetic complications.

Menopause

Inhibition of serotonin reuptake and possible oestrogenic activity provide a theoretical basis for its use in pre- and postmenopausal women with mild to moderate depression (Ofir et al 2003, Takeuchi et al 1991).

Constituents in licorice may bind to oestrogen receptors, enhance osteoblast function and attenuate vascular injury and atherosclerosis (Choi 2005; Somjen et al 2004a, 2004b) suggesting a possible role in the prevention of bone disorders and cardiovascular diseases in postmenopausal women.

Weight loss

The action of GA in blocking 11HSD type 1 at the level of fat cells may help to explain preliminary evidence suggesting an ability to reduce body fat mass and the thickness of thigh fat (Armanini et al 2003b, 2005).

Addison's disease

The ability of licorice to reduce cortisol breakdown provides a theoretical basis for its use in Addison's disease, either as a stand-alone treatment, when adrenocortical function is not severely impaired, or as an adjunct to cortisone therapy. While studies in the 1950s confirm this use (Borst et al 1953, Calvert 1954, Pelser et al 1953), recent studies are not available. A case report exists of an 11-year-old boy with hypoparathyroidism and Addison's disease developing hypermineralocorticoidism following excessive intake of licorice (300–400 g/day, equivalent to 600–800 mg GL) concurrently with hydrocortisone and 9-alpha-fluorocortisol. Pseudohyperaldosteronism persisted after treatment with 9-alpha-fluorocortisol was withdrawn and hydrocortisone was reduced; however, symptoms only diminished after the complete withdrawal of licorice. It was suggested that inhibition of 11HSD by licorice was responsible due to increased levels of free cortisol (Doeker & Andler 1999).

Hypercholesterolaemia

Preliminary studies in rats suggest a possible role for licorice root powder in the treatment of hypercholesterolaemia; however, clinical trials in humans need to be conducted to investigate this effect (Visavadiya & Narasimhacharya 2006).

Depression

Licorice extract (150 mg/kg) appears to exert a monoamine oxidase inhibiting effect in rats, increasing brain noradrenaline and dopamine, and resulting in an antidepressant effect comparable to that of imipramine (15 mg/kg i.p.) and fluoxetine (20 mg/kg i.p.) (Dhingra & Sharma 2006). Further studies are required to elucidate these effects in humans.

DOSAGE RANGE

- Fluid extract (1:1): 2–4 mL three times daily or 15–40 mL/week (Australian manufacturer recommendations).
- Root: 5–15 g/day (equivalent to 200–600 mg of GL).
- Tea: pour 150 mL boiling water over one teaspoon (2–4 g) licorice root, simmer for 5 minutes and filter through a tea strainer after cooling.
- Chronic gastritis: one cup of licorice tea after each meal.

According to clinical studies

- Chronic duodenal ulcers: 3800 mg/day of DGL (in five divided doses) before meals and at bedtime.
- Ideally, licorice extracts should contain > 30 mg/mL GL.

ADVERSE REACTIONS

Many of the adverse effects attributed to licorice are due to GA at doses above 100–400 mg/day. For this reason, the DGL may be safer and more appropriate in cases where GL or GA is not required for efficacy.

Side effects may be more pronounced in people with essential hypertension who appear to be more sensitive to the inhibition of 11HSD by licorice than normotensive subjects (Sigurjonsdottir et al 2003).

- Hypercortisolism and pseudohyperaldosteronism — associated with sodium retention, potassium loss and suppression of the renin–angiotensin–aldosterone system and presenting as hypertension, fluid retention, breathlessness, hypernatraemia and hypokalaemia (Bernardi et al 1994, Blachley & Knochel 1980, Dellow et al 1999, Kageyama et al 1997, Wash & Bernard 1975).
- Hypokalaemia — may present as hypotonia and flaccid paralysis, peripheral oedema, polyuria, proximal myopathy, lethargy, paraesthesiae, muscle cramps, headaches, tetany, breathlessness and hypertension (deKlerk et al 1997, Eriksson et al 1999). In practice, licorice is often mixed with the potassium-rich herb dandelion leaf, which also has mild diuretic effects.
- Hypokalaemic paralysis — although rare, some cases have been reported as a result of chronic licorice use (Corsi et al 1983, Lin et al 2003, Shintani et al 1992, van-den-Bosch et al 2005). A case report of a young female presenting with acute onset quadriparesis secondary to severe hypokalaemia has been attributed to a polyherbal preparation containing licorice (Mukherjee et al 2006).
- Rhabdomyolysis — a number of cases are reported in the scientific literature (Firenzuoli & Gori 2002, van-den-Bosch et al 2005) as a result of severe hypokalaemia.
- Dropped head syndrome — a case report exists of dropped head syndrome (isolated weakness of the extensor muscles of the neck) due to licorice-induced hypokalaemia (Yoshida & Takayama 2003).
- Hypertension encephalopathy may occur even at low doses in susceptible patients with 11-beta-HSD deficiency (Russo et al 2000).
- Reduced 11-beta-HSD activity may have a role in increased sodium retention in pre-eclampsia, renal disease and liver cirrhosis. Reduced placental levels may explain the link between reduced birth weight and adult hypertension (the Barker hypothesis) (Quinkler & Stewart 2003).
- Juvenile hypertension — inhibition of 11HSD may also contribute to a rare form of juvenile hypertension (Chamberlain & Abolnik 1997, White et al 1997).
- Visual disturbance — ingestion of high doses of licorice (110–900 g) has been reported to elicit symptoms of visual disturbance in a case series of

five patients. This may be attributed to the possible ability of licorice to 'stimulate retinal and occipital vasospasm and vasospasm of vessels supplying the optic nerve' (Dobbins & Saul 2000).

SIGNIFICANT INTERACTIONS

Controlled trials exist that have identified drug interactions. However, in most cases, the interactions are based on evidence of pharmacological activity, case reports or theoretical reasoning. The DGL form is considered safer and less likely to result in drug interactions.

Glabridin is a substrate of P-glycoprotein (P-gp/MDR1) (Cao et al 2007); therefore, potential drug–glabridin interactions need to be considered until more clinical data are available (Yu et al 2007).

Acetylsalicylic acid and other gastro-irritant anti-inflammatory drugs

Co-administration with licorice may reduce gastro-irritant effects induced by drug therapy — potentially beneficial interaction. 1993, Tawata et al 1992). Whether the effect is clinically significant for licorice remains to be determined — use high doses with caution.

Antihypertensives

High-dose GL taken long term can lead to increased blood pressure, thereby reducing drug efficacy. Caution — monitor blood pressure when high-dose licorice preparations are taken for longer than 2 weeks.

Chemotherapy (paclitaxel and vinblastine)

A constituent of licorice has demonstrated significant potentiation of paclitaxel and vinblastine chemotherapy in vitro (Rafi et al 2000). Observe.

Cimetidine and other H2 antagonists

Adjunctive licorice treatment may enhance ulcer-healing drug effects — potentially beneficial interaction.

Corticosteroids

Concurrent use of licorice preparations potentiates the effects of topical and oral corticosteroids (e.g. prednisolone). Some practitioners employ licorice to minimise requirements for or aid in withdrawal from corticosteroid medications. Beneficial interaction is possible under professional supervision, but patients may require a reduction in corticosteroid dosage to avoid corticosteroid excess (Chen et al 1991, Homma et al 1994).

Diclofenac sodium (NSAID)

In vitro studies have shown that the addition of GL enhanced the topical absorption of diclofenac sodium (Nokhodchi et al 2002), which may be a beneficial interaction.

Digoxin

Hypokalaemia increases sensitivity to cardiac glycoside drugs, therefore increased digoxin toxicity is possible when licorice is used in high doses for more than 2 weeks. A case report exists of congestive heart failure caused by digitalis toxicity in an elderly man taking a licorice-containing Chinese herbal laxative (Harada et al 2002). Avoid long-term use of high-dose licorice preparations and digoxin concurrently.

Diuretics (including loop, thiazide and potassium-depleting)

Case reports exist in which patients experience hypokalaemia and hypertension with concomitant use of licorice and diuretics (deKlerk et al 1997, Farese et al 1991, Folkerson et al 1996) due to increased potassium excretion. Avoid long-term use of licorice and diuretics concurrently unless under professional supervision — monitor potassium levels.

Oral contraceptive pill

An increased risk of side effects such as hypokalaemia, fluid retention and elevated blood pressure due to increased mineralocorticoid effect exists. This has been demonstrated in case reports (Bernardi et al 1994, deKlerk et al 1997). Use this combination with caution when licorice is used in high dose or for more than 2 weeks and observe patients closely.

Potassium

Licorice may reduce the effect of potassium supplementation. A case report exists of a 69-year-old female developing hypokalaemia while taking potassium supplements and a mouth freshener containing licorice concurrently. The daily intake of GA was estimated at 6–10 mg/day (Kageyama et al 1997). In many cases potassium supplementation may be beneficial in reducing the hypokalaemic side effects of licorice.

Testosterone

Licorice may decrease testosterone levels, although clinical tests have produced conflicting results (Armanini et al 1999, 2003a, 2004, Sakamoto & Wakabayashi 1988, Takeuchi et al 1991) — observe and monitor patients for reduced testosterone effects.

Drugs metabolised by liver enzymes CYP3A4, 2B6, 2C9, 2E1 or 1A1

Licorice inhibits CYP3A4 in vitro (Budzinski et al 2000), the glabridin constituent inhibits CYP2B6, 2C9 and 3A4 in vitro (Kent et al 2002), GA inhibits its expression of CYP2E1 in animal studies (Jeong et al 2002) and GL enhances the detoxifying activity of CYP1A1 (Chan et al 2003). Until testing in humans can establish whether the effects are clinically significant and relevant to licorice in therapeutic doses, caution is advised if licorice is administered with drugs chiefly metabolised by these enzymes. (See chapter on Interactions for more information.)

CONTRAINDICATIONS AND PRECAUTIONS

Licorice should be used with caution in people with hypertension (or a genetic predisposition to hypertension) or fluid retention, and is contraindicated

in hypotonia, severe renal insufficiency, hypokalaemia, liver cirrhosis and cholestatic liver disease (Blumenthal et al 2000). The effects are likely to be dose dependent and more likely in people with essential hypertension with a particular tendency to 11HSD inhibition by licorice (Sigurjonsdottir et al 2001, 2003). It is also contraindicated in people with a deficiency in 11HSD (Russo et al 2000).

Long-term use (> 2 weeks) at therapeutic doses should be monitored closely due to the potential side effects. Additionally, a high-potassium low-sodium diet should be consumed during treatment (Bradley 1992, McGuffin et al 1997).

As licorice may questionably reduce testosterone levels in men, it should be used with caution in men with a history of impotence, infertility or decreased libido (Armanini et al 1999, Zava et al 1998).

PREGNANCY USE

Licorice is contraindicated in pregnancy. A Finnish trial found that high consumption of licorice during pregnancy increased the likelihood of early delivery but did not significantly affect birth weight or maternal blood pressure (Strandberg et al 2001).

PRACTICE POINTS/PATIENT COUNSELLING

- Licorice has been used as a food, flavouring agent and medicine since ancient times.
- It exhibits mineralocorticoid, anti-inflammatory, antioxidant, mucoprotective and ulcer-healing activity in humans. Antiviral, antibacterial, antitumour, expectorant and hepatoprotective effects have also been demonstrated in animal or test tube studies. Significant effects on oestrogen and testosterone levels remain to be established in controlled trials as evidence is inconsistent.
- Licorice is a popular treatment for respiratory tract infections, gastrointestinal ulcers and dyspepsia. It is also used to treat chronic stress and numerous other conditions, largely based on evidence of pharmacological activity.
- GA has been used topically as an anti-inflammatory agent and also together with cortisone preparations to increase effects.
- High-dose licorice (> 100 mg GL) used for more than 2 weeks can induce hypokalaemia and pseudoaldosteronism in susceptible individuals. As such, it should be used with caution and under professional supervision. Additionally, it interacts with numerous medicines. The DGL form is considered safer.

PATIENTS' FAQs

What will this herb do for me?

Licorice has many effects in the body, the most well-established ones being reducing inflammation, enhancing healing of peptic ulcers and treating infections such as bronchitis and cough.

When will it start to work?

Beneficial effects in peptic ulcer occur within 6–12 weeks, although DGL is usually used to avoid side effects. Symptoms of dyspepsia should respond within the first few doses. Effects in bronchitis will vary between individuals.

Are there any safety issues?

Used in high doses for more than 2 weeks, licorice can induce several side effects such as raised blood pressure and fluid retention and may interact with a number of drugs. The DGL form is considered safer.

Lutein and zeaxanthin

BACKGROUND AND RELEVANT PHARMACOKINETICS

Lutein and its isomer, zeaxanthin, are yellow-coloured, xanthophyll carotenoids that are not converted into vitamin A. The bioavailability of lutein and zeaxanthin from food sources is influenced by the food matrix and by the type and extent of food processing, but most notably by the presence of fat in the diet (Castenmiller et al 1999), with dietary fat intake being inversely related to serum levels (Nolan et al 2004). Cooking may increase their bioavailability by disrupting the cellular matrix and protein complexes, and supplemental sources may be significantly more bioavailable than food sources (Castenmiller et al 1999). It has also been observed that plasma responses to cholesterol and carotenoids are related (Clark et al 2006) and that the bioavailability of zeaxanthin from freeze-dried wolfberries is enhanced 3-fold when consumed in hot skimmed milk compared to hot water or warm milk (Benzie et al 2006). One clinical study found that plasma lutein was higher when lutein was consumed with a high-fat spread (207% increase) than with a low-fat spread (88% increase) (Roodenburg et al 2000). This was supported by a small in vitro study showing that dietary lutein is absorbed more efficiently with 24 g of avocado oil or 150 g of avocado fruit (Unlu et al 2005). For each 10% increase in dietary lutein and zeaxanthin, serum levels are seen to increase by 1% (Gruber et al 2004).

When ingested, lutein and zeaxanthin are transported from the intestine to the liver via chylomicrons. They are then transported via LDL and HDL to various parts of the body (Yeum & Russell 2002). Lutein and zeaxanthin are present in the eye, blood serum, skin, cervix, brain, breast and adipose tissue. In the eye, lutein is more prominent at the edges of the retina and in the rods (Bernstein 2001, Bone et al 1997). Lutein appears to undergo some metabolism in the retina to *meso*-zeaxanthin. Zeaxanthin is primarily concentrated in the centre of the retina and the cones, where it is present in concentrations nearly 1000-fold of those found in other tissues, thus giving the macula lutea or yellow spot of the retina its characteristic colour (Krinsky et al 2003). It is suggested, however, that during supplementation with xanthophylls, lutein is predominantly deposited in the fovea, while zeaxanthin deposition appears to cover a wider retinal area (Schalch et al 2007).

Lower serum concentrations of zeaxanthin have been associated with male gender, smoking, younger age, lower non-HDL cholesterol, greater ethanol consumption and higher body mass index (BMI) (Brady et al 1996). Lutein and zeaxanthin, together with other carotenoids, have also been found to be lower in people with chronic cholestatic liver disease, which can be attributed to malabsorption of fat-soluble vitamins, as well as other mechanisms of hepatic release (Floreani et al 2000). In an epidemiological study involving 7059 participants, lower serum lutein and zeaxanthin levels were significantly associated with smoking, heavy drinking, being white, female, or not being physically active, having lower dietary lutein and zeaxanthin, a higher percentage of fat mass, a higher waist–hip ratio, lower serum cholesterol, a higher white blood cell count and high levels of C-reactive protein (Gruber et al 2004).

In a pharmacokinetic study involving 20 healthy volunteers, serum zeaxanthin levels were found to have an effective half-life for accumulation of 5 days and a terminal elimination half-life of around 12 days (Hartmann et al 2004). This was confirmed

by another study that also found that lutein did not affect the concentrations of other carotenoids in healthy volunteers (Thurmann et al 2005). Similarly, high doses (50 mg) of beta-carotene over 5 years were not found to influence serum levels of lutein and zeaxanthin (Mayne et al 1998). It has been suggested that the associations between macula pigment density and serum lutein, serum zeaxanthin and adipose lutein concentrations are stronger in men (Broekmans et al 2002, Johnson et al 2000) and that the processes governing accumulation and/or stabilisation of zeaxanthin in fat tissue are different for males and females (Nolan et al 2004). This is supported by the finding that serum lutein and zeaxanthin concentrations vary with the menstrual cycle, with levels being higher in the late follicular than in the luteal phase (Forman et al 1998).

CHEMICAL COMPONENTS

Lutein and zeaxanthin are isomers and have identical chemical formulas, differing only in the location of a double bond in one of the hydroxyl groups. Lutein is known as beta, epsilon-carotene-3,3′-diol, whereas zeaxanthin is known as all-*trans* beta-carotene-3,3′-diol.

FOOD SOURCES

Foods differ in their relative amounts of lutein and zeaxanthin, with lutein generally being more abundant. Lutein is found in dark green leafy vegetables such as spinach and kale, as well as in sweet corn and egg yolks, whereas zeaxanthin is found in sweet corn, egg yolk, orange peppers (capsicums), persimmons, tangerines, mandarins and oranges.

Lutein and zeaxanthin are primarily extracted from marigold flowers (*Tagetes erecta*) for use in supplements and are available in either free or esterified form. The esters typically contain two fatty acid groups that must be cleaved by pancreatic esterases and their absorption requires higher levels of dietary fat (Roodenburg et al 2000); however, addition of omega-long-chain polyunsaturated fatty acids to oral supplementation of lutein/zeaxanthin has not been found to change serum levels of lutein and zeaxanthin (Huang et al 2008).

DEFICIENCY SIGNS AND SYMPTOMS

It has been suggested that zeaxanthin and lutein be considered conditionally essential nutrients because low serum levels or low dietary intakes are associated with low macular pigment density (Mares et al 2006) and increased risk of age-related macular degeneration (ARMD) (Semba & Dagnelie 2003).

Epidemiological studies have also found an association between low serum carotenoid levels, including lutein and zeaxanthin levels, with all-cause mortality (De Waart et al 2001), the risk of inflammatory polyarthritis (Pattison et al 2005), breast cancer (Tamimi et al 2005), prostate cancer (Jian et al 2005), colon cancer (Nkondjock & Ghadirian 2004), cervical cancer (Garcia-Closas et al 2005, Kim et al 2004), human papilloma virus persistence (Garcia-Closas et al 2005), type 2 diabetes and impaired glucose metabolism (Coyne et al 2005), chronic cholestatic liver diseases (Floreani et al 2000), Alzheimer's disease and vascular dementia (Polidori et al 2004), and low fruit and vegetable consumption (Al-Delaimy et al 2005).

Carotenoids have also emerged as an excellent tissue marker for a diet rich in fruits and vegetables, and measurement of plasma and tissue carotenoids is considered to have an important role in defining optimal diets (Al-Delaimy et al 2005, Brevik et al 2004, Handelman 2001).

MAIN ACTIONS

Antioxidant

Lutein and zeaxanthin are both powerful antioxidants, with activity having been demonstrated in a number of in vitro and in vivo tests (Higashi-Okai et al 2001, Iannone et al 1998, Naguib 2000, Muriach et al 2008). In vitro studies of human lens epithelial cells also indicate that their antioxidant activity may protect the lens from UVB radiation (Chitchumroonchokchai et al 2004). According to animal studies, lutein increases glutathione levels and reduces retinal apoptosis following ischaemic reperfusion (Dilsiz et al 2005).

Blue light filter

The yellow colour of lutein and zeaxanthin is due to their ability to absorb blue light, which is believed to contribute to their protective function because blue light is at the high energy, and therefore the most damaging, end of the visible spectrum (Krinsky et al 2003). Lutein and zeaxanthin thus serve as 'natural sunglasses' (Rehak et al 2008) that act as an optical filter for blue light, reducing chromatic aberration and preventing damage to the photoreceptor cell layer (Krinsky et al 2003).

Macular pigment development

Lutein and zeaxanthin are entirely of dietary origin and are initially absent in newborns but gradually accumulate over time (Nussbaum et al 1981). It has been generally accepted that macular pigment density decreases with age; however, there are conflicting results. In one prospective, observational study involving 390 patients, macular pigment density was not found to change significantly with age, even when elderly subjects with cataracts and ARMD were considered (Ciulla & Hammond 2004). Other studies, however, have found that macular pigment does indeed decline with age in both normal eyes (Beatty et al 2001, Bernstein et al 2002) and those with ARMD (Bernstein et al 2002) and Stargardt macular dystrophy (Zhao et al 2003), but not in retinitis pigmentosa or choroideremia (Zhao et al 2003).

Although lutein and zeaxanthin levels in the serum, diet and retina correlate, the nature of the relationships between lutein and zeaxanthin in foodstuffs, blood and the macula are confounded by many variables, including processes that influence digestion, absorption and transport and accumulation and stabilisation of the carotenoids in the tissues (Beatty et al 2004). It is suggested, however, that lutein and zeaxanthin are transported into an individual's retina in the same proportions found in his or her blood (Bone et al 1997). Two clinical

studies have demonstrated that increasing lutein intake will increase macular pigment density within 4 weeks (Berendschot et al 2000, Hammond et al 1997). Clinical studies have confirmed the association between macular pigmentation, dietary lutein intake and serum lutein levels (Burke et al 2005, Mares et al 2006). However, in small clinical trials, lutein supplementation did not produce improvement in visual function in people with healthy eyes (Bartlett & Eperjesi 2008, Rosenthal et al 2006) or improvement in contrast sensitivity in people with ARMD (Bartlett & Eperjesi 2007). In another trial, however, lutein supplementation was seen to improve visual performance at low illumination, yet this was not correlated with macular pigment density (Kvansakul et al 2006).

Immunomodulation

Lutein modulates cellular and humoral-mediated immune responses, according to animal studies (Kim et al 2000a, 2000b). In particular, high levels of C-reactive protein and a high white blood cell count have been identified in individuals with low serum levels of lutein (Gruber et al 2004). In a case-controlled study, serum lutein and zeaxanthin, together with other carotenoids, were also found to be lower in children with acute phase infections compared to healthy controls (Cser et al 2004).

Photoprotection

According to animal studies, lutein reduces the risk of sunburn, as well as the local UVB radiation-induced immune suppression and reactive oxygen species generation (Lee et al 2004), as well as directly protecting against photoageing and photocarcinogenesis (Astner et al 2007). A protective effect on skin cancer, however, has not been observed in human cohort studies. One prospective cohort study involving 43,867 men and 85,944 women found no significant inverse association between intake of lutein and squamous cell carcinoma (Fung et al 2003), while an increased risk of squamous cell carcinoma was observed for people with multiple prior non-melanoma skin cancers and high serum levels of lutein and zeaxanthin (Dorgan et al 2004).

While a protective effect against skin cancer is uncertain, there is evidence to suggest that supplementation with lutein and zeaxanthin may improve general skin health and simultaneously help to minimise signs of premature ageing (Maci 2007). A double-blind, placebo-controlled study that examined surface lipids, hydration, photoprotective activity, skin elasticity and skin lipid peroxidation found that oral and/or topical administration of either lutein or zeaxanthin provided antioxidant protection with the greatest protection being seen with combined administration of lutein and zeaxanthin (Palombo et al 2007). The clinical significance of these findings is uncertain.

CLINICAL USE

Age-related macular degeneration

The evidence that lifetime oxidative stress plays an important role in the development of ARMD is now compelling (Hogg & Chakravarthy 2004). ARMD is thought to be the result of free radical damage to photoreceptors within the macula, and therefore it is suspected that inefficient macular antioxidant systems play a role in disease development. Low levels of lutein and zeaxanthin in the diet, serum or retina, as well as excessive exposure to blue light and cigarette smoking, are therefore considered to increase the risk of ARMD (Bone et al 2003); however, an 18-year prospective follow-up study of 71,494 women and 41,564 men aged >50 years found that lutein/zeaxanthin intake as assessed by a semiquantitative food-frequency questionnaire was not associated with the risk of self-reported early ARMD (Cho et al 2008). Interestingly, two case-controlled studies have found that lycopene, rather than lutein or zeaxanthin, was reduced in the serum of ARMD patients (Cardinault et al 2005, Mares-Perlman et al 1995). It was suggested that this result could be due to antioxidant protection of lutein and zeaxanthin by lycopene or different dietary habits.

Epidemiological and autopsy studies have found an inverse relationship between lutein and zeaxanthin intake and macular pigment density (Bone et al 2001, Curran-Celentano et al 2001). The presence of unusually high levels of macular carotenoids in older donors who were regularly consuming high-dose lutein supplements further supports the hypothesis that long-term lutein supplementation can raise levels of macular pigment (Bhosale et al 2007).

Plasma lutein and macular pigment density have been demonstrated to increase with lutein supplementation in ARMD patients (Bernstein et al 2002, Wang et al 2007) and healthy controls (Koh et al 2004), suggesting that a diseased macula can accumulate and stabilise lutein and/or zeaxanthin (Koh et al 2004) and that ARMD is not associated with intestinal malabsorption of carotenoids. This has led to the suggestion that abnormalities in the metabolism of lutein and zeaxanthin in ARMD may reside in the uptake of lutein and zeaxanthin from the plasma and transport into the retina (Wang et al 2007). This is supported by a lutein and zeaxanthin supplementation study that found that macular pigment density did not increase in many subjects despite rises in serum concentrations (Trieschmann et al 2007).

While conclusive evidence as to whether increased intake of lutein or zeaxanthin will reduce the incidence of ARMD is still unavailable (Berendschot et al 2002, Broekmans et al 2002, Hammond et al 1997), recent studies have produced encouraging results for people with preexisting ARMD. Improvements of up to 92% in visual acuity tests were observed when subjects consumed a diet designed to contain approximately 150 g of spinach 4–7 times a week (Richer 1999), and in 30 patients with early ARMD and visual acuity of 6/9 or better daily supplementation with lutein, vitamin E and nicotinamide for 180 days improved macular function (Falsini et al 2003).

The results from the Lutein Antioxidant Supplementation Trial provide further support for lutein supplementation in ARMD (Richer et al 2004). This was a double-blind, randomised, placebo-controlled study involving 90 subjects

Clinical note — Age-related macular degeneration (ARMD)

ARMD is the leading cause of blindness in people over 65 years of age (Pratt 1999). Its exact aetiology is unknown; however, several risk factors have been established such as lighter iris colour, positive family history, lifestyle factors (e.g. cigarette smoking), hypertension, female gender and low serum concentrations of carotenoids (Cardinault et al 2005). The disease causes a loss of central vision and can impair most activities essential for independent living, such as reading, driving and writing. The prevalence of ARMD and its social and economic consequences are increasing in line with the ageing population.

with atrophic ARMD who were given 10 mg lutein, 10 mg lutein plus broad-spectrum antioxidants/vitamins/minerals, or placebo for 1 year. At baseline and every 4 months during the study period, subjects were examined for changes in macular pigment density, photostress recovery, contrast sensitivity and visual acuity. Both the lutein and lutein plus antioxidant groups achieved an increase of 36% and 43%, respectively, in macular pigment density, whereas the placebo group experienced a slight decrease. Significant improvements in visual acuity, objective visual function parameters, photostress recovery and contrast sensitivity were also observed with lutein therapy (Richer et al 2004).

Cataracts

Lens density has been found to inversely correlate to macular lutein and zeaxanthin levels (Hammond et al 1997) and numerous observational studies have found that increased consumption of foods high in lutein and zeaxanthin is associated with a decreased risk for cataracts (Brown et al 1999, Tavani et al 1996, Delcourt et al 2006). In one study involving 77,466 female nurses from the Nurses' Health Study, those with the highest quintile for consumption of zeaxanthin and lutein were found to have a 22% reduction in the risk of cataract extraction (Chasan-Taber et al 1999). Similarly, a study of 1802 women aged 50–79 found that women in the highest quintile category of diet or serum levels of lutein and zeaxanthin were 32% less likely to have nuclear cataract as compared with those in the lowest quintile category (Moeller et al 2008). A further epidemiological study of 3271 Melbourne residents found that while cortical and posterior subcapsular cataracts were not significantly associated with lutein or zeaxanthin intake, high dietary lutein and zeaxanthin intake was inversely associated with the prevalence of nuclear cataract (Vu et al 2006). The link between lutein and cataracts is further supported by a small randomised, placebo-controlled trial of 17 patients with clinically diagnosed age-related cataracts that found that supplementation with lutein 15 mg three times weekly for up to 2 years resulted in improved visual performance (visual acuity and glare sensitivity) compared with placebo (Olmedilla et al 2003).

These results contrast with those from a cohort study of 478 women without previously diagnosed cataracts, which failed to detect a significant inverse relationship between lutein intake and lens opacities over a 13–15-year follow-up period (Jacques et al 2001).

Retinitis pigmentosa

In a double-masked, randomised, placebo-controlled crossover trial, supplementation with 10 mg/day for 12 weeks followed by 30 mg/day for 12 weeks was found to improve visual field and possibly visual acuity in 34 patients with retinitis pigmentosa (Bahrami et al 2006). A further study found that daily supplementation with 40 mg of lutein over 9 weeks followed by 20 mg for a further 16 weeks significantly improved visual acuity in 16 subjects with retinitis pigmentosa, many of whom were also taking other supplements (Dagnelie et al 2000).

Atherosclerosis

Oxidative modification of LDL in the vascular wall seems to be a key factor in atherosclerosis development and thus lipid-soluble antioxidants that can protect LDLs may have a role in atherosclerosis prevention (Cherubini et al 2005); however, the relationship between lutein and zeaxanthin status and atherosclerosis is unclear.

Plasma levels of lutein, beta-cryptoxanthin and zeaxanthin were correlated to carotid intima–media thickness in a 3-year case-controlled study of 231 subjects (Iribarren et al 1997), as well as in an 18-month epidemiological study of 573 subjects, suggesting that these carotenoids may be protective against early atherosclerosis (Dwyer et al 2004). Lutein intake has also been found inversely associated with the risk of ischaemic stroke in an observational study involving 43,738 males (Ascherio et al 1999), as well as being inversely associated with the risk of subarachnoid haemorrhage in a cohort study of 26,593 male smokers (Hirvonen et al 2000). Serum levels of lutein and zeaxanthin, however, were not associated with atherosclerosis risk in a case–control study involving 108 cases of aortic atherosclerosis in an elderly population (Klipstein-Grobusch et al 2000).

The foregoing findings contrast with those from two case-controlled studies that found a positive correlation between lutein and zeaxanthin levels and cardiovascular risk. A nested, case–control study of 499 cases of cardiovascular disease with matched controls taken from the Physicians' Health Study found that concentrations of plasma lutein, zeaxanthin and retinol corresponded to a moderate increase in cardiovascular disease (Sesso et al 2005). Similarly, myocardial infarction risk was positively associated with lutein and zeaxanthin levels in adipose tissue and the diet in a case-controlled study of 1456 cases of first acute myocardial infarction and matched controls (Kabagambe et al 2005). The clinical significance of these findings is unclear and requires further investigation.

Alzheimer's dementia

Dementia has been found to be associated with increased protein oxidative modification and the depletion of a large spectrum of antioxidant micronutrients, including lutein and zeaxanthin (Polidori et al 2004). A clinical study of 25 subjects with mild cognitive impairment, 63 subjects with AD and 56 healthy individuals found that serum lutein levels were lowest in the first two groups, particularly those with AD (Rinaldi et al 2003), while a double-blind trial of 49 women aged 60–80 years found improved cognitive function after supplementation with a combination of docosahexaenoic acid and lutein (Johnson et al 2008).

Cancer prevention

High dietary intake of lutein has been associated with reduced risk of some cancers, most notably endometrial and ovarian cancer, but not all cancers, according to epidemiological evidence (Freudenheim et al 1996, Fung et al 2003, Gann et al 1999, Giovannucci et al 1995, Huang et al 2003, Ito et al 2003, Lu et al 2001, McCann et al 2000, Michaud et al 2000, Nomura et al 1997, Schuurman et al 2002, Terry et al 2002).

Lung cancer

The link between carotenoid intake and lung cancer has undergone extensive scrutiny and extensive epidemiological evidence suggests a reduction in lung cancer risk with high dietary intake of carotenoids (Cooper et al 1999). Initial research used food composition tables and therefore focused on beta-carotene, for which data were available; however, the dietary intake of beta-carotene and other carotenoids such as lutein and zeaxanthin is highly correlated (Ascherio et al 1992) and as food composition data for these nutrients have become available, studies have suggested a link between dietary lutein intake and reduced lung cancer risk (Cooper et al 1999).

Three large population studies of diet and lung cancer have revealed a non-significant association between high lutein intake and lower risk of lung cancer (Ito et al 2003, Michaud et al 2000, Ziegler et al 1996), and a significant trend was observed in another population-based case–control study (Le Marchand et al 1993). A nested case–control study also found that serum lutein and zeaxanthin were lower in those with lung cancer than in controls (Comstock et al 1997). These results are contrasted with those from a case–control study of 108 cases of lung cancer in a Chinese occupational cohort that found that higher serum carotenoid levels, including lutein and zeaxanthin, were significantly associated with increased lung cancer risk among alcohol drinkers, while having a possible protective association among non-drinkers (Ratnasinghe et al 2000).

Cervical cancer

A recent systematic review suggests that lutein/zeaxanthin is likely to have a protective effect for cervical neoplasia and possibly for human papilloma virus persistence (Garcia-Closas et al 2005).

Endometrial cancer

An epidemiological study involving 232 patients with endometrial cancer and 639 controls found that an intake of more than 7.3 mg/day of lutein was associated with a 70% reduced risk of endometrial cancer (McCann et al 2000).

Ovarian cancer

A case–control study found that weekly intake of lutein of more than 24 mg was associated with a 40% reduction in the risk for developing ovarian cancer compared with weekly consumption of less than 3.8 microgram (Bertone et al 2001).

Breast cancer

High lutein and zeaxanthin intake has been related to reduced risk of breast cancer (Dorgan et al 1998, Toniolo et al 2001). High lutein intake (> 7 mg/day) was associated with a 53% reduction in the risk of developing breast cancer compared with low consumption (< 3.7 mg/day) in a population-based case–control study of 608 premenopausal women over age 40 (Freudenheim et al 1996). Similar risk reductions were found in a nested case–control study of 540 New York women (Toniolo et al 2001) and another nested case–control study of 969 cases of breast cancer and matched controls from the Nurses' Health Study found that the risk of breast cancer was 25–35% less for women with the highest quintile compared with that for women with the lowest quintile of lutein/zeaxanthin and total carotenoid intake (Tamimi et al 2005). Although this association is encouraging, another study of 4697 women followed over 25 years found no significant relationships between lutein intake and breast cancer risk (Jarvinen et al 1997).

Gastric cancer

High serum lutein levels have been associated with a higher incidence of gastric carcinoma, according to a cohort study of 29,584 patients with oesophageal and stomach cancer (Abnet et al 2003); however, this association requires further investigation.

Bowel cancer

The relationship between lutein and zeaxanthin intake and colon cancer is uncertain. A case–control study involving 1993 cases of colon cancer and 2410 controls found that lutein intake, as measured by a food-frequency score, was inversely associated with colon cancer and another case–control study of 223 subjects with histologically confirmed colon or rectal cancer identified a non-significant inverse association with lutein (Levi et al 2000). A cohort analysis of 5629 women, however, found no such association (Terry et al 2002). More recently, a case-controlled study found that women with high intakes of long-chain polyunsaturated fatty acids had an inverse association between lutein and zeaxanthin intake and the risk of colon cancer (Nkondjock & Ghadirian 2004). Further investigation is required to clarify these findings because animal studies suggest low doses of lutein inhibit aberrant crypt foci formation, whereas high doses may increase the risk by 9–59% (Raju et al 2005).

Prostate cancer
Overall, epidemiological evidence suggests that lutein and zeaxanthin intake has no influence over the risk of prostate cancer (Bosetti et al 2004, Gann et al 1999, Giovannucci et al 1995, Huang et al 2003, Lu et al 2001, Nomura et al 1997, Schuurman et al 2002). However, when lutein was included as part of a mixed carotenoid and tocopherol extract, the combination was effective in an in vitro study of prostate cancer cell lines (Lu et al 2005) and a case-controlled study of 130 patients with adenocarcinoma of the prostate found that prostate cancer risk was seen to decline with increasing consumption of carotenoids, including lycopene, alpha-carotene, beta-carotene, beta-cryptoxanthin, lutein and zeaxanthin (Jian et al 2005).

Laryngeal cancer
A case–control study involving 537 subjects identified an inverse relationship between dietary lutein and zeaxanthin intake, together with the intake of other carotenoids, and the risk of laryngeal cancer (Bidoli et al 2003).

OTHER USES
Lutein and zeaxanthin may be used as part of a general antioxidant supplement, often taken in conjunction with other carotenoids in cases where there is known or suspected increased oxidative load.

DOSAGE RANGE

According to clinical studies
- Macular protection: lutein 6–20 mg/day; zeaxanthin 2–5 mg/day.
- Cataracts — improving visual performance: lutein 15 mg three times weekly.

TOXICITY
There is strong evidence for the safety of lutein at intakes up to 20 mg/day, although much higher levels have been tested without adverse effects and may be safe (Shao & Hathcock 2006).

ADVERSE REACTIONS
Insufficient reliable information available.

SIGNIFICANT INTERACTIONS

Vitamin C
Lutein showed increased antioxidant efficacy with vitamin C in an animal study (Blakely et al 2003). Further to this, a small in vivo study showed 2000 mg of vitamin C enhanced the absorption of lutein (Tanumihardjo et al 2005).

Vitamin E
Vitamin E showed increased antioxidant efficacy with lutein according to an animal study (Blakely et al 2003).

Phytosterols
High dietary intake of phytosterol esters (6.6 g/day) reduced plasma levels of lutein by 14% in a small clinical trial; however, this was reversed by increasing fruit and vegetable intake (Clifton et al 2004).

Orlistat
Theoretically, long-term use of orlistat leads to reduced plasma levels of lutein due to reduced gastric absorption (Australian Medicines Handbook) — increased dietary intake of lutein should be considered.

Olestra
Lutein and zeaxanthin levels have been found to decrease with long-term use of olestra (Tulley et al 2005) — increased dietary intake of lutein should be considered.

CONTRAINDICATIONS AND PRECAUTIONS
Lutein and zeaxanthin are contraindicated in people with a hypersensitivity to these carotenoids or their food sources.

PREGNANCY USE
Eating dietary amounts of foods rich in lutein and zeaxanthin is likely to be safe. Women at risk of premature rupture of the membranes are cautioned against very high intake because one study observed a fourfold greater risk of membrane rupture with high serum lutein levels (Mathews & Neil 2005).

PATIENTS' FAQs
What will this supplement do for me?
Lutein and zeaxanthin are important for eye health and may also reduce the risk of developing endometrial and ovarian cancer over time.
When will it start to work?
Increased intake of lutein can improve macular health within 4 weeks; however, clinical effects

PRACTICE POINTS/PATIENT COUNSELLING
- Lutein and zeaxanthin are antioxidant carotenoids found in spinach, corn, egg yolk, squash and greens.
- Lutein and zeaxanthin are essential for the development of macular pigment, which protects photoreceptor cells in the retina from free radical damage.
- Epidemiological studies have generally found an inverse relationship between lutein and zeaxanthin intake and macular degeneration; however, conclusive evidence as to whether increased intakes will reduce the incidence of ARMD is still unavailable.
- One controlled study has found that long-term use of lutein supplements may increase visual performance in people with preexisting cataracts.
- High dietary intake of lutein has been associated with reduced risk of some cancers, most notably endometrial and ovarian cancer, but not all cancers, according to epidemiological evidence.
- Supplements containing lutein and zeaxanthin should be taken with food as dietary fat improves their absorption.

develop slowly and may not be detected for 6 months. In regard to improving visual performance in people with preexisting cataracts, effects take even longer (≈2 years).

Are there any safety issues?

Lutein and zeaxanthin are generally considered safe.

Lycopene

BACKGROUND AND RELEVANT PHARMACOKINETICS

Lycopene is a fat-soluble, non-provitamin A carotenoid that imparts the red colour to tomato, guava, rosehip, watermelon and pink grapefruit. Animals and humans do not synthesise lycopene, so they must depend on dietary sources. Research shows that bioavailability of lycopene varies depending on factors such as food source, other foods in the diet, the presence of other carotenoids and dietary fat, cooking temperatures and processing.

Processing, and heating in particular, has been found to significantly increase lycopene bioavailability, as it induces the isomerisation of lycopene from

the *trans*- to *cis*-configuration (Shi & Le Maguer 2000). In other words, lycopene is best absorbed from tomato products such as pastes and sauces, rather than from unprocessed fresh tomatoes.

Lycopene is widely distributed in the human body and is one of the major carotenoids found in human serum (between 21% and 43% of total carotenoids). High concentrations are found in the adrenal gland and testes, although significant amounts are also found in the liver, adipose tissue, prostate, kidney and ovaries (El Sohemy et al 2002, Gerster 1997, Johnson 1998, Stahl et al 1992). Lycopene has also been detected in high concentrations in ciliary body and retinal pigment epithelium (Khachik et al 2002).

CHEMICAL COMPONENTS

Lycopene is a 40-carbon acyclic carotene with 11 conjugated and 2 unconjugated double bonds, normally in the all-*trans*-configuration, but the double bonds are subject to isomerisation, and various *cis*-isomers (mainly 5, 9, 13 or 15) are found in plasma and plants (Holloway et al 2000). The *cis*-isomer has better bioavailability from foods.

FOOD SOURCES

The richest sources of lycopene are red tomatoes and processed tomato products. Other sources include watermelon, pink grapefruit and papaya. The lycopene content of food depends on the cultivars grown and the growing conditions.

It is currently estimated that daily intake from all dietary sources ranges between 0.5 and 27 mg/person/day or 0.08 and 0.45 mg/kg/day (Jonker et al 2003).

DEFICIENCY SIGNS AND SYMPTOMS

Although lycopene is not considered an essential nutrient, it is important for wellbeing and optimal health. As such, deficiency signs and symptoms are unknown.

MAIN ACTIONS

Antioxidant

The many conjugated double bonds of lycopene make it a powerful antioxidant (particularly against singlet oxygen and free radicals) and its activity in vitro is nearly twice as great as beta-carotene (Cantrell et al 2003, Shi & Le Maguer 2000, Tsen et al 2006).

Reduces LDL cholesterol levels and lipid oxidation

A significant 14% reduction in plasma LDL cholesterol concentrations has been shown for a dose of 60 mg/day lycopene taken over 3 months by healthy volunteers. While the mechanism of action is unclear, in vitro testing suggests 3-hydroxy-3-methylglutaryl-coenzyme A (HMG-CoA) reductase inhibition and enhancement of LDL receptor activity in macrophages (Fuhrman et al 1997). Lycopene also prevents oxidation of lipids and LDL cholesterol, according to a clinical study by Agarwal & Rao (1998). Lycopene may also reduce the formation of macrophage foam cells induced by modified LDL, via decreasing lipid synthesis and downregulating the activity and expression of scavenger receptor A, according to in vitro tests (Napolitano et al 2007).

Chemopreventative activity

Anticancer activity of lycopene has been demonstrated in cell and tissue culture studies and animal tumour models. These studies indicate that lycopene has multiple mechanisms of action, some of which remain to be fully elucidated. Lycopene appears to inhibit human cancer cell growth by interfering with growth factor receptor signalling and cell cycle progression (Fornelli et al 2007, Heber & Lu 2002, Stahl et al 2000). In vitro and in vivo evidence supports the theory that antiproliferative activity is achieved by upregulation of a gene, connexin 43, which restores direct intercellular gap junctional communication, usually deficient in many human tumours. This restoration of normal intercellular gap junctional communication is associated with decreased proliferation. Lycopene is also thought to inhibit proliferation of cancerous cells by arresting cell cycle progression, particularly at the G_1 phase, which is often up-regulated in cancer cells (Ivanov et al 2007, Nahum et al 2006, Park et al 2005). One possible mechanism for this is via the attenuation of cyclin Dl levels which acts as a growth factor sensor in G_1 phase and subsequently inhibit the action on insulin-like growth factor-1 (IGF-1)-induced cell cycle progression (Nahum et al 2006). Increased levels of IGF-1 production have been associated with an increased risk of cancer. Lycopene has been shown to decrease levels of IGF-1 (Liu et al 2008, Walfisch et al 2007), by affecting the IGF-binding proteins (IGFBPs) (Kanagaraj et al 2007, Vrieling et al 2007). However, other studies have reported that the IGFBPs made no difference to IGF-1 levels (Graydon et al 2007, Voskuil et al 2008). Investigation using animal models also suggests that lycopene may exert its chemopreventative effects by modulating lipid peroxidation and enhancing the activities of phase 2 enzymes, specifically those in the glutathione redox cycle (Bhuvaneswari et al 2001, Bhuvaneswari & Nagini 2005, Lian & Wang 2008, Velmurugan et al 2002). A cell culture study using endometrial, mammary and lung human cancer cells has identified that lycopene has stronger antiproliferative activity than alpha- and beta-carotenes (Levy et al 1995). Several in vitro studies have indicated that lycopene may have chemotherapeutic activity by promoting cancer cell apoptosis (Hantz et al 2005, Ivanov et al 2007, Kanagaraj et al 2007, Salman et al 2007). Another possible protective mechanism of lycopene is to promote methylation modulation of gene expression in several breast cancer cell lines (King-Batoon et al 2008). Lycopene may also have an anti-metastatic action in high doses (Hwang & Lee 2006, Huang et al 2007, 2008), but not at physiological doses (Burgess et al 2008).

Of special significance in prostate cancer prevention is the finding that lycopene interferes with local testosterone activation by reducing the expression of 5-alpha-reductase I in prostate tumours in a rat model (Siler et al 2004). As a consequence,

several androgen target genes in the tumours were drastically downregulated.

OTHER ACTIONS

The Antioxidant Supplementation in the Atherosclerosis Prevention (ASAP) study showed that low plasma levels of lycopene were associated with an 18% increase in intima–media thickness (IMT) of the common carotid artery wall in men as compared with men in whom plasma levels were higher than median (Rissanen et al 2002). Lycopene also shows anti-inflammatory activity (Bhuvaneswari & Nagini 2005) and antifungal action in vitro (Sung et al 2007).

A reduction in cyclosporine-induced nephrotoxicity and testicular toxicity has been identified in experimental models for lycopene (Atessahin et al 2007, Türk et al 2007). Lycopene also demonstrates protection against gentamycin-induced nephrotoxicity (Karahan et al 2005).

CLINICAL USE

The clinical effects of lycopene are studied in relation to dietary intake and oral supplementation. It should be noted that the assessment of dietary lycopene intake varies with the method used to collect dietary information and the food composition databases used to estimate nutritional content (Shils 2006).

Cancer prevention

Lycopene is often included as an ingredient in antioxidant combination supplements and is thought to contribute to risk reduction for cancer. Some studies have investigated the effects of lycopene on risk of disease, although many consider it as part of the carotenoid group and study its effects in this way. Increasingly, interventional studies with supplemental lycopene are being conducted in an attempt to determine whether stronger protective or treatment effects will ensue. Several cancers, in particular, are being targeted in research: these are prostate, stomach, cervix and breast cancers.

Total cancer risk

A 2002 Japanese study involving 2444 people who were followed for 9 years found that high serum levels of lycopene, total carotenes and carotenoids were significantly and inversely associated with subsequent mortality from all causes and cancers of all sites after adjusting for gender, age and serum levels of total cholesterol, alpha-tocopherol and retinol (Ito et al 2002).

Prostate cancer

Prospective and retrospective epidemiological studies generally indicate an inverse relationship between lycopene intake and prostate cancer risk, which is also supported by in vitro and in vivo experiments showing that oral lycopene is bioavailable, accumulates in prostate tissue, is localised to the nucleus of prostate epithelial cells and demonstrates multiple mechanisms of chemoprevention (Chan et al 2009, van Breemen & Pajkovic 2008).

A meta-analysis of 11 case–control studies and 10 cohort studies or nested case–control studies suggested there is a modest protection from prostate cancer with increased consumption of lycopene from tomato and tomato-based products, although results are not yet definitive. The association is stronger for cooked tomato products compared to raw, and in those with higher levels of serum lycopene (Etminan et al 2004).

More specifically, five studies found a 30–40% reduction in prostate cancer risk associated with high tomato or lycopene consumption, three found a non-significant 30% reduction in risk and seven were not supportive of an association. The largest epidemiological study was conducted by the Harvard Medical School, which assessed the diets of 47,894 volunteers and identified several foods as significantly associated with lower prostate cancer risk (Giovannucci et al 1995). They were tomato sauce, tomatoes and pizza, which are primary sources of lycopene. Additionally, consumption of more than 10 servings per week was required for protective effects to be observed.

A nested-controlled study within the European Prospective Investigation into Cancer and Nutrition (EPIC) study involving 966 cases and 1064 controls found an inverse association between plasma lycopene and the risk of advanced prostate cancer (Key et al 2007). According to one study, the protective effect of lycopene-containing foods may be synergistically enhanced by the consumption of green tea (Jian et al 2007). Risk reduction was also observed for men with a family history of prostate cancer having increased consumption of lycopene in the Prostate, Lung, Colorectal, and Ovarian Cancer Screening Trial ($n = 29,361$) (Kirsh et al 2006). However, no association was found between prostate cancer risk and dietary intake of either lycopene or total tomato-based products for the general study population.

Intervention studies

Besides the epidemiological data on primary prevention, there are some reports of short- to medium-term clinical intervention trials with lycopene supplement or tomatoes, although results are mixed. A small study of men with high-grade prostate intraepithelial neoplasia (HGPIN), a precursor of prostate cancer, showed that supplementation with 4 mg lycopene twice daily for 1 year had a chemopreventative effect, preventing progression of HGPIN to prostate cancer (Mohanty et al 2005). Three of four studies found that either lycopene or tomatoes significantly reduces serum levels of prostate-specific antigen (PSA) (Ansari & Gupta 2004, Bowen et al 2002, Clark et al 2006, Kucuk et al 2002). Kucuk et al conducted a randomised study involving 26 men, which found that taking a tomato oleoresin extract containing 30 mg lycopene for 3 weeks resulted in smaller prostate tumours, less involvement of surgical margins and/or extra-prostatic tissues with the cancer and less diffuse involvement of the prostate by high-grade prostatic intraepithelial neoplasia compared with controls (Kucuk et al 2001). Additionally, plasma PSA levels were reduced. Another study, by Bowen et al (2002), involving 32 patients with

localised prostate cancer found that consuming tomato sauce-based pasta dishes for 3 weeks (providing 30 mg lycopene/day) reduced serum PSA levels by 17.5% and, overall, significantly reduced DNA damage in both leucocyte and prostate tissue. A lycopene supplement (Lycored softules) for 3 months in 20 patients with metastatic hormone refractive prostate cancer (HRPC) significantly reduced PSA levels and provided relief in bone pain and lower urinary tract symptoms (Ansari & Gupta 2004). HRPC was defined as an increase in PSA levels of more than twice the normal value (0–4 ng/mL) confirmed in two consecutive determinations at 2-week intervals in the presence of castrate levels of testosterone. Interestingly, a study involving men with prostate cancer and increasing PSA levels (in three consecutive readings) showed that treatment with lycopene (15 mg/day) leads to stabilisation in PSA levels after 6 months of treatment, but no reductions after this point (Vaishampayan et al 2007).

In contrast, several studies have found no change in PSA levels with lycopene interventions. One was a dose-escalating study of 36 men, which tested high doses of lycopene in biochemically relapsed prostate cancer (Clark et al 2006). The doses studied were 15, 30, 45, 60, 90 and 120 mg/day taken for 1 year and significant elevations of plasma lycopene were noted at 3 months and then appeared to plateau for all six dose levels. Similarly, no change in PSA was found in men with high-grade prostatic intraepithelial neoplasia, atypical foci or repeated non-cancerous biopsies, after 4 months' treatment with 30 mg/day lycopene (Lyc-O-Mato®) plus a multivitamin compared to those given the multivitamin alone. Interestingly, PSA levels decreased after the first month of treatment with lycopene, but returned to baseline levels after 4 months (Bunker et al 2007). A lycopene-rich tomato supplement (30 mg lycopene/day) failed to reduce PSA levels in men with androgen-independent prostate cancer given after 4 months (Jatoi et al 2007).

Stomach

Mixed results have also been seen in studies investigating whether lycopene reduces the incidence of stomach cancer (De Stefani et al 2000, Garcia-Closas et al 1999, Jenab et al 2006, Persson et al 2008, Tsugane et al 1992, Yuan et al 2004).

The relationship between pre-diagnostic serum levels of carotenoids and risk of gastric cancer was determined in a study involving 761 middle-aged or older men in Shanghai, China, with a follow-up of 12 years (Yuan et al 2004). High serum levels of alpha- and beta-carotenes and lycopene were significantly associated with reduced risk of developing gastric cancer (all P values for trend ≤ 0.05), whereas no statistically significant relationships among the serum levels of beta-cryptoxanthin, lutein/zeaxanthin, retinol, alpha-tocopherol and gamma-tocopherol were identified with gastric cancer risk. A recent large nested-control study produced a different result and found no inverse relationship between serum lycopene and gastric cancer risk (Jenab et al 2006). Similarly, no association was found between plasma lycopene levels and gastric cancer risk in a large nested case–control study of 36,745 Japanese subjects (aged 40–69) with *Helicobacter pylori* infection (Persson et al 2008). It is possible that protective effects of lycopene are only seen in populations with low baseline levels such as China.

Cervix

Results from two case–control studies have found an association between low serum lycopene levels and existing cervical cancer, but it is uncertain whether this can be interpreted as a risk factor because depleted levels may be a result of tumour usage, the increased burden of oxidative stress or both (Nagata et al 1999, Palan et al 1996).

Breast

Dorjgochoo et al (2008) prospectively investigated the association of plasma levels of tocopherols, retinol and carotenoids with the risk of developing breast cancer among Chinese women (Dorjgochoo et al 2008). The study evaluated 365 incident breast cancer cases and 726 individually matched controls nested within a large cohort study of women aged 40–70 years at baseline. An inverse association was identified between high levels of plasma lycopene (other than *trans*, 5- and 7-*cis* or *trans*-alpha-cryptoxanthin) and risk of developing breast cancer.

Protection against chemotherapy-induced toxicity

Chemotherapy-induced toxicity resulting in organ damage can limit a patient's ability to tolerate full-dose treatment and have long-lasting effects. Efforts to reduce toxicity to enable patients to receive full treatment cycles and preserve quality of life after cancer are actively being sought. Studies with animals suggest that lycopene may be one such protective agent. Lycopene has demonstrated protection against a variety of chemotherapy-induced toxicities such as: cardiotoxicity induced by doxorubicin (Anjos Ferreira et al 2007) and adriamycin (Yilmaz et al 2006); spermiotoxicity induced by cisplatin (Atessahin et al 2006a) and adriamycin (Atessahin et al 2006b); and renal toxicity induced by adriamycin (Yilmaz et al 2006). Further studies are required to confirm that lycopene will not diminish treatment efficacy.

Prevention of cardiovascular disease

Epidemiological studies have generally shown an inverse relationship between tissue and serum levels of lycopene and risk of acute coronary event or stroke and degree of IMT of the common carotid artery (Kohlmeier et al 1997, Rissanen et al 2002, 2003, Sesso et al 2004, 2005).

Strong population-based evidence comes from the large Women's Health Study (n = 39,876), the European Community Multicenter Study on Antioxidants, Myocardial Infarction and Breast Cancer (EURAMIC) study and the Kuopio Ischaemic Heart Disease Risk Factor study (Kohlmeier et al 1997, Rissanen et al 2003, Sesso et al 2004).

In the Women's Health Study, higher plasma lycopene concentrations were associated with a lower risk of cardiovascular disease (Sesso et al 2004). Specifically, for cardiovascular disease, exclusive of angina, women in the upper three quartiles had a significant multivariate risk reduction of 50% compared with those in the lowest quartile. For the EURAMIC study, 1379 individuals (662 patients, 717 controls) from 10 European countries were recruited (Kohlmeier et al 1997). Needle aspiration biopsy samples of adipose tissue were taken shortly after myocardial infarction, and levels of alpha- and beta-carotenes, lycopene and alpha-tocopherol were measured. After adjusting for age, body mass index, socioeconomic status, smoking, hypertension, and maternal and paternal histories of heart disease, only lycopene levels were found to be protective. The effect also appeared to be dose dependent. In contrast, Sesso et al (2005) found no association between plasma lycopene concentrations and cardiovascular disease in middle-aged and older men in a prospective, nested, case–control study (Sesso et al 2005).

In the Kuopio Ischaemic Heart Disease Risk Factor study, 1028 middle-aged men (aged 46–64 years) from Finland were examined and classified into quartiles according to their serum lycopene concentration (Rissanen et al 2003). The men in the lowest quartile had a significantly higher mean IMT of the common carotid artery (CCA-IMT) and maximal CCA-IMT than the others. Once again, a dose-dependent effect was observed as the mean and maximal CCA-IMT increased linearly across the quarters of serum lycopene concentration. This particular finding is important because increased IMT of the CCA has been shown to predict coronary events.

Reducing risk of macular degeneration

Lycopene supplements are sometimes used to reduce the risk of developing macular degeneration and generally support eye health. In general, it is taken in combination with other carotenoids, such as zeaxanthin and lutein, for this indication, for which there is supportive evidence (Cardinault et al 2005). Few studies are available to determine whether lycopene as a sole agent exerts clinically significant protective effects. One cohort study of 159 older people found no inverse association between lycopene intake and 5-year incidence of early age-related macular degeneration (ARMD) (Flood et al 2002). Alternatively, a recent study comparing 34 patients with ARMD to 21 control subjects found that of the serum carotenoid concentrations measured, only lycopene was decreased significantly in the serum LDL and HDL fractions ($P < 0.05$).

Cataract prevention

Studies have identified protective effects for lycopene against oxidative changes in human lens epithelial cells in vitro and reduced incidence and grading of cataract in test animals (Gupta et al 2003, Mohanty et al 2002, Pollack et al 1996). A cross-sectional survey of 372 older volunteers also produced positive results, finding that the risk of cortical cataract was lowest in people with the highest plasma concentrations of lycopene (Gale et al 2001). Similarly, Dherani et al (2008) identified that serum lycopene was inversely associated with the risk of developing cataracts in a cross-sectional study of people aged ≥50 years conducted in North India (Dherani et al 2008).

Protection against UV-induced photodamage

Oral ingestion

Long-term supplementation with lycopene or tomato-derived products rich in lycopene for 10–12 weeks is effective in decreasing skin sensitivity to UV-induced erythema in healthy volunteers and may contribute to life-long protection against harmful UV radiation (Stahl et al 2006). This supports the results of earlier studies. Stahl & Sies (2002) demonstrated that increasing lycopene intake to 16 mg/day (using tomato paste) for 10 weeks provided significant protection against erythema formation following UV irradiation, compared with placebo (Stahl & Sies 2002). The protective effects appear to develop slowly, as tests conducted at 4 weeks found no significant changes. Protective effects were also seen in another study that compared the synthetic lycopene with concentrated tomato extract (Lyc-O-Mato) (Aust et al 2005). The daily dose of lycopene was approximately 10 mg/day, which was lower than in the previous study. Again, 12 weeks were required to detect significant protective effects against UV-induced erythema and the effect was more pronounced in the group using a natural lycopene source.

Topical use

Results from an experimental model show that topical lycopene also has protective effects against acute UV-induced photodamage (Andreassi et al 2004, Fazekas et al 2003). Furthermore, it may act as a preventative agent via inhibition of epidermal ornithine decarboxylase activity, reducing inflammatory responses, maintaining normal cell proliferation and possibly preventing DNA damage, as indicated by blocking the necessitating step of apoptosis following UVB injury.

Male infertility

Lycopene is present in seminal plasma and plays a role in protecting the spermatozoa from oxidative stress. Significantly lower levels of lycopene have been found in the seminal fluid of immunoinfertile compared to fertile men (Palan & Naz 1996). In a clinical trial of 30 men aged 23–45 years with idiopathic infertility, supplementation with 2000 microgram lycopene twice daily improved several sperm parameters. After 3 months, 66.6% of cases showed improvement in sperm concentration (median 22 million/mL), 53% in sperm motility (median of 25%) and 46% in morphology (10%), whilst 40% of cases had improvement in all three parameters (Gupta & Kumar 2002).

Gingivitis
Chandra et al (2007) evaluated the effectiveness of lycopene on its own or combined with oral scaling (OS) and placebo with and without OS in the treatment of gingivitis in a randomised double-blind placebo-controlled trial. After 2 weeks, the group receiving lycopene with OS had a significant reduction in the Bleeding Index compared to the placebo group without OS, and both lycopene groups (with and without OS) had significant reductions in the Gingival Index compared to the placebo groups (with and without OS) (Chandra et al 2007).

Asthma
The association between lycopene and asthma is unclear. Some studies have identified lower levels of lycopene in the serum (Riccioni et al 2006, 2007) and whole blood (Wood et al 2005) to be associated with bronchial asthma, whereas other studies have found no association (Ford et al 2004, Schock et al 2003). It is also unclear whether lowered lycopene levels found in some asthmatic individuals are a consequence of the disease or a contributing factor.

The role of lycopene in exercise-induced asthma is controversial. In a randomised placebo-controlled trial, a daily dose of lycopene (30 mg/day for 1 week) in young athletes did not affect lung function after exercise and did not provide any protective effect against difficulty in breathing (measured by forced expiratory volume) compared to the placebo group (Falk et al 2005). However, this finding is in contrast to an earlier double-blind randomised controlled clinical trial, which found that lycopene (Lyc-O-Mato 30 mg/day) for 1 week protected asthmatic subjects against exercise-induced asthma (Neuman et al 2000).

Skin integrity
Low levels of antioxidants appear to be associated with increased roughness of the skin (reflecting increased depth and density of the furrows and wrinkles of the skin). A study involving 20 healthy volunteers aged between 40 and 50 years found higher levels of lycopene in the skin were significantly correlated to better skin integrity (Darvin et al 2008).

Bacterial prostatitis
In an animal model of chronic bacterial prostatitis, concurrent treatment of lycopene and ciprofloxacin (antibiotic) showed a statistically significant decrease in bacterial growth and improvement in prostatic inflammation compared with the control group and the ciprofloxacin-only group (Han et al 2008). The clinical significance of this finding remains to be tested.

Osteoporosis risk
Oxidative stress has been associated with increased risk of osteoporosis. The role of lycopene in reducing bone turnover was examined in a cross-sectional study of 33 postmenopausal women aged 50–60. In a dose-dependant manner, higher serum lycopene levels were associated with lower levels of cross-linked *N*-telopeptides of type I collagen (a marker of bone resorption) and lower protein oxidation. This suggests that lycopene may be beneficial in reducing the risk of osteoporosis in postmenopausal women; however, clinical studies are required to confirm significance (Rao et al 2007).

Benign prostate hyperplasia
A pilot study found that lycopene may inhibit the progression of benign prostatic hyperplasia (BHP). After 6 months of treatment with lycopene (15 mg/day), volunteers had reduced serum PSA levels, improved symptoms and less increase in prostate size (assessed by trans-rectal ultrasonography and digital rectal examination) compared to the placebo group (Schwarz et al 2008).

OTHER USES
General antioxidant nutrient.

DOSAGE RANGE

Based on available evidence
- Hypercholesterolaemia: 60 mg/day.
- One large study on lycopene and prostate cancer suggested that a daily intake of approximately 6.5 mg was protective (Giovannucci et al 1995).
- Sunburn protection: 10–16 mg/day.

TOXICITY
Animal studies have shown that 600 mg lycopene/kg/day is not toxic (Jonker et al 2003). There is good evidence of safety at intakes up to 75 mg/day (the new Observed Safe Level), although much higher levels have been tested without adverse effects (Shao & Hathcock 2006).

ADVERSE REACTIONS
Animal studies have demonstrated that 600 mg lycopene/kg/day does not produce adverse effects and is well tolerated (Jonker et al 2003). This level is far in excess of usual dietary intake in humans.

SIGNIFICANT INTERACTIONS

Drugs reducing fat absorption (e.g. cholestyramine, orlistat)
Drugs that reduce fat absorption, such as cholestyramine, colestipol and orlistat, may also reduce the absorption of lycopene — separate doses by at least 2 h.

CONTRAINDICATIONS AND PRECAUTIONS
Hypersensitivity to lycopene or its food sources.

PREGNANCY USE
Eating dietary amounts of foods rich in lycopene is likely to be safe.

PATIENTS' FAQs
What will this supplement do for me?
Lycopene is an antioxidant vitamin that may reduce the risk of developing some forms of cancer, cardiovascular disease and cataracts. It also protects the skin from sunburn and may reduce cholesterol levels when ingested in high doses.

PRACTICE POINTS/PATIENT COUNSELLING

- Lycopene is a fat-soluble, non-provitamin A carotenoid that imparts the red colour to tomatoes and is most bioavailable from processed food sources such as tomato paste.
- Lycopene has antioxidant and cholesterol-lowering activity and may reduce the risk of developing cardiovascular disease, according to epidemiological evidence.
- Epidemiological evidence generally suggests that higher intakes of tomato-based products reduce the risk of prostate cancer and possibly stomach cancer and cataracts.
- Preliminary evidence suggests that intervention with tomato-enriched products or lycopene may decrease tumour size in localised prostate cancer and reduce PSA levels.
- Increased intake of lycopene has also been associated with reduced risk of cortical cataract and sunburn. Preliminary evidence also suggests topical application of lycopene protects against UV-induced erythema (sunburn).

When will it start to work?

Risk reduction is likely to be a result of many years of consistently high intakes. Protective effects against sunburn have been reported after 10 weeks.

Are there any safety issues?

Safety studies conducted in animals suggest that lycopene is very safe and well tolerated.

L-Lysine

BACKGROUND

L-Lysine is absorbed from the small intestine and is transported to the liver via the portal circulation where it is involved in protein biosynthesis and is partly metabolised.

CHEMICAL COMPONENTS

L-Lysine is the biologically active stereoisomer of lysine.

MAIN ACTIONS

Essential amino acid

The human body cannot synthesise L-lysine so it must be taken through the diet. The richest sources of L-lysine are animal proteins such as meat and poultry. It is also found to lesser extents in eggs, beans and dairy products (Bratman & Kroll 2000).

Antiviral

L-Lysine has an inhibitory effect on the multiplication of HSV in cell cultures (Griffith et al 1981, Milman et al 1980). It appears to act as an antimetabolite and competes with arginine for inclusion into viral replicative processes (Griffith et al 1981). As such, lysine retards the viral growth promoting action of arginine.

Calcium regulation

L-Lysine may be involved in the cellular absorption, regulation and use of calcium (Civitelli et al 1992). In vitro tests with human osteoblasts indicate that lysine has a positive effect on osteoblast proliferation, activation and differentiation (Torricelli et al 2003).

OTHER ACTIONS

L-Lysine is required for biosynthesis of collagen, elastin and carnitine.

CLINICAL USE

Herpes simplex — prevention and treatment

A number of clinical studies have investigated the effects of oral L-lysine supplementation as prophylaxis or treatment of herpes virus infections, overall producing contradictory results (Digiovanna & Blank 1984, Griffith et al 1978, 1987, McCune et al 1984, Milman et al 1978, 1980, Thein & Hurt 1984, Walsh et al 1983, Wright 1994).

One randomised, double-blind crossover study found that supplementation with 1248 mg/day of L-lysine decreased the recurrence rate of HSV attacks in non-immunocompromised subjects, but did not shorten healing time during an outbreak (McCune et al 1984). Another double-blind trial compared the effects of 1000 mg L-lysine three times daily for 6 months with placebo treatment in 52 subjects. This time, not only was L-lysine found to decrease recurrence rates, but also symptoms were significantly diminished in severity and healing time significantly reduced (Griffith et al 1987). An open study of 45 patients with recurring HSV infection found that L-lysine supplementation accelerated recovery and reduced recurrence. The doses used were between 312 and 1200 mg/day in single or multiple doses (Griffith et al 1978). Thein and Hurt (1984) conducted a 12-month, double-blind crossover trial involving 26 subjects with recurring herpes lesions and found that a dose of 1000 mg/day had protective effects against lesion formation. Furthermore, once supplementation ceased, an increase in lesion frequency occurred. This study went further than others, identifying that serum lysine levels need to exceed 165 nmol/mL in order for clinical effects to become significant.

Two further double-blind studies produced negative results. Doses of 1000 mg or 1200 mg/day

were tested, both failing to produce prophylactic or treatment effects for herpes simplex (Digiovanna & Blank 1984, Milman et al 1980).

However, an epidemiological survey of 1543 volunteers asking about the perceived effectiveness of lysine supplements to treat herpes infections over a 6-month trial period indicated positive results (Walsh et al 1983). Of those people with cold sores or fever blisters, 92% claimed lysine supplements were 'very effective' or 'an effective form' of treatment and 81% of those with genital herpes and who had tried other forms of treatment also claimed positive results.

The effect of lysine on herpes may depend on variables such as the overall dietary ratio of lysine to arginine and the additional dose of supplemental lysine. In practice, doses of > 3000 mg/day are used as treatment during an acute episode, based on the positive findings of the Griffith study. This is combined with a diet low in arginine-rich foods, such as chocolate, peas, nuts and beer, and high in lysine-rich foods such as baked beans and eggs.

A small pilot study examined the use of a topical preparation SuperLysine Plus+ cream containing lysine plus other nutrients (zinc oxide, vitamins A, D, E, and lithium carbonate 3X) and botanicals (extracts of propolis, calendula, echinacea and goldenseal) in relieving the symptoms of herpes simplex. Patients with signs and symptoms of an active cold sore of less than 24 hours duration applied the ointment to the lesions 2-hourly during waking hours. Symptoms including severity of tingling, burning, and tenderness showed significant improvement by day 3 except oozing, and 40% of patients had full resolution; 87% of patients had full resolution after day 6 (Singh et al 2005).

OTHER USES

Osteoporosis prevention

Two studies have investigated the effects of oral L-lysine supplementation on calcium use to determine whether L-lysine has a role in the prevention of osteoporosis. In these tests, oral L-lysine was shown to significantly increase intestinal absorption of calcium and decrease renal excretion in both healthy women and those with osteoporosis (Civitelli et al 1992).

Anxiety and mood disturbances

According to a randomised, double-blind trial, fortification of lysine in a wheat-based (L-lysine deficient) diet significantly reduced anxiety score in males, but not females with high baseline anxiety. It is suspected that L-lysine's action as a 5-HT_4 receptor antagonist and benzodiazepine receptor agonist are responsible for the observed effect (Smriga et al 2004). In a recent double blind, randomised placebo-controlled study, Smriga et al (2007) evaluated the efficacy of combined lysine and arginine supplementation on reducing anxiety and stress response hormonal levels. Patients were given 1.32 g each of L-lysine and L-arginine twice daily for 1 week, estimated to be a 50% increase in total intake. Compared to placebo, long-term and stress-induced anxiety levels were reduced in both genders in the treatment group, and basal levels of salivary cortisol and chromogranin-A (a measure of sympathetic stress response) were significantly reduced in males (Smriga et al 2007). In contrast, a prospective study of 29,133 men (aged 50–69 years) found no association between L-lysine intake and depressed mood (Hakkarainen et al 2003).

Cancer treatment (in combination)

A formulation of lysine combined with other compounds (proline, arginine, vitamin C and green tea extract) has been used in several in vitro and in vivo studies suggesting it may be beneficial in cancer treatment by inhibiting growth, invasion and metastasis of tumour cells via inhibiting metalloproteinases which trigger excellular matrix degradation (Roomi et al 2004, 2005a–e, 2006a–e; Roomi 2006). In contrast to this, however, an in vivo study conducted on mice found L-lysine and vitamin C Lysin C Drink®, alone or in combination with epigallocatechin-gallate (EGCG) and amino acids Epican forte®, was not effective as a prophylactic or treatment in reducing primary tumour growth (neuroblastoma model) or in preventing metastases (Lode et al 2008).

Lysinuric protein intolerance (LPI)

LPI is an autosomal recessive transport disorder of the cationic amino acids which leads to decreased intestinal absorption and excessive renal loss of lysine, arginine and ornithine. Usual treatment involves restriction of protein and citrulline supplementation, which corrects many side effects except those related to lysine deficiency. Long-term low dose lysine supplementation improves plasma lysine concentration in patients and may help correct chronic lysine deficiency without causing side effects such as hyperammonaemia (Tanner et al 2007).

DOSAGE RANGE

Herpes simplex infections

- Prevention: 1000–3000 mg/day.
- Acute treatment: minimum 3000 mg/day in divided doses taken between meals until lesions have healed.

Osteoporosis prevention

- 400–800 mg L-lysine taken together with calcium supplementation.

TOXICITY

Not known.

ADVERSE REACTIONS

Doses greater than 10–15 g/day may cause gastrointestinal discomfort with symptoms of nausea, vomiting and diarrhoea.

SIGNIFICANT INTERACTIONS

Calcium

Clinical tests have found L-lysine enhances intestinal absorption and decreases renal excretion of calcium (Civitelli et al 1992) — potentially beneficial interaction.

PRACTICE POINTS/PATIENT COUNSELLING

- L-Lysine is an essential amino acid found in foods such as animal proteins, eggs and milk.
- It has been shown to inhibit HSV multiplication in vitro.
- Supplemental L-lysine is popular as a prophylactic and treatment for HSV.
- Studies have yielded inconsistent results suggesting that there may be individual variation in responses.
- Doses used as prophylaxis range from 1000–3000 mg/day with treatment doses generally above 3000 mg/day.
- L-Lysine may also enhance intestinal absorption of calcium and reduces its renal excretion.

CONTRAINDICATIONS AND PRECAUTIONS

Contraindicated in people with the rare genetic disorder hyperlysinaemia/hyperlysinuria (Hendler et al 2001). High-dose lysine supplements should be used with caution in hypercalcaemic states, and by people with kidney or liver disease.

PREGNANCY USE

Safety is unknown for high-dose supplements; however, dietary intake levels are safe.

PATIENTS' FAQs

What will this supplement do for me?

L-Lysine supplements may reduce the frequency and severity of herpes simplex outbreaks. It may also improve the way the body absorbs and retains calcium.

When will it start to work?

Studies suggest that several months' treatment may be required, with a long-term approach recommended.

Are there any safety issues?

L-Lysine appears to be a very safe supplement, although safety has not been established in pregnancy and lactation for high-dose supplements.

Magnesium

HISTORICAL NOTE 'Magnesium' comes from the name of the ancient Greek city Magnesia, where large deposits of magnesium were found. In the form of Epsom salts, magnesium has long been used therapeutically as a laxative although it is also used in many other ways, such as a foot soak to soften rough spots and absorb foot odour and as a bath additive to ease muscle aches and pains.

BACKGROUND AND RELEVANT PHARMACOKINETICS

Magnesium (Mg) is the fourth most abundant cation in the body, with 50–60% sequestered in the bone, the remainder distributed equally between muscle and non-muscular soft tissue. Only about 1% of total body Mg is found in the extracellular fluid. Dietary intake, renal and intestinal function finely balance and maintain plasma Mg concentrations.

Absorption of dietary Mg starts within 1 h of ingestion, with salts of high solubility having the most complete absorption (e.g. magnesium citrate). Magnesium absorption requires selenium, parathyroid hormone and vitamins B_6 and D and is hindered by phytate, fibre, alcohol, excess saturated fat and the presence of unabsorbed fatty acids, high phosphorus or calcium intake (Johnson 2001, Saris et al 2000). However, calcium is no longer perceived to be as antagonistic to Mg uptake as previously thought, while research using test meals may show negative interaction — in contrast to long-term balance studies (Andon et al 1996, Fine et al 1991, Gropper et al 2009, Lewis et al 1989). Some authors suggest that such nutrient interactions only become significant in situations of low Mg intake (Gropper et al 2009, Lewis et al 1989). Healthy people absorb 30–40% of ingested Mg; increasing to 70% bioavailability in cases of low intake or deficiency (Braunwald et al 2003). Although currently it is undisputed that Mg metabolism is regulated, the identity of such regulators remains largely obscured (Gropper et al 2009). While a number of hormones affect magnesium homeostasis they fail to explain every facet. Our understanding is further complicated in light of magnesium's counter-control of these hormones.

While hormones central to calcium homeostasis, e.g. parathyroid hormone (PTH), play a role in Mg metabolism this is a greatly diminished one compared to calcium (Shils & Rude 1996). Additional regulators include adrenergic signalling pathways, insulin, oestrogen and growth hormone (Rude & Shils 2006). Some researchers suggest that the real locus of control over Mg homeostasis may be independent of hormones; instead a combination of fractional absorption, renal excretion and transmembranous cation flux (Gropper et al 2009).

Once absorbed, Mg travels to the liver, enters the systemic circulation and is transported around the body, to be ultimately excreted via the kidneys, with urine representing the major excretory pathway. Consequently, the kidney is pivotal in homeostatic control, rapidly adjusting to changing dietary intake (Rude & Shils 2006). Renal handling of Mg is subject to additional negative influences. For example, increased calcium (≈ 2600 mg/day) (NHMRC 2005), sodium, protein, caffeine and alcohol consumption (Gropper et al 2009, Rude & Shils 2006), B_6 depletion (Turnlund et al 1992), glycosuria (Khan et al 1999, Rude & Shils 2006, Turnlund et al 1992, Walti et al 2003), elevated thyroid hormones (Wester 1987) protein intakes either above or below recommended levels (Wester 1987) and increases in net endogenous acid production (Rylander et al 2006) — all impair the kidney's capacity to reabsorb magnesium. Additional minor losses occur through sweat and faeces (Gropper et al 2009, Rude & Shils 2006).

Magnesium assessment

In spite of intense ongoing research, there is still no simple, rapid and accurate laboratory test to determine total body Mg status in humans (Arnaud 2008, Feillet-Coudray et al 2000). In particular, as with many of the minerals, there is an urgent need to identify a functional or biological marker of Mg status, similar to the role of ferritin in iron assessment (Arnaud 2008). While serum testing is still frequently performed, it is only indicative of severe depletion, as evidenced by values < 0.75 mmol/L and while some studies demonstrate a correlation between these values and the Mg content of other tissues, many do not (Arnaud 2008). Some researchers suggest that serum values 0.75–0.85 mmol/L warrant further investigation with more sensitive tests.

Erythrocytes naturally contain large amounts of Mg and experimental depletion is reflected by declining RBC concentrations within weeks. A criticism of this method relates to repletion studies which found greater increases in serum Mg following supplementation than reflected in the RBC; however, one could argue that the diminished response is a more accurate reflection of delayed intracellular recovery. Both animal and human studies have shown Mg concentrations in white blood cells, e.g. lymphocytes, to be a particularly accurate indicator of Mg content of both skeletal and cardiac tissues, which, given their functional significance, represents an attractive option. Actual muscle biopsies are believed to be an excellent indicator of body status, however, due to their invasive nature, is rarely used (Arnaud 2008).

Increasingly, however, Mg loading tests are being considered the gold standard of Mg assessment (Arnaud 2008). The procedure involves either oral or IV loading with Mg (e.g. 500–700 mg) followed by collection of 24-h urine. Generally, excretion of < 70% is considered indicative of Mg deficiency. One of the significant disadvantages of this method is the lack of standardisation, e.g. form and dose of Mg administered, which is critical for ensuring

its sensitivity and reproducibility. Additionally, this test should only be used in individuals with healthy renal function generally and absorptive capacity, specifically, in oral loading.

FOOD SOURCES

Good dietary sources of Mg include legumes, wholegrain cereals, nuts, dark green leafy vegetables, cocoa, soy flour, seeds, nuts, mineral water and hard water.

DEFICIENCY SIGNS AND SYMPTOMS

When reduced intakes or increased losses of Mg, potassium or phosphorus occur (the three major intracellular elements), losses of the others generally follow. As such, many deficiency symptoms are also due to alterations in potassium and/or phosphorus status and manifest as neurological or neuromuscular symptoms.

Symptoms of deficiency include:

- anorexia and weight loss
- nausea and vomiting
- muscular weakness and spasms
- numbness, tingling, cramps
- spontaneous carpal–pedal spasm
- vertigo, ataxia, athetoid, chorioform movements
- lethargy
- difficulty remembering things
- apathy and melancholy
- confusion
- dysregulation of biorhythms (some sleep and mental health disorders including insomnia)
- depression
- mental confusion, decreased attention span and poor concentration
- personality changes
- hyper-irritability and excitability
- vertigo
- cardiac arrhythmia, tetany and ultimately convulsions can develop if deficiency is prolonged.

Although Mg deficiency is a common clinical problem, serum levels are often overlooked or not measured in patients at risk for the disorder. About 10% of patients admitted to hospitals and up to 65% of patients in intensive care units may be Mg deficient (Braunwald et al 2003).

Low Mg states are associated with several serious diseases such as congestive heart failure, ischaemic heart disease, cardiac arrhythmias, hypertension, mitral valve prolapse, metabolic syndrome, diabetes mellitus, hyperlipidaemia, pre-eclampsia and eclampsia (Fox et al 2001, Guerrero-Romero & Rodriguez-Moran 2002, Rude & Shils 2006). Epidemiological evidence suggests that a low dietary intake of Mg is also associated with impaired lung function, bronchial hyperreactivity and wheezing, and risk of stroke (Ascherio et al 1998, Hill et al 1997). Magnesium deficiency may also play a role in the pathophysiology of Tourette's syndrome (Grimaldi 2002).

Primary deficiency

A primary deficiency is rare in healthy people as the kidneys are extremely efficient at maintaining Mg homeostasis. Studies of experimental Mg depletion demonstrate that it takes months of intentional Mg deprivation to induce a deficiency and even then, its presentation is 'vague' and idiosyncratic (Shils & Rude 1996, Wester 1987).

Marginal deficiencies are far more common and very often undiagnosed. There is evidence that daily Mg intake has declined substantially since the beginning of last century, with dietary surveys showing the average intake in Western countries is often below the recommended daily intake (RDI) (Ford & Mokdad 2003, Lukaski 2000, Rude & Shils 2006, Saris et al 2000).

Secondary deficiency

In contrast to the low rates of reported primary Mg deficiency, secondary deficiency is common in both the acute and chronically ill (Gropper et al 2009, Shils 1964). Most Mg deficiencies occur due to a combination of insufficient dietary intake and/or intestinal malabsorption and increased Mg depletion. There are many factors that predispose to deficiency and these are listed in the table below.

Medicines increasing risk of deficiency

Many pharmaceutical drugs have the potential to cause hypomagnesaemia.

MAIN ACTIONS

Magnesium plays an essential role in a wide range of fundamental biological reactions in the body. It is involved in over 300 essential enzymatic reactions and is necessary for every major biological process. It is especially important for those enzymes that use nucleotides as cofactors or substrates and plays a role in many processes that are of central importance in the biochemistry of each cell, particularly in energy metabolism. It is also required for many other important biological functions such as:

- nerve conduction
- regulation of vascular tone
- muscle activity
- amino acid and protein synthesis
- DNA synthesis and degradation
- immune function
- natural calcium antagonist.

Interaction with other nutrients

Magnesium is extremely important for the metabolism of calcium, potassium, phosphorus, zinc, copper, iron, sodium, lead, cadmium and the intracellular homeostasis and activation of thiamine (Johnson 2001). It acts as a calcium antagonist and positively interacts with nutrients such as potassium, phosphorus, vitamin B_6 and boron.

OTHER ACTIONS

In its macro form, oral inorganic Mg salts have a laxative and antacid activity and are practically insoluble in water.

CLINICAL USE

In practice, Mg is administered by various routes such as intramuscular injection and intravenous infusion. This review will focus only on oral Mg, as this is the form most commonly used by the general public, outside the hospital setting.

Risk Factors for Magnesium Depletion	
Dietary	Excessive intake of ethanol, salt, phosphoric acid (soft drinks), caffeine Protein-energy malnutrition. There is evidence that Mg balance remains positive despite < RDI intake as long as protein > 30 g/day
Endocrine disorders	Hyperaldosteronism Hyperparathyroidism with hypercalcaemia Hyperthyroidism Diabetes mellitus and glycosuria
Lifestyle	Profuse sweating Intense, prolonged stress
Gastrointestinal disorders (gastrointestinal tract [GIT] absorptive surface pathology or reduced transit time or increased upper GIT loss)	Coeliac disease Infections Inflammatory bowel diseases Malabsorption syndromes Pancreatitis Partial bowel obstruction Vomiting/diarrhoea
Elevated cortisol levels	Chronic stress Sleep deprivation Athletes and high frequency exercise
Pharmaceutical drugs	Aminoglycoside antibiotics Cisplatin Corticosteroids Cyclosporin Loop diuretics Tetracycline antibiotics
Renal	Metabolic disorders Acidosis Nephrotoxic drugs (e.g. cisplatin, cyclosporin)
Other	Hyperthermia Hypercatabolic states such as burns Phosphate depletion Potassium depletion Pregnancy Lactation (prolonged (>12 months) or excessive lactation) Excessive menstruation Long-term parenteral nutrition combined with loss of body fluids (e.g. diarrhoea) Parasitic infection (e.g. pinworms)

(From Braunwald et al 2003, Johnson 2001, McDermott et al 1991, Sanders et al 1999, Shils et al 1999)

Deficiency: treatment and prevention

Magnesium supplementation is traditionally used to correct deficiency states or avoid deficiency in people at increased risk, such as people with malabsorption syndromes and chronic alcoholics (Saris et al 2000). Low serum Mg levels < 0.7 mmol/L (1.8 mg/dL, 1.5 mEq/L) are indicative of Mg deficiency, although symptoms occur when serum Mg is < 0.5 mmol/L (1.2 mg/dL, 1.0 mEq/L) (Braunwald et al 2003).

Cardiovascular disease

A protective effect from hard water consumption, and in particular Mg intake from this source, against cardiovascular disease has been hypothesised for many years, culminating in a meta-analysis which determined a pooled odds ratio of 0.75 for cardiovascular mortality (Catling et al 2008), although not all studies on this topic concur with these findings (Morris et al 2008). Additional epidemiological evidence continues to strongly link Mg deficiency to numerous cardiovascular disease (CVD) presentations (Alon et al 2006, Flight & Clifton 2006, Gropper et al 2009, Haenni et al 1998, Klevay & Milne 2002, Ma et al 1995, Rude & Shils 2006, Song et al 2006) including congestive heart failure, ischaemic heart disease, cardiac arrhythmias, hypertension, mitral valve prolapse, stroke, non-occlusive myocardial infarction and hyperlipidaemia (Fox et al 2001, Frishman et al 2005, Guerrero-Romero & Rodriguez-Moran 2002, Rasmussen et al 1988, Saris et al 2000).

Although the pathophysiology of each condition is multifactorial, the multiple biological effects of Mg in the cardiovascular system suggest an important cardioprotective role. In the heart, Mg acts as a calcium-channel blocker and promotes resting polarisation of the cell membrane, thereby

reducing arrhythmias (Shattock et al 1987). It also helps to prevent serum coagulation (Frishman et al 2005). Low Mg selectively impairs the release of NO from the coronary endothelium, resulting in vasoconstriction and possibly coronary embolism. Mg plays a role in blood lipid levels with detrimental changes, e.g. increased oxidation of LDLs, as well as generally increased oxidation, evident in hypomagnesaemia (Rude & Shils 2006). In experimental animals, dietary Mg deficiency exacerbates atherosclerosis and vascular damage because it has a modulatory role in controlling lipid metabolism in the arterial wall.

Mitral valve prolapse

It has been suggested that hypomagnesaemia is common in patients with mitral valve prolapse and therefore supplementation to correct this deficiency could exert beneficial clinical effects (Kitlinski et al 2004). In 1997, one study of 141 subjects with symptomatic mitral valve prolapse confirmed this suspicion by identifying hypomagnesaemia in 60% of patients (Lichodziejewska et al 1997). A randomised, double-blind, crossover study followed those Mg-deficient people and found that 5 weeks' Mg supplementation significantly alleviated symptoms of weakness, chest pain, dyspnoea, palpitation and anxiety (Lichodziejewska et al 1997). The dose regimen used was three tablets of magnesium carbonate 600 mg (7 mmol elementary Mg) daily for the first week followed by two tablets daily until the fifth week.

Symptoms of coronary artery disease (CAD)

In 2003, the results from a multicentre, multinational, prospective, randomised, double-blind and placebo-controlled trial showed that 6 months' oral Mg supplementation in patients with CAD results in a significant improvement in exercise tolerance, exercise-induced chest pain, and quality of life (QOL) (Shechter et al 2003). The study used oral magnesium citrate (15 mmol twice daily) as Magnosolv-Granulat (total Mg 365 mg). Previously, randomised placebo-controlled studies have shown that oral Mg supplementation in CAD patients is associated with significant improvement in brachial artery endothelial function and inhibits platelet-dependent thrombosis, providing several potential mechanisms by which Mg could beneficially alter outcomes in these patients (Shechter et al 1999, 2000).

Hypertension

Epidemiological evidence suggests an inverse relationship between blood pressure and serum Mg while large well-designed prospective studies report that Mg-rich diets may lower blood pressure, particularly in older individuals (Sontia & Touryz 2007). Magnesium modulates vascular tone and reactivity both directly, e.g. calcium-channel blocker, and indirectly, e.g. prostacyclin, and alters vascular responsivity to vasoactive agonists. However, Mg deficiency does not appear universal amongst hypertensive patients and several sub-groups have been identified as characteristically demonstrating both pathologies. These include individuals of African descent, obese patients, patients with severe or malignant presentations and those also diagnosed with metabolic syndrome.

This may partly explain the mixed findings produced from Mg supplementation studies, as well as additional heterogeneities in study designs such as the salts used, dose administered, sample size and trial duration (Sontia & Touryz 2007). Modest but significant success (≈ -2 to 5 mmHg), however, has been achieved particularly in those patients deficient at baseline, black individuals and those patients with diuretic-associated hypertension (Rude & Shils 2006, Sontia & Touryz 2007, Witteman et al 1994).

Stroke

A prospective study of 43,738 men (Health Professional Follow-up Study) conducted over 8 years showed an inverse association between dietary Mg intake and the risk of total stroke (Ascherio et al 1998). This association was stronger in hypertensive than normotensive men and was not materially altered by adjustments for blood pressure levels. A study has confirmed that this protective effect is maintained in male smokers (Larsson et al 2008). Following adjustment for age and other cardiovascular risks, high Mg intake was associated with a statistically significant reduced risk of cerebral infarct, with a relative risk of 0.85 across men of all ages or 0.76 in those men aged < 60 years, while the dietary intake of other minerals did not appear to convey any protection. At the other end of the spectrum, it is interesting to note that low concentrations of Mg in the serum or cerebrospinal fluid in acute ischaemic stroke patients at admission or within 48 hours of onset of the stroke predicts both greater neurological deficits, e.g. paresis, and higher 1 week mortality (Bayir et al 2009, Cojocaru et al 2007).

Dyslipidaemia

Oral Mg supplementation (magnesium oxide 12 mmol/day) taken over 3 months effectively reduced plasma lipids compared with placebo in people with ischaemic heart disease (Rasmussen et al 1989). The double-blind study showed that Mg produced a statistically significant 13% increase in molar ratio of apolipoprotein A1:apolipoprotein B compared with a 2% increase in the placebo group. This was caused by a decrease in apolipoprotein B concentrations, which were reduced by 15% in the Mg group as compared with a slight increase in the placebo group. Additionally, triglyceride levels decreased by 27% after Mg treatment. Overall, these beneficial results are associated with a decrease in cardiovascular mortality.

Arrhythmia prevention in congestive heart failure

Although Mg is usually administered intravenously when indicated in this condition, one controlled study using oral Mg showed that it significantly reduced the incidence of arrhythmias in patients with stable congestive heart failure (Bashir et al 1993). The double-blind crossover study used magnesium chloride (3204 mg/day in divided doses).

Postoperative recovery from cardiac surgery

An interesting Australian study employed a range of preoperative treatments addressing mental, physical and metabolic components, including magnesium. The results of this preliminary study, using 1200 mg magnesium orotate, together with 300 mg CoQ10, 300 mg alpha-lipoic acid and 3 g omega-3 essential fatty acids (EFAs) administered daily 1 month prior to surgery, suggest an enhanced postoperative recovery and improved quality of life (Hadj et al 2006). IV administration of Mg sulfate is also used to reduce the risk of atrial fibrillation postsurgery (Burgess et al 2006).

Calcium and hormone replacement therapy (HRT): a deadly mix in postmenopausal women?

The failure of oestrogen replacement therapy to protect against cardiovascular disease in the Women's Health Initiative (WHI) Study has provoked much reflection amongst researchers. One theory pertains to oestrogen's role in Mg homeostasis and Mg's antagonism of calcium (Seelig et al 2004). In high oestrogen states, Mg uptake by tissues is stimulated (Seelig et al 1993). In scenarios of inadequate Mg, however, this action results in low serum Mg concentrations and in particular an increased ratio of serum calcium to magnesium. This in turn promotes a pro-thrombotic environment, as a result of calcium's promotion of the coagulation cascade and vasoconstrictive effects. The group of researchers supporting this theory points to the promotion of a high calcium diet and/or calcium supplementation in postmenopausal women, in the face of inadequate Mg consumption, as being behind the increased vascular events (particularly of a thromboembolic nature) evident in the WHI and other calcium supplementation studies in postmenopausal women (Bolland et al 2008).

Migraine headaches: prevention

People who suffer with recurrent migraines appear to have lower intracellular Mg levels (demonstrated in both red and white blood cells) than those who do not experience migraines. (See 'Feverfew' monograph for more information about migraine aetiology.) The low Mg level is believed to result in cerebral artery spasm and increased release of substance P and other pain mediators (Woolhouse 2005).

Two randomised, double-blind studies using high-dose oral Mg have found it to be useful in migraine sufferers, reducing frequency and/or number of days with migraine headache (Peikert et al 1996, Taubert 1994). One placebo-controlled study using a lower dose found no benefit in reducing the frequency of migraine headaches (Pfaffenrath et al 1996).

A dose of 24 mmol Mg (600 mg trimagnesium dicitrate) taken daily over 12 weeks produced a 42% reduction in frequency of attack compared with 16% with placebo in one study of 81 patients, with a mean attack frequency of 3.6 migraine headaches each month (Peikert et al 1996). Effects were observed after week 9 and treatment also significantly decreased the duration of each migraine. Significant decreases in migraine frequency were also observed in a crossover study that used the same dose and form of oral Mg (Taubert 1994).

Menstrual migraine headache

Oral Mg supplementation decreases pain, premenstrual symptoms and the number of days with migraine headache, according to one double-blind placebo-controlled study (Facchinetti et al 1991a). Treatment consisted of 360 mg/day of Mg (pyrrolidone carboxylic acid) starting on day 15 of the menstrual cycle and continuing until the onset of menses.

Migraine prophylaxis in children

Oral magnesium oxide (9 mg/kg/day) given in three divided doses with food may decrease headache frequency and severity according to a multicentre, randomised, double-blind, placebo-controlled trial (Wang et al 2003). The 16-week study involved children aged 3–17 years who reported a 4-week history of at least weekly, moderate-to-severe headache with a throbbing or pulsatile quality, associated anorexia/nausea, vomiting, photophobia, sonophobia or relief with sleep, but no fever or evidence of infection. Of note, 27% of subjects (n = 42 magnesium oxide; n = 44 placebo) failed to complete the study, thereby hindering interpretation of the results.

Attention deficit and hyperactivity disorder (ADHD)

Several studies have demonstrated a positive correlation between Mg status and ADHD pathology. Reported prevalence of hypomagnesaemia varies between 50% and 95% (Kozielec & Starobrat-Hermelin 1997, Mousain-Bosc et al 2004) A hypothesised genetic mutation involves the TRPM6 gene which is crucial for Mg transport and homeostasis, therefore making deficiency possible irrespective of adequate intake (Mousain-Bosc et al 2004). There have been two Mg supplementation studies in combination with vitamin B_6 (6 mg/kg/

Clinical note — What is the link between magnesium and migraine?

Magnesium seems to play a significant role in the pathogenesis of migraine, with low brain levels and impaired Mg metabolism reported in migraine sufferers (Thomas et al 2000). Magnesium has an effect on serotonin receptors, NO synthesis and release and a variety of other migraine-related receptors and neurotransmitters. It is also essential for mitochondrial function within the cell. The available evidence suggests that up to 50% of patients during an acute migraine attack have lowered levels of ionised Mg (Mauskop & Altura 1998). Pilot studies of migraine patients have suggested that disordered energy metabolism or Mg deficiencies may be responsible for hyperexcitability of neuronal tissue in migraine patients (Boska et al 2002). As such, factors that decrease neuronal excitability, such as Mg, may alter the threshold for triggering attacks (Boska et al 2002).

day ± 0.6–0.8 mg/kg/day vitamin B_6) (Mousain-Bosc et al 2004), with both producing significant behavioural improvement.

Autism spectrum disorders (ASD)

Research suggests that ASD sufferers generally demonstrate red blood cell Mg depletion (Mousain-Bosc et al 2006, Strambi et al 2006). In spite of two negative reviews published 10 years apart (Nye & Brice 2005, Pfeiffer et al 1995), enthusiasm regarding the use of Mg as an adjunct to high-dose vitamin B_6 therapy (6 mg/kg/day with 0.6–0.8 mg/kg/day vitamin B_6) (Kidd 2002, Mousain-Bosc et al 2006) in ASD continues. This may ultimately prove successful given the limited trials, poor methodological rigour to date (Nye & Brice 2005, Pfeiffer et al 1995) and preliminary evidence from two small successful trials (Kidd 2002).

Kidney stone prevention

Magnesium deficiency is one of many risk factors for the development of kidney stones (Anderson 2002). Others include nutritional deficiencies of water, calcium, potassium and vitamin B_6, excessive intakes of animal protein, fat, sugar, oxalates, colas, alcohol, caffeine, salt and vitamin D, lifestyle factors and a positive family history.

A prospective double-blind study of 64 patients who were randomly assigned to receive placebo or potassium–magnesium citrate (42 mEq potassium, 21 mEq magnesium and 63 mEq citrate) daily for up to 3 years showed that the combination supplement reduced the risk of developing recurrent calcium oxalate kidney stones by 85% (Ettinger et al 1997).

Premenstrual syndrome (PMS)

Three early double-blind studies using oral Mg supplements in women with PMS produced positive results for decreasing symptoms such as fluid retention and mood swings (Facchinetti et al 1991b, Rosenstein et al 1994, Walker et al 1998). According to these, clinical effects develop slowly, starting during the second menstrual cycle.

Although it is not clear what mechanism of action is responsible, a number of studies have identified decreased Mg concentrations in both red blood cell and mononuclear blood cells of women with PMS (Rosenstein et al 1994) and therefore the suggestion is that the clinical benefits were secondary to repletion. The results of a more recent study strongly challenge these earlier findings (Khine et al 2006). The Mg status of 17 PMS patients and 14 age-matched controls was comprehensively assessed using four different techniques: serum, red blood cell and mononuclear blood cell concentrations, together with a Mg loading test. The results failed to demonstrate a relationship between Mg status and the diagnosis or severity of PMS. In addition to this, while subsequent Mg treatment in PMS patients produced robust reductions in symptom ratings, these were highly comparable with the placebo response. The latter throws speculation upon the positive results of open label studies of Mg in PMS, such as the 35% reduction in symptoms demonstrated after 3 months treatment with Mg 250 mg/day, demonstrated by Quaranta et al (2007).

Dysmenorrhoea

A Cochrane review of seven randomised trials investigating the effects of various treatments for dysmenorrhoea included three trials comparing Mg with placebo. Overall, Mg was found to be more effective than placebo for pain relief and resulted in less extra medication being required (Wilson & Murphy 2001).

Osteoporosis prevention

Magnesium comprises about 1% of bone mineral and is involved in a number of activities supporting bone strength, preservation, and remodelling. Epidemiological studies have linked increased Mg consumption, as part of an alkaline diet, with improved bone mineral density (Tucker et al 1999). Chronic Mg deficiency compromises bone health by increasing the size and brittleness of the bone crystals, inducing hypocalcaemia and possibly increasing inflammatory cytokines (Rude & Shils 2006). Therefore, low Mg states increase the risk of osteoporosis. Several studies have investigated the effects of supplemental Mg on bone density, generally yielding positive effects.

One long-term study has reported an increase in bone density for magnesium hydroxide supplementation in a group of menopausal women (Sojka & Weaver 1995). After the 2-year test period, fracture incidence was also reduced. Another 2-year study showed that Mg supplementation in postmenopausal women with osteoporosis results in increased bone mass at the wrist after 1 year, with no further increase after 2 years of supplementation (Stendig-Lindberg et al 1993). The regimen used here was oral Mg 750 mg/day for the first 6 months followed by 250 mg/day thereafter.

Asthma

There is ongoing evidence of low intracellular (both red and white blood cells) Mg in asthmatics in some (Dominguez et al 1998, Mircetic et al 2001, Sedighi et al 2006) but not all studies. Healthy Mg concentrations inhibit calcium entering smooth muscles such as those in the airways and therefore potentially reduce bronchospasm (Dominguez et al 1998, Gropper et al 2009). In addition to this, Mg influences pulmonary vascular muscle contractility, mast-cell granulation and neurohumoral

> ***Clinical note — Peak bone mass***
> The best opportunity to influence bone mass occurs early in life. It has been estimated that approximately 40% of peak bone mass is accumulated during adolescence with peak bone mass in the hip achieved by age 16–18 years (Weaver 2000). The spinal vertebrae are still able to increase in mass until the third decade of life, when total peak bone mass reaches 99% by age 26.6 years (± 3.7 years). As such, ensuring an adequate intake of calcium and Mg early in life is essential for attaining optimal bone mass.

mediator release (Mathew & Altura 1988). Although it is most often used as an infusion or in an inhaled form for this indication, results of two randomised, double-blind studies suggest that oral supplements also significantly alleviate asthma symptoms (Bede et al 2003, Hill et al 1997). Hill et al found that treatment improved symptoms, although it failed to change objective measures of airflow or airway reactivity and Bede et al found a significant decrease in bronchodilator use after 8 weeks compared with placebo. This was a 12-week study using oral magnesium citrate in 89 children (4–16 years) with mild or moderate persistent bronchial asthma. The dose used was 200 mg daily for children aged 7 years and 290 mg for those older than 7 years. Adding to this, a randomised double-blind trial of magnesium glycine (300 mg/day) in 37 subjects aged 7–19 years over 2 months resulted in statistically significant reduction in bronchial reactivity, skin responses to recognised antigens and salbutamol use in the treatment versus the placebo group (Gontijo-Amaral et al 2007).

Pregnancy

A 2001 Cochrane review of seven studies involving 2689 women concluded that although not all trials were positive, oral Mg taken before the 25th week of gestation was associated with a lower frequency of preterm birth, a lower frequency of low birthweight and fewer small-for-gestational-age infants.

Additionally, fewer hospitalisations during pregnancy and fewer cases of antepartum haemorrhage were associated with Mg use.

Unfortunately, a lack of high-quality evidence precludes conclusively stating that dietary Mg supplementation during pregnancy is beneficial, according to the authors, with further research still required to confirm these findings (Makrides & Crowther 2001).

Pre-eclampsia

While a consistent relationship between Mg status and risk of pre-eclampsia has not been established, an interesting longitudinal study revealed that while serum Mg levels decline in both healthy and pre-eclamptic pregnant women, such a decrease occurs earlier in those women who later develop this condition (Sontia & Touryz 2007).

Pregnancy-induced leg cramps

A 2002 Cochrane review of five randomised trials of treatments for leg cramps in pregnancy concluded that the best evidence is for magnesium lactate or citrate taken as 5 mmol in the morning and 10 mmol in the evening for pregnant women experiencing leg cramps (Young & Jewell 2002).

Diabetes mellitus

A strong association between Mg, diabetes and hypertension has been reported in the literature (Ascherio et al 1998, Sontia & Touryz 2007). Deficiency aggravates insulin resistance and predisposes diabetics to cardiovascular diseases.

Type 1 diabetes mellitus (T1DM)

Hypomagnesaemia is present in 25–38% of all diabetic patients secondary to glycosuria and Mg redistribution (Paolisso et al 1992). Such depletion may occur early in the pathology, with T1DM children demonstrating progressive deterioration of serum levels within 2 years of diagnosis in some (Tuvemo et al 1997) but not all studies (Matthieson et al 2004). Magnesium depletion in T1DM has also been linked to earlier atherosclerotic development (Atabek et al 2006, Djurhuus et al 1999), polyneuropathy (De Leeuw et al 2004), advanced retinopathy (de Valk et al 1999) and immunosuppression (Cojocaru et al 2006). Supplementation studies have produced mixed results (Eibl et al 1998); however, Mg supplementation may reduce risks of secondary pathology.

Consistent with these findings, some researchers suggest T1DM patients receive a high dose in the first month of treatment to normalise red blood cell and serum Mg and then remain on continuous lower dose supplementation (e.g. 300 mg/day) in order to avoid a return to hypomagnesaemia (Eibl et al 1998).

Type 2 diabetes mellitus (T2DM)

Epidemiological studies have drawn a link between poor dietary and/or serum Mg and an increased risk of T2DM (Chambers et al 2006, He et al 2006, van Dam et al 2006). In one large study those in the lowest tertile of Mg and fibre intakes exhibited a 3–4 times greater risk (Bo et al 2006). Serum Mg depletion is also evident in ≈ 25–38% patients. Hypomagnesaemia in diabetic patients appears to exacerbate impaired insulin resistance, elevated fasting blood glucose and HbA_{1c} concentrations (He et al 2006, Walti et al 2003). Oral Mg (magnesium chloride 2.5 g/day for 4 months) adjunctive to hypoglycaemic medication has produced reductions of fasting glucose (−37.5%), HbA_{1c} (−30.4%), and homeostasis model assessment (HOMA)-IR index (−9.5%) and insulin (Rodriguez-Moran & Guerrero-Romero 2003), while other studies demonstrate increased insulin levels with improved action (Paolisso et al 1992). In another study, a combination of Mg (200 mg/day), zinc (30 mg/day) and vitamins (C 200 mg/day and E 150 mg/day) over 3 months significantly increased levels of HDL and apo-A1 24% and 8.8%, respectively (Farvid et al 2004).

Several randomised studies investigating oral Mg supplementation have shown improvements in diabetic control (Paolisso et al 1992, Rodriguez-Moran & Guerrero-Romero 2003). A double-blind trial that involved 63 patients with type 2 diabetes (treated with glibenclamide) and reduced serum Mg levels demonstrated that the addition of oral Mg over 16 weeks significantly improves insulin sensitivity and metabolic control (Rodriguez-Moran & Guerrero-Romero 2003).

Constipation

In high doses Mg exerts a laxative effect, which is used in practice for the short-term treatment of constipation and in order to get the bowel ready for

Clinical note — Magnesium citrate and orotate: superior supplements?

Magnesium supplements come in a variety of salts (citrate, oxide, gluconate, acetate, orotate, etc.), however their bioavailability varies. Current evidence, although not clearly demonstrating superiority of one preparation over another, supports the use in general of organic over inorganic forms (Coudray et al 2005, Firoz & Graber 2001, Lindberg et al 1990, Walker 2003). In particular, investigations of magnesium orotate (Lindberg et al 1990), citrate (Walker 2003) and gluconate (Coudray et al 2005) demonstrate high solubility and bioavailability. Magnesium orotate has attracted further attention regarding its potential synergism with magnesium in terms of repair of damaged myocardium (Classen 2004, Zeana 1999).

According to one randomised, double-blind, placebo-controlled study, magnesium amino chelate and magnesium citrate are better absorbed than magnesium oxide in healthy individuals (Walker et al 2003). Of the three, magnesium citrate led to the greatest increase in mean serum Mg, a result evident after acute dosing (24 h) and chronic dosing (60 days). Furthermore, although mean erythrocyte Mg concentration showed no differences among groups, chronic magnesium citrate supplementation resulted in the greatest mean salivary Mg concentration compared with all other treatments.

surgical or diagnostic procedures. It is often used in the form of magnesium hydroxide (milk of magnesia) or magnesium sulfate (Epsom salts).

Dyspepsia

As magnesium hydroxide (milk of magnesia), Mg is used to reduce symptoms of dyspepsia and gastric acidity and acts as an antacid by forming magnesium chloride in the stomach. Magnesium oxide is also used for its antacid properties, which are greater than magnesium carbonate and sodium bicarbonate (Reynolds et al 1982). Magnesium trisilicate is the form used when a prolonged antacid activity is required.

Chronic leg cramps

Two randomised, double-blind studies have investigated the use of oral Mg supplements in people with leg cramps. Frusso et al (1999) conducted a crossover trial involving 45 individuals who had experienced at least six cramps during the previous month. Subjects were given 1 month of oral magnesium citrate (900 mg twice daily) followed by a matching placebo for 1 month, or visa versa. This treatment regimen failed to reduce the severity, duration or number of nocturnal leg cramps. In contrast, Roffe et al (2002) tested magnesium citrate equivalent to 300 mg magnesium in subjects suffering regular leg cramps and identified a trend towards fewer cramps with active treatment (P = 0.07). Significantly more subjects thought that the treatment had helped after magnesium than after placebo — 36 (78%) and 25 (54%) respectively. Interestingly, in both studies patients improved over time regardless of the treatment they received.

Although two additional studies in athletes found no correlation between cramping incidence and serum Mg, the authors suggest that the cramping was caused by increased neuromuscular excitability (Schwellnus et al 2004, Sulzer et al 2005), which is a classic feature of Mg deficiency (Rude & Shils 2006). As is the case with much Mg research, more accurate and validated assessment methods may be required to elicit the true relationship between Mg status and this presentation.

OTHER USES

Oral Mg supplements are used in a variety of different conditions, most notably those involving muscle spasm or tension, pain and/or psychological and physical symptoms of stress and hyperexcitability. This includes irritable bowel syndrome (IBS), restless legs syndrome, fibromyalgia, chronic fatigue syndrome, anxiety states, tension headaches and insomnia. Preliminary evidence also suggests that it may be beneficial for women with detrusor muscle instability (incontinence) or sensory urgency.

DOSAGE RANGE

Australian RDI for adults

- Men
  - 19–30 years: 400 mg/day.
  - > 30 years: 420 mg/day.
- Women
  - 19–30 years: 310 mg/day.
  - > 30 years: 320 mg/day.
- Pregnancy
  - ≤ 18 years: 400 mg/day.
  - > 18 years: 350 mg/day.
- Lactation
  - ≤ 18 years: 360 mg/day.
  - > 18 years: 310 mg/day.

According to clinical studies

- Hypertension: 360–600 mg/day.
- Arrhythmia prevention in congestive heart failure: magnesium chloride 3204 mg/day in divided doses.
- Migraine: 600 mg trimagnesium dicitrate daily.
- Migraine prophylaxis in children: magnesium oxide (9 mg/kg/day).
- PMS fluid retention symptoms: 200 mg magnesium (as magnesium oxide) daily.
- PMS mood swings: magnesium pyrrolidone carboxylic acid (360 mg) taken three times daily, from day 15 of the menstrual cycle to the onset of menstrual flow.
- Mitral valve prolapse: three tablets magnesium carbonate 600 mg (7 mmol of elementary Mg) daily for the first week followed by two tablets daily.
- CAD symptoms: oral magnesium citrate (15 mmol twice daily as Magnosolv-Granulat, total magnesium 365 mg).
- Postoperative recovery from cardiac surgery: 1200 mg magnesium orotate in combination with 300 mg CoQ10, 300 mg alpha-lipoic acid and 3 g omega-3 oils taken daily 1 month prior to surgery.

- T1DM: initial high dose to normalise serum levels and then continuous 300 mg daily.
- T2DM: 2.5 g magnesium dichloride daily or 300 mg elemental Mg in combination with 30 mg zinc, 250 mg vitamin C and 150 mg vitamin E daily.
- ADHD: 6 mg/kg/day ± 0.6–0.8 mg/kg/day vitamin B_6.
- ASD: 6 mg/kg/day ± 0.6–0.8 mg/kg/day vitamin B_6.
- Kidney stone prevention: magnesium hydroxide 400–500 mg/day.
- Nocturnal leg cramps: magnesium citrate equivalent to 300 mg magnesium daily.
- Paediatric asthma: magnesium citrate 200–300 mg daily.
- Osteoporosis prevention: 250 mg taken at bedtime on an empty stomach, increased to 250 mg three times daily for 6 months, followed by 250 mg/day for 18 months.

ADVERSE REACTIONS

The most common adverse effects of oral supplements are diarrhoea (18.6%) and gastric irritation (4.7%) (Peikert et al 1996). Typically, doses of inorganic preparations supplying above 350 mg/day (elemental) may be associated with adverse effects. Dividing total daily supplemental amounts over 2–3 separate doses may help to reduce this risk and maximise bioavailbility.

SIGNIFICANT INTERACTIONS

The interactions included in this section are relevant for oral supplementation and do not refer to other administration routes, although there may be an overlap.

Alcohol

Alcohol consumption results in increased urinary losses of Mg and therefore with higher chronic ingestion additional Mg replacement may be necessary.

Aminoglycosides (e.g. gentamycin)

Drug may reduce absorption of Mg — monitor for signs and symptoms of Mg deficiency, as increased Mg intake may be required with long-term therapy.

Anti-arrhythmic drugs

Additive effect theoretically possible because high-dose oral Mg exerts anti-arrhythmic activity according to one clinical study — observe patients taking this combination.

Calcium

Magnesium and calcium deficiencies usually co-exist due to magnesium's key role in active PTH and vitamin D production (Gropper et al 2009, Rude & Shils 2006, Wester 1987). Conversely, if Mg intakes are excessive calcium levels decline due to inhibition of PTH release and increased renal excretion. There is additional redistribution with impaired calcium influx and release from intracellular stores. Magnesium can also bind calcium-binding sites and mimic its actions (Gropper et al 2009, Rude & Shils 2006).

Calcium-channel blockers

Magnesium may enhance the hypotensive effect of calcium-channel blockers: monitor patients and their drug requirements — possible beneficial interaction.

Fluoroquinolones

Magnesium may decrease absorption of fluoroquinolone antibiotics — separate doses by at least 2 h before or 4 h after oral Mg.

Loop diuretics and thiazide diuretics

Increased Mg intake may be required with long-term therapy because these drugs increase Mg loss — monitor Mg efficacy and status with long-term drug use.

Potassium

Hypomagnesaemia results in hypokalaemia due to increased potassium efflux from cells and renal excretion (Gropper et al 2009, Rude & Shils 2006).

Potassium-sparing diuretics

May increase the effects of supplemental Mg — observe patients taking this combination.

Tetracycline antibiotics

Tetracyclines form insoluble complexes with Mg, thereby reducing absorption of both — separate doses by at least 2 h.

CONTRAINDICATIONS AND PRECAUTIONS

- Magnesium supplementation is contraindicated in renal failure and heart block (unless a pacemaker is present).
- Hypermagnesaemia can develop in patients with renal failure and receiving Mg-containing antacids or laxatives and with accidental Epsom salt ingestion.
- Overuse of magnesium hydroxide or magnesium sulfate may cause deficiencies of other minerals or lead to toxicity.

PREGNANCY USE

Pregnant women and nursing mothers are advised to consume sufficient Mg (see Australian RDI under *Dosage range*).

PATIENTS' FAQs

What will this supplement do for me?

Magnesium is essential for health and wellbeing. Although used to prevent or treat deficiency states, it is also used to alleviate many conditions such as cardiovascular disease and PMS, and prevent migraine and muscular spasms.

When will it start to work?

This will depend on the indication it is being used to treat.

Are there any safety issues?

In high doses, supplements can cause diarrhoea. High-dose supplements should not be used by people with severe kidney disease or heart block.

PRACTICE POINTS/PATIENT COUNSELLING

- Magnesium is an essential mineral in human nutrition with a wide range of biological functions.
- Low Mg states are associated with several serious diseases such as congestive heart failure, ischaemic heart disease, cardiac arrhythmias, hypertension, mitral valve prolapse, metabolic syndrome, stroke, diabetes mellitus, hyperlipidaemia, pre-eclampsia and eclampsia.
- Although supplementation is traditionally used to correct or avoid deficiency states, research has also shown a role in the management of numerous disease states, e.g. asthma, cardiovascular disease, PMS, dysmenorrhoea, migraine prevention, diabetes, kidney stone prevention, osteoporosis prevention, dyspepsia and constipation. Preliminary research also suggests a possible benefit in ADHD, autism, women with detrusor muscle instability (incontinence) and pregnancy-induced leg cramps.
- Oral Mg supplements are also used in a variety of different conditions, most notably those involving muscle spasm or tension, pain and/or psychological and physical symptoms of stress and hyperexcitability.
- Numerous drug interactions exist, so care should be taken to ensure safe use.

Meadowsweet

HISTORICAL NOTE Meadowsweet was one of the most sacred herbs used by ancient Celtic druid priests, hundreds of years ago (Blumenthal et al 2000). Modern-day aspirin owes its origins to the salicin content isolated from meadowsweet in the early 1800s. In fact, the name aspirin relates to this herb's former genus name 'Spiracea'.

COMMON NAME
Meadowsweet

OTHER NAMES
Bridewort, dolloff, dropwort, fleur d'ulmaire, gravel root, lady of the meadow, meadow-wort, queen of the meadow, spireae flos.

BOTANICAL NAME/FAMILY
Filipendula ulmaria (family Rosaceae)

PLANT PART USED
Aerial parts

CHEMICAL COMPONENTS
Phenolic glycosides, essential oil, tannins, mucilage, flavonoids (up to 6% in fresh flowers) and ascorbic acid. The herb also contains various salicylate constituents including methyl salicylate, salicin and salicylic acid.

MAIN ACTIONS

Gastroprotective effects
In vivo tests have identified protective effects against stomach ulcers induced by acetylsalicylic acid, but no protection was seen against ulcers produced under high-acid environments or due to stimulation by histamine (Barnaulov & Denisenko 1980). Based on these observations, it appears that the effect may involve a prostaglandin (PG)-mediated mechanism.

Hepatoprotective
An in vivo trial has demonstrated the hepatoprotective and antioxidant effects of meadowsweet (Shilova et al 2006). Meadowsweet extract (70% ethanol, 100 mg/kg) was shown to improve liver function in carbon tetrachloride (CCL4)-induced hepatitis in rats. In many parameters, the extract was shown to be more effective than Carsil, a silymarin preparation well known for its hepatoprotective ability.

OTHER ACTIONS
In vitro tests have identified antioxidant and anticoagulant activities (Calliste et al 2001, Liapina & Koval'chuk 1993). Bacteriostatic activity has also been reported in vitro against *Staphylococcus aureus*, *S. epidermidis*, *Escherichia coli*, *Proteus vulgaris* and *Pseudomonas aeruginosa* (Rauha et al 2000). Whether meadowsweet exerts anti-inflammatory and analgesic effects because of its

high salicylate content is unknown and remains to be tested.

CLINICAL USE

Meadowsweet has not been significantly investigated under clinical trial conditions, so evidence is largely derived from traditional, in vitro and animal studies.

Supportive therapy for colds

Commission E approval for this condition is based on historical use in well-established systems of medicine, in vitro tests and animal studies (Blumenthal et al 2000).

Acne

Researchers believe that Filipendula may stimulate the skin's natural immune mechanisms, reducing bacterial colonies and therefore limiting the complications of acne (Lenaers et al 2007). Volunteers used the Filipendula preparation twice a day for 28 days and found a reduction in acne spots by 10%, an improvement in the homogeneity of the skin grain by 21% and a reduction of inflammatory lesions by 20%. Bacterial infiltration of lesions was also reduced by 22%.

Gastrointestinal conditions

Meadowsweet is often used to treat gastrointestinal conditions associated with hyperacidity, such as gastritis, acidic dyspepsia and peptic ulceration. In vivo testing has found a decoction made from flowers of meadowsweet reduced experimentally induced ulcers caused by acetylsalicylic acid. Additionally, it promoted healing of chronic stomach ulcers induced by ethanol (Barnaulov & Denisenko 1980). Currently, there is no evidence available to confirm an antacid activity.

Conditions associated with mild-to-moderate pain

Based on its significant salicylate content, meadowsweet is also prescribed for conditions associated with mild-to-moderate pain. However, no clinical study is available to confirm efficacy.

OTHER USES

Meadowsweet has traditionally been used as a treatment for diarrhoea based on the herb's appreciable tannin content. It has also been used for conditions associated with mild-to-moderate pain (most likely due to the herb's significant salicylate content), fever and inflammation.

DOSAGE RANGE

As no clinical trials are available to determine effective doses, the following doses are a general guideline.

- Fresh flowers: 2.5–3.5 g/day.
- Fresh herb: 4–5 g/day.
- Infusion: steep 2–3 g in 150 mL boiled water for 10 min and drink as hot as tolerable.
- Fluid extract (1:1) (g/mL): 2–3 mL/day.

TOXICITY

Not known.

ADVERSE REACTIONS

Although salicylates are present, they appear to cause less gastrointestinal irritation than acetylsalicylic acid. In fact, a meadowsweet preparation protected against acetylsalicylic acid-induced stomach ulcers in vivo (Barnaulov & Denisenko 1980).

SIGNIFICANT INTERACTIONS

Controlled studies are not available; therefore, interactions are based on evidence of activity and are largely theoretical and speculative.

Aspirin and simple analgesics

Theoretically, meadowsweet may enhance anti-inflammatory and antiplatelet effects. Observe patients taking this combination — beneficial interaction possible.

Iron

Separate doses of iron and meadowsweet by 2 hours.

Warfarin

As increased bleeding may occur, observe patients taking warfarin concurrently. The herb has been shown to exert anticoagulant activity in vitro and in vivo, but the clinical significance of these results is unknown (Liapina & Koval'chuk 1993).

CONTRAINDICATIONS AND PRECAUTIONS

Meadowsweet should not be taken by people with salicylate sensitivity. Suspend use of concentrated extracts 1 week before major surgery.

PREGNANCY USE

Safety unknown.

PATIENTS' FAQs

What will this herb do for me?

Traditionally, the herb has been used to treat gastrointestinal complaints such as dyspepsia and diarrhoea, urinary tract infections and joint aches and

PRACTICE POINTS/PATIENT COUNSELLING

- Meadowsweet is traditionally used as a herbal antacid, analgesic and antipyretic, antidiarrhoeal and treatment for urinary tract infections.
- Commission E approves its use as supportive therapy for the common cold.
- It contains several different salicylates that are thought to be responsible for much of its clinical activity; however, this remains to be proven.
- Although it contains salicylates, the herb does not appear to cause significant gastrointestinal irritation and may, in fact, have anti-ulcer activity.
- People who are salicylate sensitive should not take this herbal medicine.
- In practice, it is often combined with herbs such as chamomile and marshmallow in the treatment of gastrointestinal complaints.

pains. It is also used as supportive therapy for the common cold.

When will it start to work?

Symptomatic relief should be experienced within the first few doses.

Are there any safety issues?

People who are salicylate sensitive should not take meadowsweet.

Mullein

HISTORICAL NOTE Over the centuries, mullein has been used in various ways. Taken internally, it has been used to treat respiratory conditions and tumours; applied topically, its use has been to relieve itch and dress wounds. It was also used to make candlewicks for casting out evil spirits. Due to its robust nature, mullein is now considered a serious weed pest of roadsides and industrial areas in countries such as the USA.

OTHER NAMES

Aaron's rod, Adam's flannel, blanket herb, bunny's ears, candlewick plant, flannel-leaf, great mullein, Jacob's staff, flannelflower, gidar tamaku, hare's beard, hedge taper, longwort, Our Lady's flannel, rag paper, shepherd's club, shepherd's staff, torch weed, velvet plant, wild ice leaf, woollen, woolly mullein.

BOTANICAL NAME/FAMILY

Verbascum densiflorum, *Verbascum phlomoides*, *Verbascum thapsus* (family Scrophulariaceae)

PLANT PARTS USED

Flower — dried petals, leaves

CHEMICAL COMPONENTS

The flower contains water-soluble mucilage, polysaccharides, flavonoids (including apigenin, luteolin, kaempferol and rutin), caffeic acid derivatives, iridoid monoterpenes, triterpene saponins (verbascosaponin), sterols and invert sugar.

One of the most investigated constituents isolated from *Verbascum* spp. plants is verbascoside, an iridoid glucoside. Whether the pharmacological effects demonstrated for this single constituent can be extrapolated to explain those for mullein is uncertain, as the effects of any herb are due to a number of phyto-constituents and their interaction with each other and the body. As such, information about verbascoside is included here in order to provide a further insight into the herb, but it should be interpreted accordingly.

Verbascoside has also been isolated from other herbs such as *Verbena officinalis*, *Echinacea purpurea* roots, *Euphrasia pectinata*, *Phlomis longifolia*, *Pedicularis plicata*, *Duranta erecta*, *Marrubium alysson*, *Leonurus glaucescens* and *Ballota nigra* (Calis et al 1992a, b, Deepak & Handa 2000, Ersoz et al 2000, 2001, Liao et al 1999, Seidel et al 2000, Sloley et al 2001, Takeda et al 1995).

> ***Clinical note — Natural mucilages found in herbs***
>
> Mucilages are large, highly branched polymeric structures made from many different sugar and uronic acid units. They are hydrophilic and are capable of trapping water, causing them to swell in size and develop a gel-like consistency. The gels tend to have soothing properties and can be broken down by bowel flora when taken internally (Mills & Bone 2000). They are known to have beneficial effects on burns, wounds and ulcers when applied externally, and on gastric inflammation and irritation and diarrhoea when taken internally.

MAIN ACTIONS

Mullein has not been significantly investigated under clinical trial conditions, so evidence is derived from traditional, in vitro and animal studies.

Demulcent and emollient

Traditionally, these actions were thought to occur primarily within the respiratory system, especially the lungs. However, topical preparations of mullein also exert an emollient action on the skin (Blumenthal et al 2000). This is most likely due to the herb's high mucilaginous content.

Antimicrobial

Antiviral action

Mullein extract exhibits in vitro antiviral activity against fowl plague virus, several influenza A strains and influenza B strain, as well as HSV (McCutcheon et al 1995, Serkedjieva 2000, Slagowska et al 1987, Zanon et al 1999, Zgorniak-Nowosielska et al 1991). Antiviral activity has been demonstrated for both infusions and alcoholic extracts (Serkedjieva 2000).

Antibacterial action

In vitro studies have demonstrated antibacterial activity for mullein extracts (aqueous, ethanol and methanol) against *Klebsiella pneumonia*, *Staphylococcus aureus*, *Staphylococcus epidermidis* and *Escherichia coli* (Turker & Camper 2002). Of the three extracts tested, the aqueous extract exhibited the strongest antibacterial action.

Antitumour

Some plants, such as mullein, were used in folk medicine as sources of antitumour remedies. An in vitro study has identified inhibitors of protein biosynthesis in *Verbascum thapsiforme* flowers. Researchers found that a saponin glycoside and its aglycon, isolated from the flowers, directly inactivates ribosomes (Galasinski et al 1996). The constituent, verbascoside, has been shown to inhibit telomerase activity in human gastric carcinoma cells in test tube studies, resulting in inhibition of tumour growth (Zhang et al 2002). Cytotoxic effects for verbascoside have also been identified against rat hepatoma and sarcoma cells, and cytostatic activity on human epithelial carcinoma cells (Saracoglu et al 1995).

OTHER ACTIONS

The verbascoside constituent demonstrates antioxidant activity in vitro (Gao et al 1999). The saponins in mullein are thought to exert an expectorant activity; however, further investigation is required to confirm this.

CLINICAL USE

Mullein has not been subjected to significant clinical investigation; therefore, information is generally derived from traditional usage, phytochemical research or evidence of pharmacological activity. In practice, this herbal medicine is often combined with other herbs in order to strengthen clinical effects.

Chronic otitis media

To date, no controlled studies are available to determine the clinical effectiveness of mullein as a standalone treatment. However, two double-blind studies that tested a herbal combination ear-drop product (containing mullein) in children have produced positive results. The first study involved 103 children aged 6–18 years and found that a naturopathic herbal ear drop known commercially as Otikon (consisting of *Allium sativum*, *Verbascum thapsus*, *Calendula* flowers and *Hypericum perforatum* in olive oil) was as effective as local anaesthetic ear drops (containing ametocaine and phenazone in glycerin) in the management of ear pain associated with acute otitis media. Treatment lasted for 3 days and produced a statistically significant improvement (Sarrell et al 2001). The second was a randomised, double-blind study involving 171 children aged 5–18 years who had otalgia and clinical findings associated with middle-ear infection (Sarrell et al 2003). Children receiving herbal ear drops containing *Allium sativum*, *Verbascum thapsus*, *Calendula* flowers, *Hypericum perfoliatum*, lavender and vitamin E in olive oil achieved better pain relief than controls; however, the pain appeared to be self-limiting with significant improvements seen in all groups over 3 days. The dose used was 5 drops three times daily.

Productive and dry cough

Traditionally, mullein is combined with other demulcent or expectorant herbal medicines such as *Glycyrrhiza glabra*, *Tussilago farfara* and *Althaea officinalis* in the treatment of productive cough.

Commission E approves the use of mullein flowers for catarrhs of the respiratory tract (Blumenthal et al 2000). This is largely based on traditional use extending back to ancient times, and phytochemical investigation from in vitro and in vivo studies.

Topical use

Mullein is used topically for wounds, burns, bruises, haemorrhoids and pruritus, and to soften the skin. The high mucilage and tannin content of the herb provides a theoretical basis for its use in these situations as an antipruritic and astringent agent. The leaves are used topically to soften and protect the skin. To date, no controlled studies are available to determine its effectiveness.

OTHER USES

Mullein is included in herbal combination treatments for a variety of respiratory conditions such as bronchitis, asthma and tracheitis. Traditionally it is also used for diarrhoea, dysentery, haemorrhoids and laryngitis. In manufacturing, mullein is used as a flavouring component in alcoholic beverages.

DOSAGE RANGE

- Fluid extract (1:1): 1.5–2 mL twice daily.
- Tincture (1:5): 7.5–10 mL twice daily.
- Dried leaf: 12–24 g/day.
- Decoction: 1.5–2 g of herb in 250 mL of cold water, brought to the boil for 10 minutes, taken twice daily.

ADVERSE REACTIONS

A case of contact dermatitis has been reported (Romaguera et al 1985).

SIGNIFICANT INTERACTIONS

Controlled studies are not available.

CONTRAINDICATIONS AND PRECAUTIONS

Insufficient reliable information is available.

PREGNANCY USE

Insufficient reliable information is available; however, Commission E states that no restrictions are known (Blumenthal et al 2000).

PATIENTS' FAQs

What will this herb do for me?

Mullein has been used since ancient times as a treatment for productive coughs and catarrhal states. In modern times, it is also used to treat chronic otitis media, and has antiviral action against influenza virus and HSV. Currently, more scientific investigation is required to confirm efficacy for these indications.

PRACTICE POINTS/PATIENT COUNSELLING

- Mullein flowers have been used since ancient times as an expectorant and anticatarrhal agent in conditions of productive cough and respiratory infections.
- It is most commonly used in combination with other demulcent and expectorant herbal medicines in the treatment of productive and dry cough.
- In vitro studies have identified antiviral and antibacterial activity.
- Mullein has not been subjected to significant clinical investigation; therefore, information is generally derived from traditional usage or evidence of pharmacological activity. As such, Commission E approves its use for catarrhs of the respiratory tract.
- Used in the form of a herbal combination ear drop, significant anaesthetic activity has been demonstrated.

When will it start to work?

Ear drops containing mullein within a herbal combination exerted significant anaesthetic effects within 1–2 days.

Are there any safety issues?

Although safety has not been scientifically established, a long history of use suggests that it is a safe substance when used at the recommended doses.

Myrrh

HISTORICAL NOTE The resin that seeps out of the bark of the *Commiphora* plant has been considered an important medicinal product in the Middle East, China and India since biblical times. Because of its antimicrobial activity, myrrh has historically been used, alone and in combination with other herbs, to treat infections and inflammations of the oral cavity, in purification rituals, to embalm bodies, dress infected wounds and as a treatment for leprosy.

COMMON NAME

Myrrh

OTHER NAMES

Abyssinian myrrh, bal, bol, common myrrh, heerabol, hirabol myrrh, gum myrrh tree, gummi myrrh, Somali myrrh, Yemen myrrh

BOTANICAL NAME/FAMILY

Commiphora molmol (family Burseraceae)

PLANT PARTS USED

Gum resin, stem, leaves

CHEMICAL COMPONENTS

Myrrh contains three main components: gum resin 30–60%; alcohol-soluble resins 20–40%; volatile oils (2–10%).

Guggul is the oleo-gum-resin exudate from *Commiphora mukul*, which is also used therapeutically and has been scientifically investigated.

Resins are sticky, water-insoluble substances that are secreted where a plant is damaged by incision or natural causes. The viscous substance hardens shortly after secretion, but may be returned to a liquid state with heating. Resins tend to be soluble in alcohol. Guggulipid is extracted from guggul and contains plant sterols (guggulsterones E and Z) which are thought to be its main pharmacologically active constituents (Ulbricht et al 2005).

MAIN ACTIONS

Antiseptic

Antifungal and antibacterial activities have been observed in vitro against standard pathogenic strains of *Escherichia coli*, *Staphylococcus aureus*, *Pseudomonas aeruginosa* and *Candida albicans* (Dolara et al 2000). The oleo-gum-resin of *C. mukul* was shown to be comparable to kanamycin against both Gram-positive and Gram-negative bacteria in vitro (Saeed & Sabir 2004).

Antiparasitic

Antiparasitic effects have been shown against *Schistosoma mansoni* in mouse livers in vitro (Hamed & Hetta 2005). Liver enzymes were significantly decreased after treatment with myrrh (*C. molmol*), whilst ova and worms' numbers were noticeably decreased. An in vivo study in the same year also produced promising results (Massoud et al 2005). Myrrh (500 mg/kg) was given for 5 days, 8 weeks postinfection. The animals were sacrificed after 12 weeks from the beginning of the experiment and myrrh was found to be comparable to cremophore EL, both producing approximate normal liver histology as compared to untreated animals. Another study compared the toxicity of myrrh to the commonly-used antischistosoma drug Praziquantel. Praziquantel is well known for its toxicity and it would be a distinct advantage if another safer product could be found. The researchers reported that myrrh is a safe and promising alternative without hepatotoxic, genotoxic and carcinogenic consequences.

Mirazid, an oleo-resin, derived from myrrh may also be effective against heterophyiasis with an animal study reporting a 100% reduction in worm load after 3 days (Fathy et al 2005).

Lipid-lowering effects

Several mechanisms of action are considered responsible for this effect. The guggulsterones act as antagonists of the bile-acid receptor and of the farsenoid X receptor, which are involved in bile-acid regulation and cholesterol metabolism. Crude guggul contains ion-exchange resins that may remove bile from the intrahepatic circulation (Urizar et al 2002, Wu et al 2002).

According to one review, 11 clinical studies have generally demonstrated that guggulipid from *C. mukul* significantly reduces triglyceride and total cholesterol levels; however, results from a recent double-blind randomised study were negative (Ulbricht et al 2005).

Anti-inflammatory

Myrrhanol A, a triterpene isolated from *C. mukul* gum resin, produces potent anti-inflammatory activity, as observed in an animal model of inflammation. In this study, anti-inflammatory activity was more marked than that of hydrocortisone (Kimura et al 2001). An animal model of rheumatoid arthritis (RA) confirmed significant anti-inflammatory effects with oral administration, also resulting in decreased joint swelling (Sharma & Sharma 1977). The essential oil of myrrh has also been shown to inhibit IL-6, probably due to down-regulating PGE2 production but not via nuclear factor kappaB inhibition in human gingival fibroblasts (Tipton et al 2006). Conversely, guggulsterone from *C. mukul* has demonstrated anti-inflammatory effects by decreasing nuclear factor kappaB and therefore tumor cell-induced osteoclastogenesis in vitro (Ichikawa & Aggarwal 2006).

Local anaesthetic

Several compounds found within myrrh exert local anaesthetic activity, chiefly by blocking the inward sodium current across membranes (Dolara et al 2000).

OTHER ACTIONS

Antispasmodic

One major component, T-cadinol, and several minor components possess smooth muscle-relaxing properties according to ex vivo tests (Andersson et al 1997, Claeson et al 1991).

Increases glucose tolerance

An extract of myrrh effectively increased glucose tolerance in both normal and diabetic rats (Al-Awadi & Gumaa 1987). Guggulipid (20 g/kg) improved glucose tolerance in another in vivo study (Cornick et al 2008). The purified ethyl ester of commipheric acid (150 mg/kg, twice daily) also lowered fasting blood glucose, insulin and triglycerides leading researchers to propose that this constituent may be at least partly responsible for the antidiabetic effects; however, oral bioavailability is poor.

Local astringent and enhanced wound healing

Myrrh has astringent activity, promotes tissue granulation and enhances wound healing (Blumenthal 2000).

CLINICAL USE

Topical treatment of oral or pharyngeal inflammation

Often used as a component of gargles, mouthwashes or paints for these indications, there are few controlled clinical trials or in vitro studies on the effects of myrrh on cells derived from the human oral cavity. A 2003 in vitro study investigating the effects of myrrh oil on a number of key cells implicated in gingivitis found that low concentrations of myrrh oil reduced gingival fibroblast production of proinflammatory cytokines and, therefore, the participation of these cells in gingival inflammation

associated with gingivitis and periodontitis (Tipton et al 2003). This is thought to be, at least in part, due to inhibition of PGE2 (Tipton et al 2005).

Commission E approved myrrh for these indications (Blumenthal 2000).

External treatment of minor inflammatory conditions and wounds

Myrrh is incorporated into salves and topical preparations for the treatment of bed sores, minor wounds and haemorrhoids. Although no clinical trials are available, the antimicrobial, anti-inflammatory, astringent and local anaesthetic activities of myrrh provide a theoretical basis for efficacy.

Osteoarthritis

A small, uncontrolled trial of *C. mukul* for patients with osteoarthritis (n = 30) demonstrated that treatment with 500 mg (3.5% guggulsterones) of the herb, three times daily for 2 months resulted in reduced joint inflammation, swelling and pain (Singh et al 2003). Although this suggests that the effects may be clinically significant, further investigation is required.

Hyperlipidaemia, hypercholesterolaemia, hypertriglyceridaemia

Various RCTs have investigated the effects of guggulipid on high-blood levels of lipids, cholesterol and triglycerides with inconsistent results. Overall, effects seem to be more likely in Indian populations than people eating Western diets; however, the reason for the discrepancy is unknown.

Szapary et al (2003) conducted a double-blind, placebo-controlled, randomised trial with 103 subjects with LDL cholesterol levels of 3.37–5.19 mmol/L. A standardised dose of 1000 mg of guggulipid (containing 2.5% guggulsterones) was given to one treatment group, while a higher standardised dose of 2000 mg was given to the other, three times daily for 8 weeks. Results showed a decrease of LDL cholesterol in the placebo group of 5%, an increase of 4% in the 1000 mg group and an increase of 5% in the 2000 mg group. Overall this constituted a 9% and a 10% increase in LDL cholesterol with guggulipid treatment. In comparison, several randomised clinical trials and in vivo tests using various extracts of guggul have reported significant lowering of total cholesterol, triglycerides and LDL cholesterol levels and increases in HDL cholesterol (Gopal et al 1986, Malhotra et al 1977, Nityanand et al 1989, Singh et al 1990). In two reports, the duration of the lipid-lowering effect continued for 6–20 weeks after discontinuation of therapy (Gopal et al 1986, Nityanand et al 1989). One clinical study showed that the lipid-lowering effects of a preparation of guggul fraction A (1.5 g/day) were similar to clofibrate (2 g/day) (Malhotra et al 1977). A larger study of 235 volunteers conducted under double-blind randomised conditions showed that patients with hypercholesterolaemia responded better to guggulipid (1.5 g/day) than to clofibrate (1.5 g/day). However, those with hypertriglyceridaemia responded better to clofibrate (Nityanand et al 1989). Many of these trials have been criticised for being small and methodologically flawed or poorly reported (Ulbricht et al 2005).

However, a more recent review stated a difference in opinion and concluded that the trials were of reasonable quality (Singh et al 2007). They found that over 80% of trials using guggul produced favorable results. Again, more large-scale clinical trials need to be done to assess the efficacy of guggulipid in hypercholesterolaemia.

OTHER USES

Traditional indications

Myrrh has been used in traditional Chinese medicine, Tibetan medicine, Ayurvedic medicine, Middle Eastern medicine and in Europe; therefore, it has numerous traditional indications. Myrrh has been used to treat infections, respiratory conditions, mouth ulcers, gingivitis, pharyngitis, respiratory catarrh, dysmenorrhoea, amenorrhoea, menopausal symptoms, wounds and haemorrhoids. It has also been used to treat arthritis and as an embalming agent.

Parasitic diseases

Schistosomiasis

Schistosomiasis is an important trematode infection affecting over 200 million people in the tropics and subtropics (Kumar & Clark 2002). After malaria, it is the next most important parasitic disease with chronic infection causing significant morbidity. Currently, the drug praziquantel is often recommended, but it does not affect the immature stage and may not abort an early infection. Additionally, a drug-resistant strain has developed (Beers & Berkow 2003). Due to these factors, there is great interest in discovering alternative treatments.

One clinical study involving 204 patients with schistosomiasis produced impressive results with a 3-day oral dose regimen producing a cure rate of 92% (Sheir et al 2001). Re-treatment of non-responders increased the overall cure rate to 98%. A field study produced similar results with 97.4% of subjects infected with the *Schistosoma haematobium* strain and 96.2% infected with the *S. mansoni* strain successfully clearing the parasite after ingesting 1200 mg of *Commiphora molmol* daily for 6 days (Abo-Madyan et al 2004a). However, two randomised trials, controlled with the drug praziquantel, have both shown little effectiveness of myrrh against the parasite (Barakat et al 2005, Botros et al 2005).

Fascioliasis

Human fascioliasis occurs in Europe, Africa, China and South America and is an infection with *Fasciola hepatica*, which is acquired by eating contaminated watercress. The flukes mature in the bile ducts and cause biliary tract obstruction and liver damage (Beers & Berkow 2003).

A small study of seven infected patients found that treatment with myrrh over 6 consecutive days produced alleviation of all symptoms and signs, and a dramatic drop in egg count, with eggs no longer detected 3 weeks after treatment (Massoud

Historical note — Myrrh and mummification
Chemical treatments were an essential part of the mummification process in ancient Egypt. Several different plant products were used in the process, one of which was oil of myrrh. Interestingly, modern-day research has discovered that the oil has molluscicidal properties against several Egyptian snail species, suggesting that it may have been a wise choice for protecting mummified remains against destruction (Allam et al 2001).

et al 2001a). Furthermore, high-eosinophil counts elevated liver enzymes and *Fasciola* antibody titres returned to normal. A field study showed that myrrh (1200 mg daily for 6 days) cleared the parasite in 94.1% of infected people at the 3-month follow-up (Abo-Madyan et al 2004b).

Mosquitocidal
The oil and oleo-resin from the plant extract of *C. molmol* exhibit larvicidal activity against *Culex pipiens* larvae (Massoud et al 2001b).

Acne
Three months' treatment with guggulipid (equivalent to 25 mg guggulsterone) was found to be as effective as tetracycline in the treatment of nodulocystic acne in a randomised clinical study of 20 patients (Thappa & Dogra 1994).

DOSAGE RANGE

Internal preparations — Commiphora molmol
- Fluid extract (1:1) (g/mL): 2 mL/day.
- Tincture (1:5): 0.5–2 mL three times daily.

Internal preparations — guggulipid
- Acne: a dose equivalent to 25 mg guggulsterone taken once to twice daily.
- Hyperlipidaemia — 500–1000 mg of standardised guggulipid administered two to three times daily.

(Guggulipid preparations are often standardised to 2.5–5% of guggulsterones.)

External preparations
- Tincture (1:5) (g/mL) in 90% ethanol can be used in different concentrations to produce different therapeutic products.
- Mouthwash or gargle: 30–60 drops tincture in a glass of warm water.
- Paint: the undiluted tincture can be applied directly to gums or mucous membranes of the mouth two to three times a day.

TOXICITY
A dose of 10 mg/kg/day was given to subjects in one study with no serious adverse effects (Sheir et al 2001).

ADVERSE REACTIONS
Restlessness, mild abdominal discomfort and gastrointestinal symptoms, such as diarrhoea and nausea, have been reported, mainly with orally administered extracts. Allergic dermatitis has also been reported for topical usage. The standardised guggulsterone (guggulipid) preparations tend to be far better tolerated.

SIGNIFICANT INTERACTIONS
Interactions are theoretical and based on in vitro and in vivo data; therefore, clinical significance is unclear and remains to be confirmed.

Diabetic medication
In vivo studies suggest myrrh may have hypoglycaemic effects and therefore would have additive effects with diabetic medications. Changes in serum glucose in patients taking these medications should therefore be monitored.

Lipid-lowering medication
Guggul may have cholesterol-lowering activity and therefore have additive effects with other lipid-lowering medications — observe patients taking this combination and monitor drug requirements. Beneficial interaction is possible.

Anticoagulant and antiplatelet medication
Guggul inhibited platelet aggregation in vitro and in a clinical study; therefore, concurrent use may theoretically increase the risk of bruising and bleeding (Bordia & Chuttani 1979). It is uncertain what implications this observation has for *C. molmol* use. Observe patients taking these combinations.

Diltiazem
Reduced efficacy possible. A clinical study confirmed that guggulipid reduces bioavailability of this medicine (Dalvi et al 1994). It is uncertain what implications this observation has for *C. molmol* use. Observe patients taking this combination.

Propranolol
Reduced efficacy possible. A clinical study confirmed that guggulipid reduces bioavailability of this medicine (Dalvi et al 1994). It is uncertain what implications this observation has for *C. molmol* use. Observe patients taking this combination.

CONTRAINDICATIONS AND PRECAUTIONS
Do not use in cases of known allergy. Suspend use of guggul preparations 1 week before major surgery.

PREGNANCY USE
Safety is unknown.

PATIENTS' FAQs
What will this herb do for me?
Traditionally, the herb has been used as a mouthwash or topical paint to relieve symptoms of mouth ulcers, sore throats and gum disease. It has also been used as a topical application for inflamed skin conditions and wounds. Scientific research confirms antiseptic, anti-inflammatory and local anaesthetic effects and significant antiparasitic effects. The preparation known as guggulipid, which comes from *Commiphora* species, may lower total cholesterol levels.

PRACTICE POINTS/PATIENT COUNSELLING

- Myrrh has been used since ancient times in a variety of forms as an antiseptic, anti-inflammatory and analgesic medicine.
- It has been used as a topical preparation to reduce inflammation and enhance wound healing — in vivo evidence suggests that the anti-inflammatory activity of one of the main constituents is stronger than hydrocortisone and local anaesthetic activity is likely.
- Preliminary evidence suggests that it may be a useful treatment in gingivitis and periodontal disease.
- The preparation known as guggulipid, which comes from *Commiphora* species, may have lipid-lowering effects according to clinical studies; however, evidence is contradictory and further research is required to confirm this.
- Myrrh is not to be used in pregnancy and may interact with a number of medications when used orally.

When will it start to work?

A mouthwash or paint should provide rapid symptom relief.

Antiparasitic activity has been reported within 3 days' use in some parasitic infestations.

The lipid-lowering effects of guggulipid have been reported within 12 weeks.

Are there any safety issues?

The herb should not be taken during pregnancy and may interact with some medications.

New Zealand green-lipped mussel

HISTORICAL NOTE The Mytilidae are a family of bivalve molluscs that first appeared approximately 400 million years ago (Scotti et al 2001). In New Zealand, they include the green-lipped mussel, which is also known as *Perna canaliculus* and has the Maori name kuku. Also known as *Perna viridis*, the green-lipped mussel has been used to treat arthritis by the Maoris for many years.

BACKGROUND AND RELEVANT PHARMACOKINETICS

There is insufficient reliable information available.

CHEMICAL COMPONENTS

Green-lipped mussel contains minerals, mucopolysaccharides and numerous other constituents; however, the protein and lipid content is considered the most important for pharmacological activity. Virtually all of the protein content is comprised of pernin, a self-aggregating glycoprotein rich in histidine and aspartic acid (Scotti et al 2001).

A lipid-rich extract, prepared by supercritical fluid (CO_2) extraction of freeze-dried stabilised NZ green-lipped mussel, is commercially available as Lyprinol. The main lipid classes in this preparation are sterol esters, triglycerides, free fatty acids (mainly EPA and DHA), sterols and phospholipids (Sinclair et al 2000).

MAIN ACTIONS

Most investigation has been conducted with one of two commercial preparations: Seatone or Lyprinol.

Anti-inflammatory

Significant anti-inflammatory activity has been observed in both humans and animals with NZ green-lipped mussel (Halpern 2000, Miller & Ormrod 1980, Miller et al 1993). The mechanism of action is not well understood, but results from test tube and animal studies suggest inhibition of leukotriene B4 synthesis and PGE_2 production by activated macrophages and prostaglandin inhibitor actions (Miller & Wu 1984, Miller et al 1993).

OTHER ACTIONS

Not known.

CLINICAL USE

Few primary sources are available, so secondary sources have been used where necessary in order to provide a more complete description of the evidence available.

Rheumatoid arthritis and osteoarthritis

Arthritis is a significant problem in both humans and animals. In dogs, the most common form of joint disease is OA, which has been successfully treated by green-lipped mussel powder in one double-blind randomised study (Bierer & Bui 2002). Active treatment was shown significantly to improve total arthritic score, and alleviate joint pain and swelling at the end of week six compared with controls. More specifically, 83% of dogs in the active treatment group experienced a 30% or greater reduction in total arthritic scores and of these, 18% showed a 70% or greater improvement. Only 7% of controls showed a 30% or greater improvement with no dogs showing a 50% or greater improvement. The doses of green-lipped mussel powder ranged from 450 mg to 1000 mg/day, depending on body weight.

Clinical testing in humans has produced inconsistent results. One randomised clinical trial using Seatone in 35 patients with RA found no significant difference in chemical or clinical parameters compared with placebo, after 6 months' use (Larkin et al 1985). However, another study found that both freeze-dried powder and lipid extract of green-lipped mussel were effective in reducing symptoms in OA and RA (Gibson & Gibson 1998). Unfortunately, further details of this second study are not available. A more recent study, also conducted over 6 months, but this time comparing Lyprinol with placebo, found an improvement in mainly subjective measurements for OA; however, the results overall were still inconclusive (Lau et al 2004).

Asthma

Forty-six patients with asthma received either Lyprinol 2 capsules or placebo daily over 8 weeks under double-blind randomised test conditions (Emelyanov et al 2002). Active treatment resulted in a significant improvement on several parameters such as daytime wheeze, reduced concentration of exhaled H_2O_2 and an increase in morning PEF, compared with placebo.

OTHER USES

A preliminary animal study has shown Lyprinol to be of potential benefit in inflammatory bowel disease. As this study compared Lyprinol with both olive oil and fish oil, it suggests that another component, beyond the fatty acid content, is providing the therapeutic benefit (Tenikoff et al 2005).

DOSAGE RANGE
The studies of NZ green-lipped mussel have used 210 mg/day of the lipid extract or 1050–1150 mg/day of the freeze-dried powder.

TOXICITY
Insufficient reliable information is available.

ADVERSE REACTIONS
Gastrointestinal discomfort, gout, skin rashes and a case of granulomatous hepatitis have been reported (Ahern et al 1980, Brooks 1980).

SIGNIFICANT INTERACTIONS
Insufficient reliable information is available.

CONTRAINDICATIONS AND PRECAUTIONS
Contraindicated in people with allergies to shellfish—use with caution in people with hypertension, as the sodium content could theoretically raise blood pressure.

PREGNANCY USE
Insufficient reliable information is available to assess safety.

PRACTICE POINTS/PATIENT COUNSELLING
- New Zealand green-lipped mussel has been used to treat arthritis by the Maoris for many years.
- Significant anti-inflammatory activity has been observed in both animals and humans.
- Although a controlled study in dogs showed significant symptom relief for OA, clinical studies have produced inconsistent results.
- One controlled study has identified possible benefits in asthma.
- Insufficient reliable information is available to determine the safety of green-lipped mussel.

PATIENTS' FAQs
What will this supplement do for me?
Some studies have showed that NZ green-lipped mussel exerts significant anti-inflammatory activity, but it is uncertain whether it will relieve symptoms of OA. One small study suggests that it may relieve some symptoms of asthma.

When will it start to work?
Effects in asthma were seen after 8 weeks' use in one study.

Are there any safety issues?
It should not be taken by people with allergies to shellfish and should be used with caution by people with high blood pressure.

Noni

HISTORICAL NOTE Noni has been used throughout Southeast Asia and Polynesia for more than 2000 years as a food source, a medicine and a dye. Noni fruit was traditionally used by Polynesians to combat fatigue (Ma et al 2007) and legends tell of Polynesian heroes and heroines that used noni to survive from famine (Wang et al 2002).

COMMON NAME
Noni

OTHER NAMES
Ba Ji Tian, cheese fruit, Indian mulberry, meng-kudu, nhau, nono, nonu.

BOTANICAL NAME/FAMILY
Morinda citrifolia (family Rubiaceae)

PLANT PARTS USED
Roots, stems, bark, leaves, flowers, fruit and juice.

CHEMICAL COMPONENTS
Noni contains terpenoids, alkaloids, anthraquinones (e.g. damnacanthal, morindone and rubiadin), the coumarin scopoletin, beta sitosterol, carotene, vitamin A, flavone glycosides, linoleic acid, the orange-red pigment alizarin, L-asperuloside, caproic acid,

caprylic acid, ursolic acid, octanoic acid, potassium, vitamin C, rutin (Hiramatsu et al 1993, Wang et al 2002), as well as a natural precursor for xeronine named proxeronine (Heinicke 1985, 2001). In vitro studies suggest that the antioxidant activity is due to several compounds such as coumarin derivatives (Ikeda et al 2009) and phenolic compounds (Liu et al 2007) that may contribute individually or synergistically.

Scopoletin has been suggested as a bioactive marker and a candidate for product standardisation and pharmacokinetic studies (Issell et al 2008).

MAIN ACTIONS

Noni is purported to have many different effects including analgesic, anti-inflammatory, antioxidant, anticancer, antimicrobial, immune enhancement and antihypertensive activity.

Analgesic

Noni root extract has exhibited opioid-like properties, with dose-dependent analgesic properties in mice that were reversible by naloxone, together with sedative effects at higher doses (Younos et al 1990). Analgesic activity has also been reported in controlled trials using rats and mice (Wang et al 2002).

Antioxidant/anti-inflammatory

Fruit, leaf and root extracts have all been shown to exhibit antioxidant activity (Kamiya et al 2004, Zin et al 2006) and NO scavenging activity in vitro (Jagetia & Baliga 2004), with some extracts showing comparable antioxidant activity to tocopherol (Zin et al 2002, 2006), grape seed powder and pycnogenol (Wang et al 2002). The neolignan, americanin A, has shown to be a particularly potent antioxidant in vitro (Su et al 2005).

A 1-month double-blind, randomised, placebo-controlled trial involving 68 smokers found that 50 mL of noni juice twice daily significantly reduced plasma superoxide radicals and lipid peroxides (Wang et al 2002). Noni juice has also been shown to reduce oxidative stress and liver damage in carbon-tetrachloride treated rats (Wang et al 2002, 2008a, 2008b) as well as inhibit the in vitro enzymatic activity of cyclooxygenase-1 (COX-1) (Li et al 2003) and cyclooxygenase-2 (COX-2) (Wang et al 2002). The clinical significance of these findings is yet to be determined.

Antitumour

An alcoholic precipitate of noni juice significantly prolonged the life of mice with implanted tumours (Furusawa et al 2003, Hirazumi et al 1994). It is suggested that this antitumour activity is due to immunostimulatory activity because the noni precipitate was not directly cytotoxic to tumour cells, but did activate immune cells in vitro with its activity reduced by immunosuppressant drugs (Furusawa et al 2003, Hirazumi et al 1996). Noni juice has also been observed to increase the wet weight of thymus tissue in animals (Wang et al 2002) and to protect against 7,12-dimethylbenz(*a*)anthracene (DMBA)-induced DNA adduct formation in rats (Wang & Su 2001).

Noni improved survival times in cancer-implanted mice when combined with suboptimal doses of standard chemotherapeutic agents (Hirazumi & Furusawa 1999) and this is supported by in vitro studies demonstrating synergistic effects with chemotherapeutic agents (Furusawa et al 2003, Wang et al 2002).

In vitro studies have also found that noni fruit has antiproliferative activity against SKBR3 human breast adenocarcinoma cells (Moongkarndi et al 2004), and that glycosides extracted from noni inhibit cell transformation (Liu et al 2001) and ultraviolet-B (UVB)-induced activator protein-1 activity (Sang et al 2001, 2003). The anthraquinone, damnacanthal, is reported to stimulate UV-induced apoptosis in vitro (Hiwasa et al 1999).

Antimicrobial

Constituents of noni activity against *Escherichia coli* in vitro (Duncan et al 1998) and *Mycobacterium tuberculosis* (National Library of Medicine 2001), as well as the parasite *Ascaris lumbricoides* (Raj 1975); however, the clinical significance of this is undetermined. In vitro testing found that noni juice was as effective as sodium hypochlorite in reducing the smear layer when used as an endodontic irrigant (Murray et al 2008).

Ergogenic

Animal studies in aged mice have shown that noni juice improved endurance, balance and flexibility (Ma et al 2007).

Antihypertensive

The antihypertensive effects of the root extract of noni were first investigated in the 1950s (Ho 1955) and a hot-water extract of noni root is reported to have lowered the blood pressure of an anaesthetised dog (Youngken 1958).

Antidiabetic

In experimental diabetic models, noni extract displayed antihyperglycaemic as well as antioxidant effects (Kamiya et al 2008, Mahadeva Rao & Subramanian 2008).

OTHER ACTIONS

Noni has been shown to inhibit gastric emptying in male rats via a mechanism involving stimulation of cholecystokinin (CCK) secretion and CCK1 receptor activation (Pu et al 2004) and in vitro studies demonstrate inhibition of lipoprotein lipase suggesting potential use in weight management (Pak-Dek et al 2008).

CLINICAL USE

In recent years noni juice has been touted as a 'super juice' which enhances wellbeing. Noni has been reported to be of benefit for people with arthritis, diabetes, hypertension, muscle aches and pains, menstrual difficulties, headache, heart disease, atherosclerosis, AIDS, cancers, gastric ulcers, poor digestion, depression, senility and drug addiction (Wang et al 2002). Noni has not been significantly

investigated under clinical trial conditions, so evidence for its use is derived from traditional, in vitro and animal studies.

Anticancer

There are anecdotal reports of noni being used as an adjuvant immunotherapy for cancer (Wong 2004); however, further research is required to determine its role in clinical practice.

Hearing and mental health

A small placebo-controlled pilot study involving nine hearing impaired osteopenic or osteoporotic women found that ingestion of approximately 50 mL of noni juice over 3 months resulted in improved mental health and a mild protective effect on hearing. Further studies are required to determine the clinical significance of these findings (Langford et al 2004).

OTHER USES

Noni fruit may be used as a food source.

DOSAGE RANGE

There is little human research upon which to make accurate dosage recommendations.

- Juice of 25 mL (1 oz) twice daily (Wang et al 2002).

TOXICITY

No toxic effects have been found in rats (Mancebo et al 2002) even when given doses up to 80 mL/kg (Wang et al 2002). In vivo studies suggest the possibility of reproductive toxicity in rats (Muller et al 2009) while prenatal toxicity in developing rat embryos or fetuses revealed no evidence of toxicity (West et al 2008).

Three cases of hepatotoxicity related to noni juice consumption have been reported, with one case requiring urgent liver transplantation (Millonig et al 2005, Stadlbauer et al 2005) and the others recovering spontaneously after ceasing noni consumption (Millonig et al 2005, Stadlbauer et al 2005). Further investigation is required to determine the certainty of this causal association.

ADVERSE REACTIONS

There is insufficient reliable information available about the safety of noni. Allergenicity studies using guinea pigs report no allergic responses (Wang et al 2002).

SIGNIFICANT INTERACTIONS

There is one case report of noni juice consumption causing resistance to warfarin (Carr et al 2004). Further investigation is required to determine the certainty of this causal association.

CONTRAINDICATIONS AND PRECAUTIONS

Not known.

PREGNANCY USE

Likely to be safe when consumed in dietary amounts; however, safety is not known when used in larger quantities.

PRACTICE POINTS/PATIENT COUNSELLING

- Noni has been traditionally used as food and medicine for a wide range of medical conditions.
- Noni has not been significantly investigated in clinical studies, so its use is based on traditional evidence and laboratory and animal studies.
- Although it is likely to be safe, it is prudent to avoid using noni in amounts greater than those ingested as a food during pregnancy and to monitor clotting profiles if noni is used with anticoagulant medications.

PATIENTS' FAQS

What will this herb do for me?

Noni has not been significantly investigated under clinical trial conditions, so its use is based on traditional evidence and laboratory and animal studies.

When will it start to work?

There is little published evidence to indicate its speed of action, which will depend on the clinical use.

Are there are any safety issues?

Noni is generally considered safe and can be consumed as a food; however, the safety of large intakes is unknown.

Oats

HISTORICAL NOTE Culpeper (1652) recommended that 'a poultice made of meal of oats and some oil of bay helpeth the itch and the leprosy'. By the end of the 18th century oats was the main grain used by all levels of the population in Scotland. Students would arrive at university after the summer with a bag of oatmeal to live on during the term. The older Scottish universities still call the autumn mid-term break 'Meal Monday' because traditionally at that time the students would return home to replenish their supplies. In recent years oats has gained a reputation as a superfood due to its high nutritional content and cardiovascular benefits. It is good source of B complex vitamins, protein, fat, minerals as well as the heart healthy soluble fibre known as beta-glucan which appears to improve blood glucose and cholesterol levels (Sadiq Butt et al 2008).

OTHER NAMES

Groats, green oats, green tops, haver, oat herb, oatmeal

BOTANICAL NAME/FAMILY

Avena sativa (family Poaceae [Graminaceae])

PLANT PARTS USED

The whole flowering plant, including the oat straw and the seed (also used for porridge). Oat bran is also used in some clinical trials.

CHEMICAL COMPONENTS

Beta-glucan (soluble fibre), triterpenoid saponins (including avenacosides A and B), phenolic compounds (avenanthramides A, B, C), alkaloids (including indole alkaloid, gramine, trigonelline, avenine), sterol (avenasterol), flavonoids, starch, phytates, protein (including gluten) and coumarins.

Nutrients such as silicic acid, calcium, potassium, phosphorus, iron (39 mg/kg), manganese (8.5 mg/kg), zinc (19.2 mg/kg) (Witchl & Bisset 1991), vitamins A, B-complex, C, E and K, and amino acids.

MAIN ACTIONS

Lipid lowering

Beta-glucans increase bile acid synthesis and thus decrease serum cholesterol (Andersson et al 2002). The fibre binds to cholesterol, preventing initial absorption and enterohepatic recirculation of cholesterol, and the two are excreted together.

Clinical trials have shown that oat bran contains soluble fibres, such as beta-glucan (e.g. 75 g extruded oat bran, equivalent to 11 g beta-glucan), which nearly double the serum alpha-HC (7 alpha-hydroxy-4-cholesten-3-one) concentration within 8 hours, indicating increased bile acid synthesis and thus decreased serum cholesterol (Andersson et al 2002). Recent human studies using 75 g extruded oat bran breakfast cereal daily (containing 11.6 g native beta-glucans) have confirmed similar effects. Administration of oat bran significantly increased median excretion of bile acids by 144%, decreased cholesterol absorption by 19%, increased the sum of bile acid and cholesterol excretion by 40% and increased alpha-HC concentration (reflecting bile acid synthesis) by 57% within 24 hours of consumption (Ellegard & Andersson 2007).

Beta-glucan added to a fruit drink appears to significantly reduce both total and LDL cholesterol in human subjects without affecting fat soluble antioxidant levels (Naumann et al 2006). Triglyceride levels may also be reduced. In a randomised crossover study, 27 healthy men added oat (providing 5.7 g/day beta-glucan) or wheat (control) cereal products to their usual diets for two weeks. Peak triglyceride concentration was significantly lower in the oats group compared to controls (Maki et al 2007a).

Anti-atherogenic effects

In vitro studies suggest that the polyphenolic antioxidants known as avenanthramides, present in oats, may exert anti-inflammatory and anti-atherogenic effects (Liu et al 2004). Avenanthramides have been shown to decrease the expression of endothelial proinflammatory cytokines. This is in part due to inhibition of NF-kappaB activation via inhibiting phosphorylation of IkappaB kinase (IKK) and IkappaB, and suppressing proteasome activity (Guo et al 2008). Additionally, avenanthramide C inhibits the serum-induced proliferation of vascular smooth muscle cells and increases nitric oxide production (Nie et al 2006a, b). As chronic inflammation and proliferation of vascular smooth muscle cells are involved in the initiation and development of atherosclerosis, these mechanisms may reduce atherogenesis.

Antihypertensive effects

A reduction in blood pressure has been observed in clinical trials; however, the mechanism of action has not been fully elucidated (Pins et al 2002, Saltzman et al 2001).

Blood glucose control

Oats have been shown in clinical trials to reduce the postprandial glycaemic response (Jenkins et al 2002, Pins et al 2002, Tapola et al 2005). Whilst the mechanism of action is unclear, the ability of beta-glucans to slow stomach emptying and increase the viscosity of food in the small intestine, resulting in delayed glucose absorption, is most likely a factor (Rakel 2003). The fat content of rolled oats does not appear to be responsible for either the glycaemic or the insulinaemic response (Tuomasjukka et al 2007).

While some studies have suggested that a minimum of 4 g of beta-glucans is required to produce a significant decrease in glucose and insulin responses in healthy people (Granfeldt et al 2008), other studies suggest this dose may not exert a significant response (Biorklund et al 2008). The effect is likely to be dependent not only on the amount of beta-glucan but on the amount of extractable beta-glucan in oat products (Makelainen et al 2007), which may explain inconsistent results in clinical studies.

Antioxidant

In human trials, avenanthramides (A-C) in oats have been found to be bioavailable and increase antioxidant capacity in healthy older adults. After consumption of an avenanthramide-enriched mixture extracted from oats, plasma reduced glutathione was elevated by 21% at 15 minutes ($P \leq 0.005$) and by 14% at 10 hours ($P \leq 0.05$) (Chen et al 2007).

Antipruritic/ anti-inflammatory effects

External application of oat preparations has been shown to relieve itch (Matheson et al 2001). These effects are most likely due to the potent anti-inflammatory effects of the avenanthramide constituents (Sur et al 2008). Topical application of 1–3 ppm avenanthramides alleviated inflammation in experimental models of contact hypersensitivity, neurogenic inflammation and itch (Sur et al 2008). The high concentration of starch and beta-glucan in colloidal oatmeal (produced by finely grinding the oats and boiling it to extract the colloidal material) is responsible for the protective and water-holding functions of oats (Kurtz & Wallo 2007).

Anticarcinogenic

The beta-glucans in oats have recently demonstrated anti-cytotoxic, antimutagenic and anti-tumorogenic activity (Mantovani et al 2008), however further investigation is needed to confirm these effects.

OTHER ACTIONS

Due to its vitamin, mineral and amino acid content, oats are a nutritious food. Internally, oats also act as a bulk-forming laxative.

CLINICAL USE

Oats are not usually used as a stand-alone treatment and tend to form part of an overall management program.

Hyperlipidaemia

Several clinical trials have shown a marked reduction in total and/or LDL-cholesterol using oat-based beta-glucan containing products (Karmally et al 2005, Saltzman et al 2001, Queenan et al 2007).

Oat bran has been shown to reduce LDL-cholesterol by 16% in 140 hypercholesterolaemic subjects consuming 56 g oat bran/day for 12 weeks (Davidson et al 1991). In overweight men consuming an oat-based cereal (14 g dietary fibre) for 12 weeks, LDL-cholesterol was most significantly affected, with a reduction in concentrations of small, dense LDL-cholesterol and LDL particle number. No adverse changes occurred in blood triacylglycerol or HDL-cholesterol concentration (Davy et al 2002). In another clinical trial, a group consuming wholegrain oat-based cereals experienced a 24.2 mg/dL reduction in total cholesterol levels and a 16.2 mg/dL decrease in LDL-cholesterol levels (Pins et al 2002).

In a controlled trial 75 hypercholesterolaemic subjects were randomised to receive 6 g/day of concentrated oat beta-glucan or placebo (dextrose) for 6 weeks. Oat beta-glucan significantly reduced total cholesterol (–0.3 ± 0.1 mmol/L) and LDL-cholesterol (–0.3 ± 0.1 mmol/L), but only the reduction in LDL-cholesterol was significantly greater than in the control group. In an intestinal fermentation model the concentrated oat beta-glucan also produced higher concentrations of the short-chain fatty acid known as butyrate than guar gum and inulin, suggesting it may have benefits for colonic health (Queenan et al 2007).

A clinical trial of 38 normotensive males (mean age 59.8 years) with mild to moderate hypercholesterolaemia and a mean body mass index (BMI) of 28.3 kg/m^2 was conducted over 8 weeks. The study investigated the effects of adding high levels of monounsaturated fatty acids plus bread formulated with 6 g of beta-glucan to the American Heart Association (AHA) Step II diet plus 60 minutes walking per day. While results were impressive, it is unclear what part the beta-glucan played in isolation (Reyna-Villasmil et al 2007).

The lipid-lowering effects of a hypocaloric diet containing oats has been shown in a clinical trial to result in significantly greater decreases in total and LDL-cholesterol than a hypocaloric diet alone (Saltzman et al 2001). In addition, a RCT of moderately hypercholesterolaemic men consuming oat milk, deprived of insoluble fibre but still containing 0.5 g/100 g beta-glucan (750 mL/day) for 5 weeks, also showed a 6% reduction in total and LDL-cholesterol (Onning et al 1999). Effects on serum lipid levels in people without hypercholesterolaemia are not well supported in clinical trials (Chen et al 2006). (See Clinical note: Major lipids affecting cardiovascular disease risk, in monograph on vitamin B_3.)

A Cochrane review has suggested that 'despite the consistency of effects seen in trials of wholegrain oats, the positive findings should be interpreted cautiously. Many of the trials identified were short term, of poor quality and had insufficient power, and most were funded by companies with commercial interests in wholegrains' (Kelly et al 2007).

Hypertension

Results of RCTs suggest that consumption of oat-based cereals may reduce systolic blood pressure (SBP) and reduce or eliminate requirements for antihypertensive medications in some people (Pins et al 2002, Saltzman et al 2001).

The inclusion of wholegrain oat-based cereals was found in an RCT to decrease blood pressure in hypertensive patients and reduce requirements for antihypertensive medications. 'Seventy-three percent of participants in the oats group versus 42% in the control group were able to stop or reduce their medication by half. Treatment group participants whose medication was not reduced had substantial decreases in blood pressure' (Pins et al 2002). In another RCT, overweight subjects consuming a hypocaloric diet containing oats (45 g/4.2 MJ dietary energy/day) for 6 weeks experienced a reduction in SBP that was more significant than a hypocaloric diet alone (oats –6 ± 7 mmHg, control –1 ± 10 mmHg, $P = 0.026$). Lipid-lowering effects were also noted (Saltzman et al 2001). In another double-blind, multicentre clinical trial, 97 hypertensive patients were randomly assigned to receive a control diet or one containing oat beta-glucan for 12 weeks. Sub-group analysis revealed that only obese patients with a BMI > 31.5 kg/m^2 experienced a significant decrease in blood pressure (SBP –8.3 mmHg, DBP –3.9 mmHg) compared to controls (Maki et al 2007b). Overall, results appear to suggest greater benefits for overweight or obese individuals.

Blood sugar regulation

The ability of oats to delay glucose absorption, and therefore reduce the postprandial glycaemic response, provides a theoretical basis for their use as part of an overall treatment protocol in diabetes and hypoglycaemic conditions. An RCT of 12 patients with type 2 diabetes demonstrated that 30 g oat bran flour, high in beta-glucan, had a low glycaemic response and decreased the postprandial glycaemic response of an oral glucose load in a series of 2-hour meal glucose tolerance tests (Tapola et al 2005).

An RCT has shown that in a 50 g portion of carbohydrate, each gram of beta-glucan reduces the GI by 4 units, making it a useful adjunct to reduce the postprandial glycaemic response without affecting palatability (Jenkins et al 2002). Another trial showed a 15.03 mg/dL drop in plasma glucose levels versus controls when consuming wholegrain oat-based cereals (Pins et al 2002). Processing methods may affect the benefits of oats with a small study demonstrating that processing oat beta-glucan through enzymatic, rather than by aqueous methods, preserves the viscosity and improves postprandial glycaemic control (Panahi et al 2007).

In an uncontrolled pilot study, 14 hospitalised patients with metabolic syndrome were given a diabetes-adapted hypocaloric diet (1500 kcal/day; 50–55% carbohydrate, 15–20% protein, 30% fat) for 5 days with or without a 2-day period (third and fourth day) where the diet included 15 carbohydrate units of oatmeal (1200 kcal/day; 63% carbohydrate, 12% protein, 6% fat and 16.2 g fibre). The oatmeal intervention reduced insulin requirements by 42.5% and the effect persisted after a 4-week

outpatient period (Lammert et al 2008). The differences in calorie intake and nutritional breakdown make it difficult to attribute the observed effects to oatmeal alone and more controlled studies have been planned.

Pruritus

Oatmeal has been used traditionally to relieve the itch and irritation associated with various dry, itchy skin conditions. Colloidal oatmeal lotion has been shown to be an effective treatment for pruritus (Talsania et al 2008). These effects may be explained by the avenanthramides, potent anti-inflammatory agents that appear to mediate the anti-irritant effects of oats (Sur et al 2008). In addition, the beta-glucan and starch in colloidal oatmeal is thought to possess water-holding effects (Kurtz & Wallo 2007).

A clinical trial assessing the itch experienced by burns patients found that the group using a product with 5% colloidal oatmeal reported significantly less itch and requested significantly less antihistamine treatment than the control group (Matheson et al 2001).

Commission E approves topical use in baths for inflammatory and seborrhoeic skin disease, especially with itch (Blumenthal et al 2000).

Atopic dermatitis

In a controlled trial, an emollient treatment (containing oat extract) for 6 weeks significantly reduced high-potency topical corticosteroid consumption (–42%; $P < 0.05$) in infants with atopic dermatitis (AD). Significant effects were not demonstrated for moderate-potency corticosteroids (Grimalt et al 2007). However, it should be noted that percutaneous sensitisation to oats used in emollients and moisturisers has been reported and one study found that 32% of children with AD using oat-based creams had an oat-positive atopy patch test (APT) vs 0% of nonusers (Boussault et al 2007). Given the hyperpermeability of infant skin, topical products containing potentially allergenic food proteins should be used cautiously (Codreanu et al 2006).

OTHER USES

Traditionally, oats are considered a nervous system nutritive and therefore used during times of convalescence. More specifically, the straw is prescribed for nervous debility and exhaustion, whereas the seed is considered more stimulating and said to gently improve energy and support an overly stressed nervous system (Chevallier 1996).

Preliminary trials have suggested an improvement in sexual interest and performance in people taking oats in combination with nettles. The effects were more consistent in males than females. Further trials are required to confirm the benefits of oats in isolation (Haroian et al 1987).

Interestingly, oats are also used as supportive therapy during nicotine (Beglinger et al 1977, Schmidt & Geckeler 1976) and morphine withdrawal; however, reliable clinical evidence is currently limited and does not fully support these recommendations.

Due to its high soluble fibre content, oats are also used as an aid to weight loss. Taken before meals, they increase satiety and therefore enable smaller food portions to satisfy hunger.

DOSAGE RANGE

- 1–4 g three times daily of oatmeal or straw (Mills 1991).
- Australian manufacturers recommend 20–40 mL/week 1:2 tincture.
- Topically for itch: 5% colloidal oatmeal in a suitable carrier (Matheson et al 2001) or 100 g cut herb in a bath (Blumenthal et al 2000).
- The inclusion of wholegrain oat-based cereals or oat bran may be a useful adjunct to the treatment of hyperlipidaemia and hypertension and to delay glucose absorption — 75 g dried oatmeal (equivalent to ≈ 3 g soluble fibre daily) (Rakel 2003). Some research indicates 6 g/day of concentrated oat beta-glucan is required for lipid-lowering effects.

ADVERSE REACTIONS

Excessive intake of fibre from oats or oat bran may cause flatulence and anal irritation.

SIGNIFICANT INTERACTIONS

Controlled studies are largely unavailable; therefore, interactions are based on evidence of activity and are largely theoretical and speculative.

Antihypertensives

Additive effects are theoretically possible (Pins et al 2002); beneficial interaction is possible — observe. Patients taking oats, oat milk or oat bran should be monitored, as medication requirements may alter.

Lipid-lowering medications

Additive effects are theoretically possible — beneficial interaction is possible. Patients taking oats, oat milk or oat bran should be monitored, as medication requirements may alter. Conversely, two case reports exist of a reduced effect of lovastatin in patients taking 50–100 g oatbran daily (Richter et al 1991). As this is likely to be due to the fibre inhibiting absorption of the drug, doses should be separated by 2–3 hours.

Insulin and diabetic medications

In an uncontrolled pilot study, an oatmeal intervention reduced insulin requirements by 42.5% in hospitalised patients with metabolic syndrome; the effect persisted after a 4-week outpatient period (Lammert et al 2008). Insulin requirements should be monitored in patients taking oat beta-glucans as a change to medication dose could be required. Beneficial interaction possible under supervision.

CONTRAINDICATIONS AND PRECAUTIONS

Given the hyperpermeability of infant skin topical products containing potentially allergenic oat proteins should be used cautiously (Codreanu et al 2006). Dietary oats should not be used in cases of intestinal obstruction (Skidmore-Roth 2001).

Clinical note — Do oats interfere with nutrient absorption?
Although the high phytate content of oats would indicate a potential for reduced absorption of trace elements such as zinc, calcium and iron, one clinical trial investigating the effects of oat bran on zinc absorption found no evidence of reduced absorption (Sandstrom et al 2000).

Coeliac disease and oats consumption

In the past oats were generally contraindicated in people with coeliac disease (CD) due to their gluten content. Recent studies however have demonstrated that oats appear to be well tolerated by the majority of adults (Kemppainen et al 2007, Guttormsen et al 2008, Lundin et al 2003) and children (Holm et al 2006, Benkebil & Nydegger 2007, Hogberg et al 2004) with CD. However, some patients display a specific small intestinal T cell response to oat peptides that cannot be explained by contamination with other cereals (Ellis & Ciclitira 2008) and may experience intestinal discomfort, diarrhoea, bloating and subtotal villous atrophy (Lundin et al 2003, Peraaho et al 2004, Storsrud et al 2003b).

Food processing techniques such as kilning do not appear to either increase or decrease the antigenic potential (Kemppainen et al 2008), however some species such as the Italian variety, Astra, and the Australian variety, Mortlock, may be more reactive (Silano et al 2007).

Two recent reviews of the literature concluded that oats is well tolerated by most patients with CD (Haboubi et al 2006, Garsed & Scott 2007) but recommended the avoidance of oat products that may have been contaminated by wheat (Garsed & Scott 2007) and regular follow-up, including small bowel biopsy (Haboubi et al 2006). The Canadian Coeliac Association recommends consumption of uncontaminated oats up to 70 g (½–¾ cup)/day for adults and up to 25 g (¼ cup)/day for children (Rashid et al 2007).

PRACTICE POINTS/PATIENT COUNSELLING

- Oats are a rich source of nutrients, such as calcium, potassium, phosphorus, iron, manganese, zinc; vitamins A, B-complex, C, E and K, and amino acids. Dietary oats also contain a significant amount of soluble fibre.
- Regular intake of wholegrain oat-based beta-glucan containing cereals may have positive effects on cardiovascular disease risk factors such as hypertension, hyperlipidaemia and glucose regulation.
- Topical use of the cut herb in the bath or 5% colloidal oatmeal in a suitable carrier is used to relieve itch.
- Traditionally, oats are viewed as a nervous system nutritive and therefore used during times of convalescence.
- Patients with coeliac disease should be able to tolerate moderate amounts of oats in the diet.

PREGNANCY USE

Oral use is considered to be safe in pregnancy and lactation (NMCD 2003).

PATIENTS' FAQs

What will this herb do for me?
Oats are a concentrated nutrient source and also contain soluble fibre. They not only provide a range of vitamins and minerals, but can reduce blood pressure, cholesterol and improve blood sugar regulation.

When will it start to work?
Scientific studies have shown that oatbran and oat-based cereals containing beta glucan may reduce cholesterol levels and blood pressure within 5–6 weeks.

Are there any safety issues?
Dietary oats should be avoided in cases of intestinal obstruction.

Olive

HISTORICAL NOTE The olive tree is among the oldest known cultivated trees in the world. Several biblical references to olive suggest its use dates back to ancient times and victors in the early Olympic Games were crowned with its leaves. Olives and its associated products have been used widely as folk medicines in countries such as Spain, Italy, France, Greece, Israel, Morocco, Tunisia, Turkey and the Mediterranean islands. Today, the olive plant is most well known for its fruit crop and oil. The Mediterranean region produces approximately 98% of the world's total olive crop (≈ 11 million tons) (Delgado-Pertinez et al 2000), although the plant is also widespread on the Arabian peninsula, the Indian subcontinent and Asia. More recently, olive plantations have been developed in Australia and research is now being undertaken to identify the best species suited to the subtropical climate.

BOTANICAL NAME/FAMILY

Olea europaea L. (family Oleaceae)

PLANT PARTS USED

Fruit and leaf

Olive oil is made from the fruit and widely used in cooking. This review will focus on olive oil and olive leaf extracts.

CHEMICAL COMPONENTS

Olive oil contains high levels of monounsaturated fatty acids (chiefly oleic acid) and is also a source of at least 30 phenolic compounds including oleuropein, hydroxytyrosol and tyrosol and also flavonoids, squalene, beta-carotene, and alpha-tocopherol (Stark & Madar 2002).

Olive leaf extract also contains a variety of phenolic compounds, most importantly oleuropein, hydroxytyrosol and tyrosol, and also rutin, luteolin, catechin and apigenin, and various nutrients such as selenium, chromium, iron, zinc, vitamin C, beta-carotene and a wide range of amino acids (Polzonetti et al 2004). Unlike the olive fruit, olive leaf does not contain significant amounts of monounsaturated fatty acids, oleic acid or squalene (Stark & Madar 2002).

It is important to note that not all olive products contain the same concentration of phenolic compounds. Olive leaf extract and extra-virgin olive oil (acidity < 1%) are considered superior sources of phenolic compounds (Owen et al 2000) with extra-virgin olive oil containing higher amounts than refined virgin olive oil (Visioli & Galli 2002). Of these, olive leaf extract is the most concentrated. According to one test, total phenol levels ranging from 6360 to 8190 mg/L were identified in olive leaf extract (samples from Olive Products Australia) compared to 200–800 mg/L for extra-virgin olive oil (unpublished data, Department of Primary Industries Laboratory, Wagga Wagga, NSW, Australia).

MAIN ACTIONS

Most of the pharmacological effects for olive oil and olive leaf extract can be attributed to their main phenolic constituents, in particular oleuropein, hydroxytyrosol and tyrosol; however, several other biologically active constituents are also present.

Antioxidant

Numerous olive phenolics have strong free radical scavenging capacity and show a synergistic behaviour when combined, as occurs naturally in the fruit and leaf (Benavente-Garcia et al 2000). According to in vitro tests, the flavonoids, rutin, catechin and luteolin exert antioxidant effects almost 2.5-fold those of vitamin C and E and are comparable to that of lycopene (Benavente-Garcia et al 2000). Some clinical trials have shown improvement in the fatty acid profile of LDL cholesterol due to olive oil's antioxidant action (Cicero et al 2008, Gimeno et al 2007).

Anti-inflammatory and antithrombotic

Several constituents within olive oil and/or leaf have demonstrated anti-inflammatory properties, chiefly oleuropein, hydroxytyrosol, oleic acid, luteolin and apigenin (de la Puerta et al 2000, Marin et al 2003).

Oleuropein and hydroxytyrosol are found in both the oil and leaf and inhibit leukotriene B4 generation, which is involved in a wide range of pro-inflammatory pathways (Petroni et al 1997). These polyphenols are able to inhibit platelet aggregation and lipoxygenases and eicosanoid production (Andrikopoulos et al 2002, Gonzalez Correa et al 2008, Manna et al 2004). A reduction in platelet aggregation was also found in a study with healthy males using an olive leaf extract (Singh et al 2008). Two clinical trials found a reduction in the inflammatory marker C-reactive protein, when participants were given an olive oil-rich diet (Estruch et al 2006) and one trial also noted a decrease in interleukin-6 (Fito et al 2008).

Olive oil also contains large amounts of oleic acid, which is an omega-9 monounsaturated fatty acid that is converted to eicosatrienoic acid, which is then converted to leukotriene A3, which is a potent inhibitor of leukotriene B4 synthesis.

Anti-atherogenic

The oleic acid component modifies the vascular response to pro-atherogenic chemicals (such as high levels of cholesterol and the advanced glycation end products of diabetes) and inhibits endothelial adhesion molecule expression, according to test tube studies (Massaro & De Caterina 2002). The anti-atherogenic effects of olive oil may also be due to inhibition of platelet aggregating factor (PAF) (Karantonis et al 2006). A later animal study confirmed that olive leaf extract exerts a suppressive effect on the inflammatory response which may contribute to its anti-atherosclerotic activity (Wang et al 2008). A clinical study of 199 volunteers at

high risk of cardiovascular found that olive oil consumption protected against carotid atherosclerosis (Buil-Cosiales et al 2008)

Antimicrobial/antiviral

Oleuropein has antimicrobial activity against a variety of viruses, bacteria, yeasts and fungi (Aziz et al 1998, Bisignano et al 1999, Furneri et al 2002, Koutsoumanis et al 1998, Ma et al 2001, Markin et al 2003, Tassou & Nychas 1995, Tassou et al 1991); however, one study suggests that hydroxytyrosol has stronger broad-spectrum effects (Bisignano et al 1999). In vitro tests reveal that virgin olive oil exerts strong bactericidal activity against eight strains of *Helicobacter pylori* including several antibiotic resistant strains. Considering the phenols in virgin olive oil are stable in stomach acid, this may prove to have clinical benefits; however, further research will be needed to confirm the findings (Romero et al 2007). Another in vitro study found that olive leaf was active against some drug-resistant tuberculosis strains (Camacho-Corona Mdel et al 2008). Olive leaf extract also exhibited anti-HIV activity by blocking virus entry to the cells. Oleuropein and hydroxytyrosol are thought to be the principal components responsible for the activity (Lee-Huang et al 2007).

Antihypertensive

Studies have identified the Mediterranean diet, as an entity, and olive oil in particular, as significantly reducing arterial blood pressure in humans (Acin et al 2007, Ferrara et al 2000, Fito et al 2005, Perona et al 2004, 2006, Psaltopoulou et al 2004).

The hypotensive effect of olive leaves has also been well documented in vivo (Cherif et al 1996, Fehri et al 1994, Khayyal et al 2002, Somova et al 2003). One of the most recent studies tested a specially prepared olive leaf extract (EFLA943) and confirmed dose-dependent hypotensive activity when given orally to animals (Khayyal et al 2002). The precise mechanism of action responsible for the antihypertensive effect is unknown; however, it is suspected that improved endothelial function and/or calcium channel antagonist activity may be responsible (Gilani et al 2005).

Lipid lowering

Lipid lowering activity has been reported in some studies but is not consistent. It appears the phenolic content of olive products tested may influence results.

A randomised, crossover, controlled trial with 200 healthy male volunteers compared 25 mL/day of three varieties of olive oil and found all olive oils increased HDL cholesterol, decreased total cholesterol–HDL cholesterol ratio, decreased triglyceride levels and oxidative stress markers within 3 weeks. The greatest effects were seen for the oil with the highest polyphenolic content (Covas et al 2006). Similarly, a study of 772 people at high risk of cardiovascular disease found that an olive oil-rich diet given in the short term (3 months) reduced the cholesterol HDL ratio by 0.38 as compared to a low fat diet (Estruch et al 2006). In contrast, a dose of 50 mL/day of refined olive oil or virgin olive oil failed to significantly alter lipid profiles after 6 weeks of treatment according to a small placebo-controlled, crossover, randomised trial (Fito et al 2008). It seems that further quality clinical studies are warranted to confirm a lipid lowering effect of olive oil.

Investigation with olive leaf extracts is in its infancy to date; however, there is one open study using olive leaf extract (EFLA943) which demonstrated a reduction in cholesterol levels with treatment (Perrinjaquet-Moccetti et al 2008).

Cardioprotective

It is likely that olive oil's cardioprotective effect is multifaceted. Not only does it reduce lipid oxidation and reduce LDL cholesterol, it also reduces oxidative damage, inflammation, blood pressure, has vascular benefits and is anti-atherogenic and antithrombotic (Covas 2007). In human studies, olive oil has been shown to reduce inflammatory markers and increase antioxidant status after a meal reinforcing its cardioprotective role (Bogani et al 2007, Covas et al 2006). Extra-virgin olive oil was found to inhibit NF-(kappa)B in human monocyte/macrophages in healthy volunteers. This anti-inflammatory action is thought to assist in olive oil's cardioprotective action (Brunelleschi et al 2007).

Anticarcinogenic

Close adherence to the Mediterranean diet has been associated with a reduced risk of cancer (Mitrou et al 2007). This has prompted researchers to investigate key components of the diet, such as olive oil and its major constituents, for anticarcinogenic activity (Hamdi & Castellon 2005).

Several in vitro and in vivo studies have investigated how oleuropein and other constituents of olive exert antioxidant, antimetastatic, antimutagenic and anti-angiogenic effects (Hashim et al 2008). According to one in vitro study, oleuropein inhibits the proliferation, invasiveness and migration of advanced tumour cells (Hamdi & Castellon 2005). The maslinic and oleanolic acids in an olive fruit extract inhibited cell proliferation in vitro and encouraged apoptosis without cytotoxicity in colon-cancer cells (Juan et al 2006) Other in vitro studies have confirmed that olive oil phenols inhibit the growth of colon-cancer cells and cause apoptotic death in cancer cells (Gill et al 2005, Reyes-Zurita et al in press) and oleic acid may down-regulate the over-expression of an oncogene in some breast carcinomas causing apoptotic cell death (Menendez et al 2005). Luteolin also demonstrates antimutagenic and antitumorigenic properties in vitro (Kim et al 2003).

In vivo research with olive oil at the equivalent of normal dietary levels protected against DNA oxidative damage indicating a free radical scavenging mechanism may also be involved (Fabiani et al 2008). In vitro tests with olive leaf extract were shown to inhibit the growth of human leukaemia HL-60 cells in vitro (Abaza et al 2007, Fabiani et al 2006).

Hypoglycaemic activity

Olive leaf extract has demonstrated hypoglycaemic activity in animal models and one of the compounds responsible for this activity is oleuropeoside, which produced antidiabetic activity in animals with alloxan-induced diabetes (Gonzalez et al 1992, Manna et al 2004). Oleanolic acid is another constituent found to have antidiabetic effects in a mice model (Sato et al 2007). Conflicting results from clinical trials show one recent study suggesting that dietary olive oil reduces plasma glucose levels (Estruch et al 2006) and another small study in a group of stable coronary heart disease patients noted no change in glucose levels (Fito et al 2008).

Some researchers have suggested potentiation of glucose-induced insulin release and increased peripheral uptake of glucose as the most likely mechanism of action.

OTHER ACTIONS

Traditional texts describe the leaves as astringent and antiseptic and useful when boiled in water to create a decoction for the treatment of obstinate fevers. The oil is described as a nourishing demulcent with laxative properties. Oleuropein is the phenolic constituent responsible for the typically bitter and pungent aroma associated with olives, olive oil and leaf (Manna et al 2004).

Hypo-uricaemia

In vivo tests report that olive leaf extract has a hypouricaemic effect in treated animals (Serra-Majem et al 2003).

Homocysteine lowering

A trial with rheumatoid arthritis patients found a statistically significant reduction in homocysteine levels over an 8-week period with a freeze-dried olive vegetation water (Bitler et al 2007).

CLINICAL USE

Olive oil has been studied as a stand-alone entity in some studies; however, it is generally studied as part of the Mediterranean diet where it is the principal source of fat and considered a key contributor to the diet's many healthy benefits (Serra-Majem et al 2003). As a reflection of this, research into the Mediterranean diet is included in this monograph; however, the contribution of olive oil to these results remains unclear. In contrast, olive leaf extract has not been significantly tested under clinically controlled conditions, so evidence is mainly derived from traditional, in vitro and animal studies.

Cardiovascular disease

Prevention

It has been speculated that consumption of olive oil reduces the incidence of coronary heart disease, based on the observation that countries where the Mediterranean diet is consumed, chiefly Greece, Italy and Spain, have a lower incidence of coronary heart disease.

In 1999, the Lyon Diet Heart Study was published and is widely claimed to be a landmark study investigating whether a Mediterranean-type diet could reduce the rate of myocardial infarction (de Lorgeril et al 1999). It was a randomised secondary prevention trial that used a Mediterranean-type diet (with butter and cream replaced by a margarine based on rapeseed/canola oil and rich in alpha-linolenic acid). At a mean follow-up of 27 months, there was a 73% decrease in combined end points of cardiac death and non-fatal myocardial infarction, with a 70% decrease in cardiac death in the group eating the Mediterranean-style diet. Benefits were maintained for nearly 4 years after follow-up, which translates to 12 lives saved per 300 people in 27 months. Interestingly, these impressive results were obtained without lowering blood pressure, LDL cholesterol and triglycerides, or raising HDL cholesterol.

> ***Clinical note — What is the Mediterranean diet?***
> The Mediterranean diet studied in most trials is based on the traditional diet of Greece. It is low in saturated fat and high in monounsaturated fat (oleic acid:omega-9 = 18:1), mainly from olive oil; high in complex carbohydrates, from legumes; and high in fibre, mostly from vegetables and fruits. Total fat may be high (> 40% of total energy intake), but the monounsaturated to saturated fat ratio is around 2. The high content of vegetables, fresh fruits, cereals, and olive oil guarantees a high intake of beta-carotene, vitamins B_6, B_{12}, C and E, polyphenols and various minerals.

Several years later, data from the CARDIO2000 multicentre study was used to investigate the association between acute coronary syndromes (ACS) and a Mediterranean-style diet. Once again it was shown that the Mediterranean diet reduced the risk of developing ACS regardless of the presence of other risk factors such as hyperlipidaemia, type 2 diabetes or a sedentary lifestyle (Panagiotakos et al 2002). In this instance, primary prevention benefits were observed.

Positive results were also seen with the Indo-Mediterranean diet, which has increased intakes of whole grains, walnuts and almonds, fruit and vegetables (Singh et al 2002). The randomised trial involving 1000 patients with angina pectoris, myocardial infarction or other risk factors for coronary artery disease compared the Indo-Mediterranean diet to the Step I National Cholesterol Education Program diet and found that total cardiac end points were significantly fewer with the Indo-Mediterranean diet, as were sudden cardiac deaths and non-fatal myocardial infarctions.

Recently, a number of large, long-term studies have confirmed these findings. One epidemiological study evaluated the dietary habits of 2101 Greek men and women with no cardiovascular symptoms at baseline over 5 years. The study found that daily fruit, vegetable and olive oil intake was associated with a reduced cardiovascular risk (Panagiotakos et al 2009). A very large prospective study completed by the National Institutes of Health (NIH) in the United States showed that the Mediterranean diet

was associated with reduced all-cause and cause-specific mortality including deaths due to both cancer and cardiovascular disease (CVD) (Mitrou et al 2007). This study involved 214,284 men and 166,012 women. Another study following 40,000 migrants to Australia from Mediterranean countries revealed that the traditional Mediterranean diet was associated with reduced cardiovascular mortality (Harriss et al 2007). The Mediterranean diet can also have benefits for people with established cardiovascular disease according to a population study of 1302 patients. Those that adhered to the diet experienced a significant 27% lower mortality rate (Trichopoulou et al 2005).

Overall, these results suggest that the Mediterranean diet has both primary and secondary prevention effects.

There are also recent studies supporting the various cardioprotective actions of olive oil including a randomised, placebo-controlled study with 848 patients who had experienced a first event of acute coronary syndrome. The findings from food frequency questionnaires revealed that exclusive use of olive oil in cooking was associated with a 47% lower likelihood of having an acute coronary syndrome. This protection against coronary heart disease was not discovered with the use of other oils and fats or a combination of olive oil and other oils and fats (Kontogianni et al 2007).

Virgin versus refined olive oil?

The concentration of phenolic compounds found in olive oil varies widely depending on whether the oil is common, refined, virgin or extra virgin. It may also be affected by storage conditions, method of production and growing conditions. The main phenolic compounds, hydroxytyrosol, tyrosol and oleuropein, are highest in extra-virgin olive oil. Researchers are now comparing the different oils for their clinical effects and studies are finding that extra-virgin olive oil results in a greater antioxidant effect on lipid oxidation. It seems that a daily dose of approximately 25 mL of virgin or extra-virgin olive oil may reduce oxidative damage to LDL cholesterol (Gimeno et al 2007).

Hypertension

Both olive oil and olive leaf extract have demonstrated blood pressure lowering ability in small intervention trials, and long-term dietary intake of olive oil is associated with reduced incidence of hypertension.

Olive oil

One randomised, double-blind, crossover study compared the effects of monounsaturated fatty acid (MUFA) (extra-virgin olive oil) and polyunsaturated fatty acid (PUFA) (sunflower oil) in 23 hypertensive patients over 6 months (Ferrara et al 2000). MUFA intake resulted in significantly reduced resting blood pressure compared to the PUFA diet, but most impressively, daily drug dosage was significantly reduced with the MUFA diet (−48% vs −4%, $P < 0.005$).

A randomised, placebo-controlled, crossover study of 40 subjects with stable coronary heart disease compared the antioxidant and antihypertensive effects of two different olive oil supplements with different phenolic compound levels (refined: 14.7 mg/kg vs virgin: 161.0 mg/kg) (Fito et al 2005). Treatment with virgin olive oil rich in phenolic compounds resulted in significantly lower plasma oxidised LDL and lipid peroxide levels, together with higher activities of glutathione peroxidase. Additionally, systolic blood pressure (SBP) was significantly decreased in the hypertensive patients; however, no changes in diastolic blood pressure (DBP) were observed.

Another randomised study involving elderly patients found that increased dietary intake of virgin olive oil significantly reduced total and LDL cholesterol in normotensive but not hypertensive volunteers, whereas virgin olive oil consumption normalised SBP in this group (136 ± 10 mmHg) compared to treatment with sunflower oil (150 ± 8 mmHg) (Perona et al 2004).

In 2004, results from two large observational studies were published which further suggested that olive oil intake has significant effects on blood pressure.

One study involved assessing data from the Greek arm of the European Prospective Investigation into Cancer and Nutrition study, which included 20,343 participants (Psaltopoulou et al 2004). Intakes of olive oil, vegetables and fruit were significantly inversely associated with both SBP and DBP, whereas cereals, meat and meat products and ethanol intake were positively associated with arterial blood pressure. Mutual adjustment between olive oil and vegetables indicated that olive oil has the dominant beneficial effect on arterial blood pressure in this population.
